Preface	iii
A guide to this book	xi
Princeton University AOS 571 and 572	xvii
List of Symbols	xxxi
Part I. Mathematical methods	**1**
1 Cartesian tensor algebra	7
2 Cartesian tensor calculus	27
3 Partial differential equations	53
4 Fourier analysis	85
5 Green's function methods	109
6 Calculus of variations	165
7 Curves and surfaces	177
8 General tensors in brief	189
9 General tensor analysis	201
10 Orthogonal coordinates	225
Part II. Classical mechanics	**239**
11 Newtonian mechanics	241
12 Analytical mechanics	265
13 Particle mechanics around a rotating planet	299
14 Symmetries and conservation laws	331
15 Case studies in analytical mechanics	359
16 Lagrangian field theory	389
Part III. Fluid kinematics	**405**
17 Continuum approximation	409
18 Fundamentals of fluid kinematics	419

19 Strain and rotation 455
20 Mass conservation 477
21 Tracer conservation 501
22 Non-divergent flows 525

Part IV. Equilibrium thermodynamics 547
23 Equilibrium thermodynamics 549
24 Equilibrium thermodynamics with a geopotential 579

Part V. Dynamics of geophysical flows 599
25 Momentum dynamics 601
26 Stress in fluids 619
27 Energy and entropy in a moving fluid 661
28 Approximate hydrostatic flow 707
29 Pressure form stress 733
30 The Boussinesq ocean 759
31 Buoyancy 813
32 Geostrophy and thermal wind 847
33 Tangent plane flow balances 871
34 Ekman mechanics 887
35 Space and time dependent gravity 911

Part VI. Shallow water flows 923
36 Formulating shallow water models 925
37 Shallow water dynamics 961

Part VII. Vorticity and potential vorticity 1009
38 Vorticity and circulation 1011
39 Non-divergent barotropic flow 1035
40 Shallow water vorticity and potential vorticity 1065
41 Vorticity and circulation mechanics 1107
42 Potential vorticity mechanics 1159
43 Potential vorticity budgets 1183

Part VIII. Nearly geostrophic flows 1203
44 Models of nearly geostrophic flows 1205
45 Planetary geostrophic vorticity analysis 1237
46 Foundations of quasi-geostrophy 1259

Part IX. Linear wave mechanics 1287
47 Plane waves and wave packets 1291
48 Waves in a gently varying background 1329
49 Acoustic waves 1347
50 Interfacial waves on potential flow 1379
51 Inertial waves on an f-plane 1429
52 Barotropic vorticity waves 1443
53 Shallow water waves 1467
54 Internal gravity waves 1515

Part X. Flow instabilities 1557
55 Stability of symmetric flows 1561
56 Stability of fluid interfaces 1601
57 Shear instability 1619
58 Quasi-geostrophic waves and baroclinic instability 1655

Part XI. Generalized vertical coordinates 1691
59 Mathematical basics 1693
60 Kinematic equations 1713
61 Dynamical equations 1739
62 Isopycnal primitive equations 1751
63 Shallow water thickness weighted averaging 1765

Part XII. Scalar fields 1787
64 Tracer advection and diffusion 1789
65 Eddy and mean tracer kinematics 1841
66 Mathematics of parameterized tracer transport 1869
67 Ocean density and sea level 1899
68 Water mass transformation analysis 1923

Part XIII. Bibliography and Index 1963
Bibliography 1965
Index 1995

Contents

Preface

Geophysical fluid mechanics (GFM) is an area of physics concerned with natural fluid motion on a rotating and gravitating planet using concepts and methods from classical continuum mechanics and thermodynamics. The primary inspiration for the subject comes from the motion of fluids in the earth's atmosphere and ocean, though the principles and methods are applicable to extra-terrestrial planetary fluid flows. Geophysical fluids are in near rigid-body motion with the rotating planet, thus prompting a description from the rotating (non-inertial) planetary reference frame. Body forces from rotation (Coriolis and centrifugal) and gravitation (buoyancy) are fundamental features of the motion, as are contact forces from stresses (pressure and friction). We limit attention to the motion of a single phase of matter (gas or liquid), with the study of multiphase geophysical fluid mechanics (highly relevant to a moist atmosphere) outside our scope.

Geophysical fluid flows manifest over a huge range of space and time scales, with nonlinear interactions transferring information across these scales. Physical insights into such flows typically result from examining a hierarchy of conceptual models. Some models are formulated within the context of a *perfect fluid* comprising a single material constituent with fundamental processes limited to the reversible and mechanical. Some models consider constant density fluids, as commonly considered in classical *hydrodynamics*. Other models are posed using *real fluids* that are comprised of multiple matter constituents exposed to *irreversible processes* such as friction, mixing, and heating. Some models ignore rotation, and thus tacitly apply to flows with length scales too short to feel the Coriolis acceleration, whereas others ignore stratification, and thus focus on the dynamics of a homogeneous rotating fluid.

We develop geophysical fluid mechanics from a mathematical physics perspective, and are guided by the perspective that fundamental physical concepts are more readily understood than special cases. Furthermore, a grounding in fundamentals offers a robust and versatile framework for exploring the gamut of special cases and approximations encountered in applications. Therefore, subjects are approached by establishing general principles prior to the examination of case studies. Consistent with this approach, our treatment focuses on developing the mechanics of geophysical fluid motion, with that focus supporting theoretical explorations that often extend beyond that required for phenomenological purposes. Correspondingly, we embrace the opportunity to examine physics through multiple lenses that render a variety of perspectives and complementary insights. In a nutshell, if a physical system can be formulated and analyzed in more than one way, then we do so if it enhances pedagogy and exposes layers of understanding. As a result, brevity is sacrified to support exposition and exploration.

The presentation is based on the premise that skills in theoretical physics are optimally taught by nurturing physical reasoning, with physical reasoning supported by mathematical precision coupled to the elucidation of concepts using words and pictures. Hence, the presentation is both deductive and descriptive. The deductive approach supports understanding through the use of elementary physical notions that are expressed mathematically. The descriptive approach builds

skills in reasoning along with the ability to articulate physical ideas using words and pictures to offer substance to the maths. Readers are supported by development of the salient physics and maths in the process of building understanding. With proper study, this book should be accessible and of interest to the advanced undergraduate student or entering graduate student in fields such as atmospheric sciences, oceanography, physics, geophysics, astrophysics, engineering, and applied mathematics.

In accord with the above presentation style, we generally offer extensive details to mathematical derivations, either within the text or with specific pointers to the literature. Doing so nurtures technical skills required for the practicing theorist, and allows those with less well developed mathematical training to refine their skills and remain an active participant in the book. Exposing details also helps to unpack many of the physical concepts encapsulated by mathematical equations. As we are studying classical physics, concepts generally accord with common experience, thus affording a check on the validity of the maths. Furthermore, as we are studying physics, mathematical equations must satisfy dimensional consistency, with this constraint offering the practicing physicist a powerful tool for exposing spurious mathematical statements.

We cultivate the deductive and descriptive approaches by embracing the synergism between physics and maths, whereby physics informs the maths and maths reveals the physics. The synergism is facilitated by a presentation style inspired by *Mermin* (1989), who identified the following characteristics for the clear articulation of mathematical physics.

- RULE 1: All displayed equations are given numbers to facilitate cross-referencing. Any equation supporting another equation or a discussion is itself displayed with an equation number.

- RULE 2: Equations are referenced both by their number as well as descriptive phrases or names. Coupling maths to words supports learning, and reduces the need to flip pages to view the cited equation.

- RULE 3: Equations are part of the prose and thus subject to punctuation.

Furthermore, we consider this book's intellectual journey as one taken together by the author and reader, thus motivating use of first person plural pronouns.

Concerning the book's title

The study of rotating and stratified geophysical fluid motion largely started in the first half of the 20th century, and has evolved much over its history. During recent decades the study has seen particular evolution through deepening physical foundations, refining mathematical formulations, increasing the intellectual and predictive value of numerical simulations, extending applications across terrestrial and planetary systems, and expanding observational and laboratory measurements and techniques. What has emerged is a recognition that a fruitful study of rotating and stratified fluid flows makes use of ideas that go beyond the traditional notions of *geophysical fluid dynamics* (GFD). A contemporary practitioner develops insights by weaving together concepts and tools from mathematics, classical mechanics, fluid mechanics, thermodynamics, scalar mechanics, numerical simulations, laboratory experiments, field measurements, and data science. Acknowledging this broadening of the practice motivates the term *mechanics* in this book's title, rather than the more focused *dynamics*. It is a minor change in verbiage that reflects a broadening of the perspective pursued here.

Two pillars of theoretical geophysical fluid mechanics

We conceive of two pillars to theoretical geophysical fluid mechanics that are synergistic, thus offering lessons, guidance, and feedback to the other. The *elements pillar* comprises the physical and mathematical formulation of conceptual models used to garner insight into rotating and stratified fluid motion. This pillar is concerned with setting the stage by deductively and descriptively exposing how physical concepts are mathematically expressed in a mechanical description of geophysical flows. The complement *emergent pillar* studies solutions to equations, such as waves, instabilities, turbulence, and general circulation, all of which emerge from the equations. This book is more heavily weighted on the elements pillar. Even so, we do study circulation patterns, as well as waves and instabilities. Part of the reason for the enhanced treatment of the elements pillar concerns its relatively brief treatment commonly afforded in the literature, with the present book an attempt to slightly remedy this bias.

Some themes found in this book

This book covers an extensive number of topics in theoretical geophysical fluid mechanics. Throughout, we encounter a number of themes that appear in various guises, with the following offering a brief survey.

Causation and budgets

A great deal of this book is concerned with deriving and understanding equations that describe the evolution of fluid properties, with such equations (differential or integral) derived from physical principles such as Newton's laws of motion, thermodynamic relations, mass conservation, and vorticity mechanics. These *budget equations* form the theoretical foundation of continuum mechanics. As part of this development we often seek information about what *causes* fluid motion, making use of a variety of kinematic and mathematical frameworks. The causality question is posed when studying Newton's equation of motion, which says that acceleration (motion) arises from a net force (the cause of motion). Even though seemingly a clear decomposition of cause and effect, this fundamental statement of Newtonian mechanics offers little more than the definition of a force. We break the self-referential loop, and thus make physical progress, after specifying the nature of the force, for example gravitational, electromagnetic, as well as by offering properties of these forces as per Newton's third law (the action/reaction law).[1]

In geophysical fluid mechanics, we sometimes refer to time evolving budget equations as *evolution equations* or, more commonly, *prognostic equations*, with terms in the prognostic equation referred to as *time tendencies*. For prognostic equations, knowledge of the processes contributing to the net time tendency enables a prediction of flow properties. The question arises how to practically determine the tendencies acting in the fluid, particularly when tendencies are generally dependent on the flow itself. This question is not always simple to answer. Such is the complexity and beauty inherent in nonlinear field theories such as fluid mechanics, where cause and effect are intrinsically coupled.

We can sometimes make progress by turning the problem around, whereby kinematic knowledge of the motion offers inferential knowledge of the processes contributing to the motion. This situation is exemplified by pressure forces acting within a non-divergent flow whereby pressure provides the force that acts, instantaneously and globally, to maintain the constraint that the

[1] For more on this perspective of Newton's laws, see Chapter 1 of *Symon* (1971) or Chapter 2 of *Marion and Thornton* (1988).

velocity is non-divergent.[2] We may also make use of constraints that restrict the flow properties in manners that assist in prediction and understanding.

Constraints

Determining the forces, either directly or indirectly, provides physical insight into the cause of fluid flow and its changes. This approach is sometimes referred to a *momentum-based viewpoint* since it is based on working directly with the momentum equation (i.e., Newton's second law of motion). However, we are commonly unable to deduce the forces due to complexities inherent in nonlinear field theories. Furthermore, there are many occasions when we are simply uninterested in the forces. In these cases, we are motivated to use constraints that can allow us to sidestep forces but still garner insights into the motion.

One example of a constraint concerns the inability of fluid to flow through a solid static material boundary. To understand how this constraint impacts on the fluid, we do not need to understand details of the electromagnetic forces that underlie the resistance to this motion. Instead, we simply impose the kinematic boundary condition whereby the component of the velocity that is normal to the boundary vanishes at the boundary. The forces active within the fluid, no matter what flavor they may take, are constrained to respect the kinematic boundary condition. Another example concerns the study of vorticity developed in Part VII of this book. A variety of vorticity constraints offer the means to deduce flow properties without determining forces. Indeed, the *vorticity-based viewpoint* often provides a practical framework that is superior to the momentum-based view, thus prompting the importance of vortex mechanics in this book.

Associations and balances

Besides seeking causal relations pointing toward the future, many basic questions of fluid mechanics arise either instantaneously, as in the constraints maintaining non-divergent flows, or when the flow is steady, in which case properties at each point in space have no time dependence. In steady flows, the net acceleration, and hence the net force, vanish at each point within the fluid, although the fluid itself can still be moving (steady flows are not necessarily static). For steady flows we are unconcerned with causality since time changes have been removed. In this manner, the steady state equations are *diagnostic* rather than prognostic. Diagnostic relations thus provide mechanical statements about *associations* between physical processes that manifest as *balances*. The *geostrophic balance* is the canonical association in geophysical fluid mechanics, where the horizontal Coriolis force is balanced by the horizontal pressure gradient force. Another balance concerns the vertical pressure gradient and its near balance with the weight of fluid above a point in the fluid, with this *hydrostatic balance* approximately maintained at the large scale even for moving geophysical fluids. Further associations arise when studying steady vorticity balances, with the *Sverdrup balance* a key example that is commony used in ocean circulation theory.

We summarize the above by saying that diagnostic equations are concerned with the way things are, whereas prognostic equations point to how things will be. So although a predictive theory requires prognostic equations that manifest causal relations, an understanding of how fluid motion appears, and in particular how it is constrained, is revealed by studying diagnostic relations that expose associations through balances.

[2] For non-divergent flow, pressure acts as the *Lagrange multiplier* enforcing flow non-divergence. See Section 15 of *Serrin* (1959) for details.

Mathematical transformations between kinematic perspectives

Geophysical fluid flows are complex. Hence, it proves useful to avail ourselves of a variety of methods and perspectives that support a mechanistic description of the motion. Many methods are associated with distinct kinematic perspectives that reveal particular facets of the flow that might be less visible using alternative lenses. Examples include the Eulerian (spatial) and Lagrangian (material) kinematics used throughout fluid mechanics; the dual position space and wavevector space used for wave mechanics; the variety of vertical coordinates used for vertically stratified flows; and the analysis of motion in property spaces exemplified by watermass analysis. We make use of these perspectives throughout this book, and offer the mathematical tools needed to transform between them.

Geophysical Fluid Mechanics and Climate Science 2.0

Fluid mechanics has a history of applications that span science and engineering, from blood flow to the stability of stars and the evolution of galaxies. A key 21st century application of geophysical fluid mechanics concerns the questions of climate science associated with the uncontrolled greenhouse gas experiment pursued by industrialized civilization's carbon centered energy use. Leading order questions about climate warming have been sufficiently addressed to recognize that the planet has reached a crisis point threatening the viability of the biosphere. Even so, mechanistic answers to a number of questions remain at the cutting edge of climate science research. What will happen to the atmospheric jet stream and storm tracks in a world without summer Arctic sea ice? Will tropical storms be more powerful in a warmer world? What are the patterns for coastal sea level rise and their connections to large-scale ocean circulation? What are the key processes acting to bring relatively warm ocean waters to the base of high latitude ice shelves? How stable are the ocean and atmosphere's large-scale overturning circulations and their associated heat transport? Are there feasible and sustainable climate intervention options that equitably reduce the negative impacts of climate warming without introducing new problems? These questions, and countless others, constitute the scientific challenges of *Climate Science 2.0*.

Numerical circulation models, a core tool for Climate Science 2.0, have reached a level of maturity allowing them to vividly reveal details of the complex and multi-scaled nature of planetary fluid flow. Geophysical fluid mechanics is essential for the development of robust numerical methods used by such models, as well as subgrid scale parameterizations that capture a sensible approximate description of scales unresolved by the model. Geophysical fluid mechanics also provides the intellectual framework for developing mechanistic analyses and robust interpretations of simulated data. In this way, geophysical fluid mechanics furthers predictive capability for weather and climate forecast systems and enhances confidence in projections for future climate. Absent creative inspiration and motivation based on foundational physical sciences, such as geophysical fluid mechanics, the analysis of numerical model output can be driven more by the needs of data science than the questions of atmospheric, oceanic, or climate science. Indeed, in a world of increasingly large volumes of data, we conjecture that the marriage of fundamental physical theory to emerging data science tools will enable significant science and engineering advances that are needed to address key questions of climate science.

Moving from the numerical world to the natural world, we find that the many elements of geophysical fluid mechanics are key to the design of observational field campaigns and novel laboratory experiments, as well as for the analysis of their measurements. Such field campaigns and laboratory experiments probe process-oriented questions through the use of technologies that facilitate increasingly ambitious investigations of environmental fluid flows.

We thus conclude that the principles and methods of geophysical fluid mechanics provide the

means to conceptually digest and rationalize the underlying physics probed by both natural and simulated experiments. It also provides a mechanistic language to communicate the findings to the broader scientific community. In turn, geophysical fluid mechanics, as part of the scientific investigation of the earth's climate and the role of humans in affecting that climate, serves an essential role in humanity's quest for sustainability, equity, and justice.

About the cover

I took the cover photo of an iceberg, ocean, clouds, and sea bird (can you find the bird?) in the Orkney Passage region of the Southern Ocean during a research cruise from March-May 2017 aboard the British ship James Clark Ross. I am grateful to Alberto Naveira Garabato, the chief scientist on this cruise, for taking me to this amazing part of the planet. Although I largely pursue theoretical research, experiences with seagoing field research have greatly enhanced my scientific viewpoint and profoundly deepened a connection to the natural forces and phenomena that are in part described by geophysical fluid mechanics.

Gratitudes

This book greatly benefited from interactions with students in the Princeton University Program in Atmospheric and Oceanic Sciences. In particular, parts of this book serve as the basis for the two-semester graduate course, AOS 571 and AOS 572. Further inspiration was offered by students, postdocs, and fellow researchers and scholars encountered on my path. I also thank those who offered specific suggestions, corrections, and comments on various drafts of this book, whose names are too many to list.

I remain humbled and grateful for being part of the unique research environment cultivated at NOAA's Geophysical Fluid Dynamics Laboratory (GFDL) as well as Princeton University's Atmospheric and Oceanic Sciences program. The focus of my research concerns physical oceanography and the ocean's role in climate. The community at GFDL and Princeton University provide an ideal setting for those interested in broadening scientific perspectives while diving deep into particular research areas. As part of my research and mentoring in this community, I have encountered thinkers whose style, questions, and insights have taken root in my work. This work has also afforded me the opportunity to travel the world to interact with colleagues whose wisdom and love of the scientific endeavor are infectious and inspiring. Throughout these interactions, I have entered into trusting and non-judgmental spaces where deep learning and understanding arise. Partaking in these spaces, where heart and mind meld, has been among the most satisfying experiences of my life.

Developing a book of this nature is a not a simple endeavor. It starts modestly, grows over time, and eventually becomes a passion if not an obsession. I was particularly drawn to writing during the COVID-19 pandemic that kept the world largely sequestered at home, and I am grateful that my life situation allowed for this work to safely flourish during these otherwise very difficult times. Writing this book has been an exercise in rational thought that exemplifies the maxim "to write is to learn", as articulated by *Zinnser* (1993). It was furthermore fed by spiritual food from meditation, yoga, family, and community. In particular, each step of this project was supported by my wife, Adi, and our son, Francisco. I am deeply grateful for their patience and trust as I satisfied the goal of writing this book through countless nights, weekends, and holidays. I treasure being part of this family and I dedicate this work to you two amazing human beings.

Caveats and limitations

Although reaching some level of maturity, this book remains a work in progress not yet ready for publication. Here are just a few of the items required before it is ready for its next stage in life.

- A number of further topics will fill these pages. In particular, waves and instabilities remain a work in progress, as does the use of variational methods and Hamilton's principle.
- More effort is needed to unify notation, develop further exercises, enhance figures, improve discussions, and correct errors.
- Many sections and chapters have yet to be scrutinized by readers. Feedback is solicited particularly where the reader identifies poor or confused writing, incorrect concepts, or math errors. Nothing is too trivial for comment.

Disclaimer

Facets of this book originate from research conducted while I was a United States Government federal employee. Reference to relevant papers is provided at the appropriate place in the text. However, no sentence in this book was taken verbatim from any published papers. Rather, the material has been extensively reworked and refined to enhance pedagogical value for the student reader, thus going well beyond that appropriate for research papers or reports. Additionally, this book's writing occupied personal time and was not part of any official assigned government duty, nor did I make use of any U.S. government resources for typesetting or producing figures.

A GUIDE TO THIS BOOK AND ITS STUDY

No book is an island, with this book generously making use of other books, review articles, research papers, and online tutorials. Many readers find value in studying a subject from a variety of perspectives and voices, thus justifying the proliferation of books with overlapping subject matter. Sometimes it is merely one or two sentences that allow for an idea or concept to click within the reader's brain. We thus provide specific pointers to written and/or video presentations that offer supportive views on material in this book. Many further resources are available through a quick internet search.

There is no pretense that any reader will penetrate all topics in this book, nor read this book cover-to-cover. This recognition is particularly apparent in a world where research and educational agendas often spread rather than focus attention. Hence, an attempt has been made to facilitate picking up the book at a variety of starting points. For this purpose, each chapter and/or part is written in a reasonably self-contained manner even at the cost of modest redundancy. When redundancy becomes onerous, cross-referencing identifies allied material treated elsewhere in the book. Here we summarize the book's organization and offer some pointers on how to pursue its study.

Organization

This book is organized into parts according to their particular focus, with each chapter starting with a brief guide to the material and pointing to dependencies to other chapters. Some chapters focus on topics required for a basic understanding of the subject and offer exercises to test that understanding. Other chapters offer monograph style topics that further the foundations and exemplify applications largely taken from a selection of the author's research interests. Although this book is sizable, there are many topics omitted. These omissions reflect on the author's limited energy as well as the desire to keep the book from growing even larger.

MATHEMATICAL METHODS AND CONCEPTS

Part I presents a suite of mathematical topics that are of use for studying geophysical fluid mechanics. These chapters concern topics readily found in applied mathematics or mathematical physics texts. However, we study the material with a distinctively geophysical fluid mechanics perspective. The casual reader can skim these chapters without sacrificing too much from later chapters, assuming a working knowledge of Cartesian tensors (Chapter 1) as well as vector differential and integral calculus (Chapter 2). Where more unfamiliar math topics arise in later chapters, the reader is encouraged to return to these maths chapters to develop skills and to firm understanding. A variety of avenues for physical insights should be embraced by the practitioner of geophysical fluid mechanics, with mathematical acuity offering great rewards to the physicist.

CLASSICAL MECHANICS

Part II provides a survey of topics in classical mechanics, including the motion of particles moving around a rotating planet using methods from both Newtonian mechanics and Lagrangian mechanics. We also introduce notions arising from classical field theory, which forms a powerful theoretical foundation for continuum mechanics and wave mechanics.

KINEMATICS OF FLUID FLOW

Mechanics is comprised of kinematics (the study of intrinsic properties of motion) and dynamics (the study of forces causing motion). In Part III we initiate a study of fluid mechanics by focusing on the kinematics of fluid flow and matter transport within that flow. Our treatment exposes both the Eulerian and Lagrangian viewpoints and emphasizes the variety of kinematic notions and tools key to describing fluid motion. We also encounter facets of material transport as described by the tracer equation, thus laying the foundation for *tracer mechanics*. Fluid flow, and the transport of matter within that flow, have many features fundamentally distinct from point particle and rigid body motion, and it takes time to digest these differences.

Quite often a course in fluid mechanics skims over fluid kinematics, preferring instead to focus on dynamics. Indeed, some kinematic topics can seem a bit esoteric on first encounter, particularly the study of Lagrangian kinematics. However, an incomplete understanding of fluid kinematics can lead to difficulties appreciating facets of fluid dynamics. The reader is thus encouraged to fully study the kinematics chapters, and to revisit the material as the needs arise in later chapters. This study, generally requiring patience and persistence, will nurture the brain muscle and conceptual tools needed to deductively describe fluid motion.

THERMODYNAMICS

Part IV provides an introduction to equilibrium thermodynamics at the level commonly found in undergraduate physics courses. We pay particular attention to the role of gravity in modifying the treatment of thermodynamic equilibrium states, with gravity an essential facet of geophysical fluids. One may choose to skip this part of the book with minimal disruption to later chapters. Even so, thermodynamics is an incredibly rich subject that is central to understanding the fundamental nature of geophysical flows. Hence, it forms a central pillar in our treatment of geophysical fluid mechanics.

DYNAMICS OF GEOPHYSICAL FLUID FLOW

Part V presents the core chapters of geophysical fluid dynamics as studied in this book. Within these chapters we study how Newton's laws of mechanics and the principles of thermodynamics are used to describe fluid motion on a rotating and gravitating planet. We approach the subject by focusing on how forces that act on fluid elements lead to accelerations and thus to motion. These forces act both throughout the volume of a fluid element (*body forces* from gravity, Coriolis, and centrifugal) as well as on the boundary of a fluid element (*contact forces* from pressure and friction).

SHALLOW WATER MECHANICS

In Part VI we study the mechanics of a shallow water fluid, with a shallow water fluid comprised of hydrostatically balanced homogeneous fluid layers. The layers are also typically assumed to be immiscible, so that interactions between layers occur only via mechanical forces from pressure acting at the layer interfaces. The shallow water fluid allows us to focus on rotation and

stratification without the complexities of vertically continuous stratification and thermodynamics. Many physical insights garnered by studying shallow water fluids extend to more realistic fluids, thus making the shallow water model very popular among theorists and teachers. Indeed, *Zeitlin* (2018) provides an example of just how far one can go in understanding geophysical fluids with shallow water theory.

VORTICITY AND POTENTIAL VORTICITY

Part VII dives into the subject of vorticity and potential vorticity. This subject is rich and elegant, though it requires perhaps the most work for the student to penetrate due to the heavy reliance on vector and integral calculus. Vorticity plays a role in the motion of all geophysical fluids since motion on a rotating planet provides a nonzero *planetary vorticity* even to fluids at rest on the planet. This feature of geophysical fluids contrasts to many other areas of fluid mechanics, where irrotational flows are commonly encountered. Potential vorticity is a strategically chosen component of the vorticity vector that melds mechanics (vorticity) to thermodynamics (stratification). Material conservation properties of potential vorticity are striking and render important constraints on fluid motion. Indeed, perhaps the most practical reason to study vorticity concerns the various constraints imposed on the flow moving on a rotating and gravitating planet. These constraints provide conceptual insights and predictive power.

NEARLY GEOSTROPHIC BALANCED FLOWS

Part VIII introduces the topic of balanced models, with our attention limited to the shallow water and continuously stratified versions of quasi-geostrophy and planetary geostrophy. Balanced models generally remove the horizontally divergent motions associated with gravity waves, thus allowing a focus on the large-scale vortical motions. Balanced models have a rich history among theoretical geophysical fluid studies, providing insights into both laminar oceanic flows through planetary geostrophy, and turbulent atmospheric and oceanic flows through quasi-geostrophy.

LINEAR WAVE MECHANICS

Part IX surveys geophysical waves and the various methods used for their characterization. We include waves not commonly included in a book on geophysical fluids, such as sound and capillary waves, with these waves included here due to their ubiquity in the natural environment as well as their pedagogical value. Most focus, however, is given to waves arising from the Coriolis acceleration (inertial waves, planetary Rossby waves, topographic Rossby waves) and gravitational acceleration (surface gravity waves, internal gravity waves). Furthermore, we study linear waves and their corresponding wave packets, first studying their behavior in a homogeneous background environment where Fourier methods are available. Thereafter, we introduce the methods needed to study linear waves on a gently varying background, including the methods of geometrical optics and wave action where Fourier methods are not suited.

FLOW INSTABILITIES

In Part X we study instabilities that arise in geophysical fluid motions. We distinguish two classes of fluid instabilities: *local* or *parcel* instabilities versus *global* or *wave* instabilities. Local instabilities are afforded a local means to detect whether the fluid base state is unstable to perturbations, whereas global instabilities arise from the constructive interference of waves and so involve the solution of an eigenvalue problem. Our study of fluid instabilities introduces a suite of case studies that foster analysis and conceptual methods to establish a foundation for further

study. Geophysical fluid instability analysis remains an active area of research, with insights into the suite of primary and secondary instabilities providing compelling stories for how the ocean and atmosphere work.

GENERALIZED VERTICAL COORDINATES

Part XI brings together elements of a generalized vertical coordinate description of geophysical fluid mechanics. The chapters dive into details of the maths, kinematics, dynamics, and applications. This material is central to many current research activities, including subgrid scale parameterizations and the design of numerical atmosphere and ocean models.

SCALAR FIELDS

Part XII unpacks the mechanics of scalar fields with a focus mostly on the ocean. Here we consider active tracers (temperature and salinity), passive tracers, and buoyancy. Much of this study forms the basis of *tracer mechanics*, which has proven very important for the ocean since it is generally very difficult to measure vector fields such as velocity and vorticity, whereas tracer distributions are far more readily measured. We also consider facets of sea level analysis in this part of the book.

Written and spoken communication

To succeed in research and teaching requires one to master elements of both written and spoken communication. Here we offer a few pointers.

CLEAR THINKING LEADS TO CLEAR COMMUNICATION

Clear communication is the sign of clear thinking. Some people communicate better in writing, where one has the opportunity to carefully organize thoughts and refine the writing style. Others are better at speaking, where spontaneous and interactive reflections and experience can bolster the clarity of a presentation. Both modes of communication are important in science and engineering.

As inspiration, for both clear and obscure, pick up one a textbook or lecture notes and analyze the presentation for clarity. Where is the presentation confusing? Where is the material crystal clear? Then pick up a journal article and perform the same analysis. What is appealing? What is unappealing? Then go to the internet and find a science or engineering lecture, old or new. What makes the speaker engaging and clear, or boring and obscure?

EMPATHY IS KEY

Empathy is a basic facet of effective communication and teaching, which consists of placing the teacher/writer's mind inside that of an interested and smart reader or listener. Identify with their quest to understand new ideas and to comprehend the foundations and assumptions. Are the assumptions justified based on the audience? How compelling is the scientific story?

CLARITY HELPS, BUT SOME MATERIAL IS JUST TOUGH

Although poor communication hinders our ability to digest new ideas and concepts, it is also important to appreciate that some material is tough no matter how well it is communicated. We

should aim to make a subject matter as simple as possible, but not simpler (paraphrasing Einstein). Furthermore, it sometimes takes one or two generations of teaching before some scientific material can be sufficiently digested to allow for the core conceptual nuggets to be revealed. As an example, try reading Newton or Maxwell's original works as compared to a modern presentation of Classical Mechanics or Electromagnetism. So as we strive for clear communication, we cannot presume that clarity is sufficient to remove the struggles everyone experiences when learning.

Pointers on physics problem solving

Most people are not born with *a priori* physics problem solving skills. Rather, it takes extensive practice to develop the necessary brain muscle. Here are some general pointers to keep in mind when diving into a physics problem, whether it is for a class or the basis of a broader research question.

CHECK FOR DIMENSIONAL CONSISTENCY

The symbols we use in mathematical physics correspond to geometrical objects (e.g., points, vectors, tensors) describing a physical concept (e.g., position in space, velocity, temperature, angular momentum, stress). Hence, the symbols generally carry physical dimensions. The physical dimensions we are concerned with in this book are length (L), time (T), mass (M), and temperature. We do not consider electromagnetism. Physical dimensions of the equations must be self-consistent. For example, if one writes an equation $A = B$, where A and B have different physical dimensions, then the equation makes no sense physically. Something is wrong. Although not always sufficient to uncover errors, dimensional analysis is an incredibly powerful necessary step in debugging the maths.

CHECK FOR TENSORIAL CONSISTENCY

In the same way that mathematical equations in physics need to maintain dimensional consistency, they must also respect tensor rules. For example, the equation $A = B$ makes mathematical sense if A and B are both scalars. Likewise, $\boldsymbol{A} = \boldsymbol{B}$ makes sense if $\boldsymbol{A}$ and $\boldsymbol{B}$ are both vectors. However, if both $\boldsymbol{A}$ and $\boldsymbol{B}$ are vectors, then the equation $\boldsymbol{A} = \nabla \cdot \boldsymbol{B}$ does not make sense because the left hand side is a vector and the right hand side is a scalar. A more subtle example is when $\boldsymbol{A}$ is a vector yet $\boldsymbol{B}$ is an axial vector. In this case, $\boldsymbol{A}$ remains invariant under a change from right hand to left hand coordinates whereas $\boldsymbol{B}$ flips sign. Maintaining basic tensorial rules can be considered the next level of sophistication beyond dimensional analysis.

USE WORDS AND PICTURES

Words and pictures are important elements in explaining a problem and its solution. Hence, it is good practice to liberally sprinkle sentences in between the key equations for the purpose of explaining what the maths means using clear English. Here are some practical payoffs for this style of presentation.

- The process of explaining the maths using words and pictures requires one to dive deeper into the logic of the problem. Doing so often reveals weak points, incomplete or unmentioned assumptions, and errors. This process is a very important learning stage in preparing to stand in front of an audience to present results and to answer questions. It is a key facet of research and teaching.

- Physics teachers are often more forgiving of math errors if you convince the teacher that you have a sensible physical understanding of the problem. Plain English and pictures are very useful means for this purpose.

There is often more than one path to a solution

In physics, there is often more than one path to a solution. Pursuing distinct paths offers added physical and mathematical insight, exposes assumptions, and allows one to double-check a solution. Some of the most profound findings in physics came from pursuing distinct formulations. One example concerns the distinct formulation of mechanics offered by Newton (1642-1746), and then later by Lagrange (1736-1813) and then Hamilton (1805-1865). Had Lagrange or Hamilton rested on the merits of Newton's formulation, we may well have had a very different intellectual evolution of 19th and 20th century physics.

Princeton University AOS 571 and AOS 572

Princeton University's AOS 571 and AOS 572 are two courses that focus on geophysical fluid mechanics. The first semester, AOS 571, is concerned with developing conceptual and mathematical foundations of the subject by studying elemental features of planetary fluid motion, and by providing a mathematical physics basis for understanding these patterns. The second semester, AOS 572, makes use of the foundations from AOS 571 to study emergent phenomena arising from waves and instabilities.

DETAILS OF YOUR TEACHER AND THE COURSE

Dr. Stephen M. Griffies
`SMG@princeton.edu`
`https://stephengriffies.github.io/`
Classes are held in Guyot Hall on Monday and Wednesday 3pm-430pm.
Q & A follow the lectures.
Further help is available by appointment.
Worked homeworks to be uploaded onto Canvas before class on the due-day.
Class materials are enabled via Canvas.
Class communication is enabled via Ed Discussion.
Recorded AOS 571 class lectures (from autumn 2020) are available via Canvas.

Class structure and expectations

Our goal for this two-semester sequence of courses is develop an understanding of basic geophysical fluid mechanics, and in so doing to learn how to formulate and to solve problems. To help reach these goals, we study selected chapters from this book. Note that you will be expected to read far more material than covered in class.

As with any other topic in physics, garnering an understanding and appreciation of geophysical fluid mechanics can require effort and practice. To help that process, you are expected to read the assigned material, work through the derivations, and hand-in homework exercises. You will have many opportunities to develop the necessary brain muscle assuming you maintain the discipline to keep up with the material. Please ask questions, preferably in class, when you are unsure of anything.

Cultivating a safe space for healthy learning

A fundamental feature of any class concerns the learning environment. My aim as class teacher is to foster an inclusive, friendly, generous, patient, and non-judgmental space for learning. Key

principles that support this space include equity, diversity and inclusion, each of which are intrinsically valuable and an essential feature of ethical research and education. We also acknowledge and honor past generations whose efforts, some of which were garnered through force and oppression, have led to the rewarding environment in Princeton where we study and conduct research. It is our sincere hope that practicing the above principles will support present and future generations in a way that helps to heal past injustices. Cultivating this safe and grateful space supports deep learning while genuinely appreciating contributions from individuals without regard to race, ethnicity, culture, religion, sexual orientation, gender identity and expression, physical ability, age, socioeconomic status or nationality. As a participant in this space, we each celebrate diversity and nurture an inclusive and friendly community that is optimized for shared learning and mutual understanding.

For many, this class will require a tremendous amount of effort. It will require much focus and energy to master the material even for those with an established background. Regardless your background, talents, or interests, I am here to help. So please reach out if you are struggling. I also encourage you to develop working relations with your classmates. Homework exercises can be done collaboratively, and working with others offers great opportunities for learning.

Even if you prefer to work alone, I ask that you develop some form of a relation with one or more of your classmates. Part of this recommendation is based on the need to informally monitor our mutual health, particularly given that graduate school can be stressful. Even so, it can be a time for building deep friendships and community as we share in the process of learning how to thrive as budding researchers and scholars.

class lectures and class book

The class lectures (with the exception of turbulence in AOS 572) closely follow selected material from Griffies (2024). Prior to each class, you are expected to read through the assigned sections and view the assigned videos. During class we will discuss salient points from the readings and videos. To allow sufficient time for interactive discussion and questions, not all of the assigned reading material will be directly covered in class. Hence, you are expected to read and to understand more material than is covered on the chalkboard. Correspondingly, you are welcome to bring any questions related to the reading to the class, even if the material was not covered in class.

The pace of the lectures will be gauged by questions during the class and my sense for how well you are grokking the material. You are encouraged to follow lectures by having a copy of the class book on-hand, preferably electronically to conserve paper.

please disconnect electronics from internet during class

To support your learning and teaching experience, and those of your classmates, please ensure that you turn all electronic devices into "airplane mode" so that you are not tempted to divert attention to non-class issues. To get the most from the lectures and class time requires focused attention and active participation.

Some pointers for the problem sets

Here we consider some context for the class problem sets, which are an important part of learning the material.

aim for a balance between thorough and brief

There is often a conflict between showing full mastery of a problem and keeping the solution write-up brief. In general, there is no need to re-derive equations already presented in the book. Proper referencing of the equation is all that you need; i.e., tell me something like "starting from equation (X.YY) from Griffies book draft dated DD.MM.YY." Additionally, when presenting a derivation, you may choose to show just the key steps rather than all intermediate steps. Determining what is a "key" step is largely up to you, but it should be something you learn to do in time. Nonetheless, you are encouraged to show more than one approach to a solution.

questions for points of clarification

Questions for points of clarification will be entertained if you feel the problem is ill-posed or if you are totally lost. Email through EdDiscussion is the most efficient means to communicate to me. Responses will generally be sent back through EdDiscussion so that all students can see the response, thus keeping everyone with the same information. Correspondingly, questions within 24 hours of the deadline are generally not entertained so to ensure that all students have time to see the response.

mistakes offer important opportunities for learning

Everyone makes mistakes, some more than others. The toughest part is the self-imposed shame or embarrassment. Please try to keep a positive mind about your mistakes. As you will discover, mistakes offer significant opportunities for learning. I am a poster-child for this process!

So do not be overly anxious if you find many marks on your homeworks and exams. Rather, aim to use mistakes as learning opportunities. That is how life in academics (life in general!) works. Furthermore, be completely honest with yourself to candidly identify weaknesses. I will do my best to work personally with you if something remains uncertain or you feel there is a weakness in your skills that needs some extra help. Please seek help should you wish it. And finally, please do question my marks should you feel they are unfair or incorrect. I am prone to mistakes in my grading.

presentation of the solution: please use LaTeX

Please write clearly and legibly. I strongly encourage you to learn and to use LaTeX as this mark-up language is an indispensible tool for writing documents with or without mathematics. Indeed, LaTeX is required for all AOS 572 assignments, so it is wise to start using it for AOS 571. If you choose to hand-write your solutions, then please ensure that the equations and words are clearly written. In my experience, sloppy hand-writing generally leads to graders who are less forgiving of errors. You must convince the grader that you understand the solution and present the maths in a legible manner.

deadlines are strict in order to be fair to everyone

Please do your best to be on time with handing in homeworks and exams, with disasters, personal tragedy, and significant accidents the only excuses for late assignments. Fairness to those meeting the deadlines is the fundamental reason to insist on this rule. Additionally, I generally aim to grade the homework soon after everyone hands it in, and then to provide solutions for quick feedback. Doing so helps to identify issues and obstacles sooner rather than later. If someone is given extra time, then that delays the feedback time, thus eating into the learning experience for everyone else.

In brief: a homework problem will receive zero credit if handed in late, with rare exceptions.

General rubric for marking your work

Problem sets are marked using the following general rules, with grading less forgiving as the class progresses through the year. The following mistakes are marked by an increasing amount moving through the list.

Points about grading your work

1. sign errors: Sign errors are a nuisance. We all must spend time to uncover them. One means of detecting errors is to try explaining the maths to yourself or someone else. Does the result make sense? If not, then perhaps there is a sign error. I am generally not too upset with sign errors if they have minimal physical relevance. But when they indicate a physical misconception then I will mark it more harshly.
2. math errors: Math errors, such as those associated with basic calculus mistakes, are generally marked.
3. dimensional and tensorial errors: I am relatively unforgiving of dimensional mistakes and tensorial inconsistencies.
4. physically missing the point: Evidence of physically missing the point will generally invoke the most negative marks depending on the depth of the misconception. The best way to convince me you grasp the basic physics is to use words and pictures. If the maths is missing or totally wrong, but you present some sensible words and pictures, then that will help earn some credit.

Course material and strategies for thriving

The course material consists of a class book plus a selection of online videos. Ideally, the book material is to be read and the videos viewed **prior to each class**. Salient points related to the material will be presented during class on the chalkboard, along with further discussion and questions. We will *not* cover all the material in class that is expected to be learned as part of the reading assignments and problem sets. Since there is no laboratory portion of this class, it is very important to view the various videos linked to each lecture. More generally, you are strongly encouraged to peruse this library of classic videos that have stood the test of time for their pedagogy on various topics in fluid mechanics. Additionally, the Homsy Multi-media Fluid Mechanics lectures offer an incredibly valuable tool for basic fluid mechanics concepts. The full content of Homsy is available online through the Princeton University library.

STRATEGIES FOR THRIVING IN THIS COURSE

- ESSENTIALS FROM PROF. BAZETT FOR THE START OF THE SEMESTER
  - View this 12-minute lecture on study tips.
  - View this 12-minute lecture on how to learn effectively.
  - View this 19-minute lecture on how to write LaTeX documents using Overleaf.
- PRIOR TO EACH CLASS
  - Review material from previous lecture (5 to 10 minutes).
  - View assigned videos (5 to 45 minutes).
  - Read assigned class book sections (30-120 minutes).
- AFTER EACH CLASS
  - Reread class book material and review assigned videos.
  - Identify questions for class discussion or during Q & A session.
  - As needed, view recorded class lecture from 2020 to fill in gaps.
  - Work assigned exercises alone and then gather with classmates to discuss and complete.
- QUESTIONS: Address questions by reaching out during class, after class, during office hours, during group gatherings, or via Ed Discussion. There are no silly questions!

Grades for AOS 571

AOS 571 class grade = problem sets (75%) + final exam (25%)

Worked problem sets are due on Canvas prior to the start of class when they are due. Each problem set normally is allocated one week for completion, unless otherwise noted. Students can make use of any resources for solving problem sets, including other people. Clarification of questions can also be obtained via email to me. If you find a solution from a source other than your own head, then be sure that you fully understand both the essence and the detail of the solution. Although you are encouraged to discuss the problems with other students, you are cheating yourself if you merely parrot another person's answer without fully grokking it yourself.

There is no pretense that the exercises offered in class are clearly formulated. Indeed, a certain degree of ambiguity reflects the *status quo* in research, where formulating a novel and insightful question is generally the most difficult part of the research process. Additionally, the solutions may not be 100% correct or ideal from a pedagogical perspective. Rather, they represent a work in progress. If mistakes or ambiguities are found, then please share your questions and concerns.

There is a takehome final exam during exam period. You are asked to do the work as a solo student, with no help or consultation from another human. However, you can make use of books, notes, online resources, etc. The questions are generally taken from published papers with relevant references provided to the student.

AOS 571 course outline

Here we offer specifics of the course material covered during AOS 571. There are 24 class lecture periods of 80-90 minutes each. Most of the following topics take a full class, though some are shorter and some are longer.

0. Lecture-0 consists of pre-class study of the course introduction and mathematics refresher. This material will be assumed when starting the first lecture, so please be prepared. However, if there is a general consensus, we can have extra sessions on this material during the in-person Q & A.

    - Watch this 9-minute video from Prof. N. Hall introducing some basic images from terrestrial fluid flows.
    - Watch this 16-minute video from 3Blue1Brown on the divergence and curl operations with examples taken from fluid mechanics.
    - Read the preface to this book.
    - Read Chapter 1 on cartesian tensors.
    - Read Chapter 2 on vector calculus.
    - Read Chapter 11 on Newtonian particle mechanics.
    - Read Chapter 17 on the continuum hypothesis used for describing fluids as a continuous media.

1. Geophysical particle mechanics

    - Chapter 13: kinematics of a particle moving around a rotating sphere, including position, velocity, acceleration, Cartesian and spherical coordinates, rotating reference frame, Coriolis acceleration, planetary centrifugal acceleration
    - Chapter 13: dynamics of a particle moving around a rotating sphere using Newton's equation of motion, rotating reference frames, gravitational geopotential
    - Watch the first 5-minutes from this UCLA Spin Lab video on Coriolis effect.
    - Exercises 11.1, 13.3, 13.4, 13.7.

2. Symmetries, conservation laws, and constrained motion

    - Chapter 14: mechanical energy, potential momentum, inertial oscillations, axial angular momentum
    - Exercise 14.1

3. Fluid kinematics

    - Chapter 18: Fluid kinematics, Eulerian and Lagrangian descriptions, Galilean invariance, material time derivative, flow lines
    - 4-minute video on Eulerian and Lagrangian descriptions from Prof. Hogg
    - 27-minute video on Eulerian and Lagrangian descriptions from Prof. Lumley.
    - Exercises 18.1, 18.3

4. Mass conservation

- Chapter 20: continuity equation, mass budget for fluid elements and finite regions, kinematic boundary conditions
- 5-minute video on mass conservation from Prof. Hogg.
- Exercises 20.1, 20.2, 20.3, and 20.4

5. Tracer conservation

- Chapter 21: barycentric velocity, tracer equation, budgets for infinitesimal fluid elements, budgets for finite fluid regions, Leibniz-Reynolds transport theorem, boundary conditions

6. Kinematics of non-divergent flows

- Chapter 22: scalar streamfunction, vector streamfunction, area and volume conservation, meridional-depth overturning circulation
- 4-minute video on streamlines from Prof. Hogg.
- Exercises 22.3, 22.4, 22.5, 22.7, 22.8

7. Momentum dynamics

- Chapter 25: momentum dynamics, accelerations, contact forces, body forces, special forms of the momentum equation, axial angular momentum
- 6-minute video on momentum from Prof. Hogg.
- Exercises 25.1, 25.3 and 25.6

8. Stress in fluids

- Chapter 26: stresses and the stress tensor, linear momentum budget, relating stress to strain, form stress, boundary conditions
- 2.5-minute video on stress and strain from Prof. Hogg.
- 8-minute video on stress from Prof. Hogg.

9. Energy dynamics and filtered equations

- Chapter 27: kinetic energy, gravitational potential energy
- 8-minute video on hydrostatic pressure from Prof. Hogg.
- Exercises 27.2, 27.3

10. Pressure in fluids

- Chapter 28: primitive equations, hydrostatic approximation, hydrostatic pressure
- Chapter 29: pressure form stress
- Exercises 28.1, 28.2

11. The Boussinesq ocean

- Chapter 30: oceanic Boussinesq approximation, hydrostatic scaling, pressure and non-divergent velocity
- Exercises 30.4, 30.5

12. Buoyancy

- Chapter 31: Archimedes' principle, buoyancy, stratification, gravitational stability, mass density for perfect and realistic fluids
- 49-minute video from Prof. Lewin for an overview of buoyancy as well as other features of fluid mechanics.
- Exercises 31.1, 31.4

13. Geostrophic mechanics

- Chapter 32: Rossby number, geostrophy, planetary geostrophic equations, Taylor-Proudman, thermal wind, isopycnal form stress
- 30-minute video from Prof. Fultz for an overview of rotating fluids.
- 4-minute video from the UCLA SpinLab for examples of Taylor columns.
- Exercises 32.1, 32.2

14. Natural coordinates and Ekman mechanics

- Chapter 33: natural coordinates for horizontal (tangent plane) flow; centripetal, centrifugal, and Coriolis accelerations; exact geostrophic flow; inertial motion of fluid particles; cyclostrophic balance; gradient wind balance
- Chapter 34 on Ekman mechanics: natural coordinates, spiral motion across isobars, non-dimensionalization and the Ekman number, net mass transport
- Start around the 23-minute mark of this video from Prof. Fultz for his discussion of Ekman layers.
- Exercises 34.1, 34.2

15. Formulation of shallow water models

- Chapter 36: thickness equation, momentum equation, reduced gravity model, stacked shallow water layers, shallow water layer in a rotating tank
- 30-minute video on shallow water model from Prof. Hall.
- Exercises 36.1, 36.6

16. Shallow water dynamics

- Chapter 37: geostrophy, thermal wind, form stress, mechanical energy including available potential energy
- Exercises 37.2, 37.7, 37.8

17. Vorticity and circulation

- Chapter 38: vorticity and circulation
- 23-minute video on vorticity from Prof. Shapiro (part 1 of 2)
- Exercises 38.2, 38.3, 38.4, 38.5, 38.6.

18. Two-dimensional non-divergent barotropic vorticity model

- Chapter 39: two-dimensional barotropic vorticity model; properties of this model.
- Exercises 39.5, 39.6

19. Shallow water vorticity and potential vorticity

- Chapter 40: shallow water vorticity and potential vorticity
- Exercises 40.3, 40.4

20. Vorticity mechanics

    - Chapter 41: vortex lines and tubes, Kelvin's circulation theorem, mechanics of baroclinicity, stretching and twisting of vortex lines, β-effect
    - 21-minute video on vorticity from Prof. Shapiro (part 2 of 2).
    - 5-minute video on vortex rings and Helmholtz's theorems from the Physics Girl.
    - Exercises 41.4, 41.5, 41.6, 41.9

21. Potential vorticity mechanics

    - Chapter 42: Ertel potential vorticity, PV evolution with friction and other irreversible processes.
    - Exercise 42.1

22. Balanced models I (single layer)

    - Chapter 44: Buckingham's Π theorem, asymptotic expansion in terms of small Rossby number, shallow water planetary geostrophy and quasi-geostrophy

23. Balanced models II (continuous stratification)

    - Chapter 45: asymptotic derivation of continuously stratified planetary geostrophy and properties of these equations.
    - Chapter 46: asymptotic derivation of continuously stratified quas-geostrophy and properties of these equations.

Grades for AOS 572

AOS 572 class grade = problem sets (60%) + final report/presentation (40%)

The style of the problem sets is just as in AOS 571, but with one important addition:

all problem sets must be prepared using LaTeX.

This requirement supports your skils in preparing scientific documents using LaTeX, preferably making use of your Princeton Overleaf account. It will also prepare you for the written report.

Rather than a final exam, you will prepare a final project for AOS 572. The project consists of a written report on a non-original topic (i.e., it is not research) and a corresponding tutorial presentation emphasizing a portion of the written report. The topic of the final project is to be decied by the student and teacher and it concerns a topic directly related to waves, instabilities, and/or turbulence, with the topic chosen no later than mid-term. The topic either is one that is *not* covered in the class, or one that is pursued in much more depth than covered in class. Grades are based on mastery of the subject, skills at pedagogically communicating the subject using written and oral methods, and ability to answer fair questions from anyone in the audience.

Here are further details for the project.

- written report = 30% of class grade

1. The report surveys the physics and maths of the chosen topic in a manner allowing it to be taught to AOS 572 students. There should be deductive/pedagogical math derivations along with physical principles and connections to topics in other AOS classes. Citations should be given for all sources.
2. The report is *not* original research. Rather, it represents an intelletually digested view of a topic from the literature that is pedagogically connected to material covered in the class.
3. The report is not purely descriptive. Instead, it must meld the three pieces of clear mathematical physics: words, equations, and schematics.
4. Figures can be original or taken from other books and papers.
5. The report must be typeset in LaTeX using Overleaf and using the provided LaTeX template.
6. The report should be no less than 20 pages (excluding references), and no more than 30 pages total.
7. A thorough report draft (via Overleaf) is due no later than one week prior to the oral presentation, thus allowing the teacher to offer feedback to be addressed in the final draft.
8. Start writing soon after the middle of the semester. Homework assignments will lighten then (though not vanish) to allow time for the report.
9. Feel free to discuss with others the content of the report. However, 100% of the writing and presentation must originate from each respective student. Do not use use any generative artificial intelligence for generating the report.
10. Refer to Mermin (1989) and Griffies et al (2013) for specific pointers on writing styles. Marks will be taken off when ignoring these styles.
11. Grading rubric
    (a) intro/background (20)
    (b) concepts/methods (60)
    (c) pedagogy/clarity/style (20)

- ORAL PRESENTATION = 10% OF CLASS GRADE

1. The presentation is to the full class (and any interested visitors) using a chalkboard with zero electronic media (i.e., no slides and no videos). Eliminating all electronic media focuses efforts on the intellectual content of the report and the presentation rather than tweaking presentation aesthetics. It also provides important experience for working on the chalkboard rather than "hiding" behind electronic slides.
2. The presentation should be designed to last 15 minutes without interruptions. It is not simple to stand in front of a class and convey information. So you are strongly encouraged to practice the presentation beforehand to optimize time and clarity.
3. The 15 minute presentation is not intended to cover the full written report. Rather, the purpose is to teach the class just one or two key concepts from the report. Teaching requires a tremendous amount of study and practice. Be humble with goals for the 15 minute lecture.
4. After the presentation, 15 minutes is then devoted to questions from students, visitors, and the teacher.

5. All students must be present for all presentations.

- grading rubric

1. intro/background (20)
2. concepts/methods (20)
3. pedagogy/speaking skills (20)
4. understanding: presentation (20)
5. understanding: questions (20)

AOS 572 course outline

Here we offer specifics of the course material covered during AOS 572, which is roughly organized as 1/2-waves, 1/3-instabilities, and 1/6-turbulence.

1. Fourier analysis
   - Chapter 4: Fourier analysis
   - This video, also from 3Blue1Brown provides a visual introduction to Fourier transforms.
   - This video from 3Blue1Brown provides a visual introduction to Fourier series.
   - Exercise 4.1
2. Plane waves and wave packets
   - Chapter 47
   - Exercises 47.2, 47.3
3. Acoustic waves
   - Chapter 49
   - The second half of this video offers an introduction to acoustic waves.
   - Exercises 49.1, 49.2
4. Surface gravity and capillary waves
   - Chapter 50
   - Exercises 50.1, 50.2, 50.4, 50.6
5. Inertial waves and intro to Rossby waves
   - Chapter 51
   - Chapter 52
6. Rossby waves I (horizontally non-divergent barotropic model)
   - Chapter 52
   - Exercise 52.1
7. Rossby waves II (horizontally non-divergent barotropic model)

- Chapter 52

8. Shallow water waves I
   - Chapter 53
   - The first half of this video offers an introduction to shallow water waves.
   - Exercises 53.1 and 53.4
9. Shallow water waves II
   - Chapter 53
   - 14-minute video on gravity waves from Prof. N. Hall
   - Exercise 53.5 and 53.6
10. Internal gravity waves I
    - Chapter 54
    - Tank experiment from Prof. Peter Rhines' lab
    - Simulations from Prof. Dale Durran
    - Exercise 54.1
11. Internal gravity waves II
    - Chapter 54
    - Exercise 54.2
12. Centrifugal instability
    - Chapter 55
    - Sections 17.1 and 17.2 of *Cushman-Roisin and Beckers* (2011)
13. Inertial and symmetric instability
    - Chapter 55
    - Section 17.2 of *Cushman-Roisin and Beckers* (2011)
    - Exercises 55.1, 55.2 and 55.3
14. Rayleigh-Taylor and Kelvin-Helmholtz instability
    - Chapter 56
    - Sections 9.1 of *Vallis* (2017)
    - Wikipedia for Rayleigh-Taylor
    - Wikipedia for Kelvin-Helmholtz
15. Horizontal shear instability I
    - Section 52.5
    - Chapter 57
    - Section 3.12 of *Smyth and Carpenter* (2019)
    - Sections 9.2-9.3 of *Vallis* (2017)

- Chapter 10 of *Cushman-Roisin and Beckers* (2011)

16. Horizontal shear instability II
    - Chapter 57
    - Section 3.12 of *Smyth and Carpenter* (2019)
    - Sections 9.2-9.3 of *Vallis* (2017)
    - Chapter 10 of *Cushman-Roisin and Beckers* (2011)
    - Exercise 57.1
17. Stratified shear instability
    - Chapter 57
    - Section 11.7 of *Kundu et al.* (2016)
    - Sections 14.1 and 14.3 of *Cushman-Roisin and Beckers* (2011)
    - Chapter 4 of *Smyth and Carpenter* (2019)
18. Baroclinic instability I
    - Chapter 58
    - Chapter 8 of *Smyth and Carpenter* (2019)
    - Sections 9.4-9.8 of *Vallis* (2017)
    - Sections 17.3-17.6 of *Cushman-Roisin and Beckers* (2011)
    - Rotating tank experiment from Prof. Wing
    - Rotating tank experiment from MIT
19. Baroclinic instability II
    - Chapter 58

List of Symbols

Many symbols encountered in this book are defined local to their usage and are not used far outside of that location. Many other symbols appear in a variety of places and are included in the following list that offers a quick reminder of their meaning. Symbols are here categorized according to whether they are English (Latin-based), Greek, or mathematical operators. Note that some symbols are used for more than one meaning, with the meaning clear from the context.

NON-DIMENSIONAL NUMBERS

SYMBOL	MEANING
Bu	Burger number: Bu = (deformation radius/horizontal length scale of flow)^2 = $(L_\mathrm{d}/L)^2$
Ek	Ekman number: Ek = friction acceleration from vertical shears divided by Coriolis acceleration
Fr	Froude number: Fr = fluid particle speed divided by wave speed
Ge	Geostrophic number: Ge = Coriolis acceleration divided by pressure gradient acceleration
Kn	Knudsen number: Kn = molecular mean free path divided by macroscopic length scale
Ma	Mach number: Ma = fluid particle speed divided by sound speed
Re	Reynolds number: Re = inertial acceleration divided by frictional acceleration = $U\,L/\nu$
Ri	Richardson number: Ri = squared buoyancy frequency divided by squared vertical shear
Ro	Rossby number: Ro = inertial acceleration divided by Coriolis acceleration = $U/(f\,L)$

Latin symbols: Part I

SYMBOL	MEANING
$\mathcal{A}$	wave action
$A^{\mathrm{L}}(\boldsymbol{a}, T)$	Lagrangian representation of a fluid property; a function of material position and time, $(\boldsymbol{a}, T)$
$\boldsymbol{a}$	coordinate for material space and used to label fluid particles
$\mathbb{A}$	skew diffusion tensor: $\mathbb{A}_{mn} = -\mathbb{A}_{nm}$
A^{v}	Avogadro's number: $A^{\mathrm{v}} = 6.0222 \times 10^{23}$ mole^{-1}
b	Archimidean buoyancy with $b > 0$ for relatively light fluid: $b = -g\,(\rho - \rho_0)/\rho_0$
C	tracer concentration = mass of tracer per mass of fluid = tracer mass fraction
C_{D}	dimensionless bottom drag coefficient: $C_{\mathrm{D}} > 0$
$\mathcal{C}$	circulation of velocity around the boundary of a surface $\mathcal{C} \equiv \oint_{\partial \mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{r}$
c_{grav}	shallow water gravity wave speed: $c_{\mathrm{grav}} = \sqrt{g\,H}$
$\boldsymbol{c}_{\mathrm{g}}$	wave group velocity: $\boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k})$
C_{p}	wave phase speed
$\boldsymbol{c}_{\mathrm{p}}$	wave phase velocity: $\boldsymbol{c}_{\mathrm{p}} = C_{\mathrm{p}}\,\hat{\boldsymbol{k}}$
c_{p}	heat capacity at constant pressure: $c_{\mathrm{p}} = [\partial \mathcal{H}/\partial T]_{p,C}$
c_{s}	sound speed: $c_{\mathrm{s}}^{-2} = [\partial \rho/\partial p]_{\Theta,S}$
$\mathcal{E}$	total energy per mass of a fluid element = sum of internal plus mechanical energies
$\vec{e}_a$	basis vectors for a chosen coordinate system, with index $a = 1, 2, 3$ for 3-dimensional space.
f	Coriolis parameter, also the planetary vorticity: $f = 2\,\Omega\,\sin\phi$
f_0	Coriolis parameter at a particular latitude: $f_0 = 2\,\Omega\,\sin\phi_0$
$\boldsymbol{F}$	frictional acceleration vector
F_I^i	deformation matrix, which transforms between material and position space
$G = G^{\mathrm{grv}}$	Newton's gravitational constant: $G = 6.674 \times 10^{-11}$ N m^2 kg^{-2} $= 6.674 \times 10^{-11}$ m^3 kg^{-1} s^{-2}
$G(\boldsymbol{x}\vert\boldsymbol{x}_0)$	Green's function with $\boldsymbol{x}$ the observation point (or field point) and $\boldsymbol{x}_0$ the source point
$\mathcal{G}(\boldsymbol{x}\vert\boldsymbol{x}_0)$	Free space Green's function; i.e., the Green's function without boundaries
$\mathbb{g}$	metric tensor
$\mathcal{G}$	Gibbs potential per mass of a fluid element
g_{e}	gravitational acceleration from central gravity due to just the mass of the planet
g	effective gravitational acceleration from central gravity + planetary centrifugal: $g \approx 9.8$ m s^{-2}
g^{r}	reduced gravity defined between to shallow water layers: $g^{\mathrm{r}}_{\mathrm{k}+1/2} = g\,(\rho_{\mathrm{k}+1} - \rho_{\mathrm{k}})/\rho_{\mathrm{ref}} \ll g$
h_{k}	layer thickness for a shallow water fluid: $h_{\mathrm{k}} = \eta_{\mathrm{k}-1/2} - \eta_{\mathrm{k}+1/2} = \delta_{\mathrm{k}} \eta_{\mathrm{k}-1/2}$
h	layer thickness for a continuously stratified fluid: $h = \overline{h}\,\delta\sigma$
$\hbar$	specific thickness for a generalized vertical coordinate: $\hbar = \partial z/\partial\sigma = 1/(\partial\sigma/\partial z)$
$\mathcal{H}(x)$	Heaviside step function: $\mathcal{H}(x) = 0$ for $x < 0$ whereas $\mathcal{H}(x) = 1$ for $x > 0$
H	vertical length scale of the flow under consideration
H	sometimes used as depth of the ocean bottom: $z = -H(x, y) = \eta_{\mathrm{b}}(x, y)$
H	Hamiltonian energy function
$\mathcal{H}$	Hamiltonian density used in field theory; dimensions energy per volume (when in 3d space)
$\mathcal{H}$	enthalpy per mass of a fluid element
$\mathcal{I}$	internal energy per mass of a fluid element
i	$\mathrm{i} = \sqrt{-1}$ used for imaginary numbers
Im[ ]	imaginary part of a complex number; e.g., $\mathrm{Im}[e^{-\mathrm{i}\,\omega\,t}] = -\sin(\omega\,t)$
$\boldsymbol{J}$	tracer flux; for material tracers the dimensions are mass per time per area
$\boldsymbol{k}$	wavevector (dimensions inverse length) for a wave of wavelength $\Lambda = 2\pi/\vert\boldsymbol{k}\vert$
$\hat{\boldsymbol{k}}$	unit vector in the direction of a wave: $\boldsymbol{k} = \hat{\boldsymbol{k}}\,\vert\boldsymbol{k}\vert$ (as distinct from the vertical unit vector, $\hat{\boldsymbol{z}}$)
$\vert\boldsymbol{k}\vert$	wavenumber: $\vert\boldsymbol{k}\vert = 2\pi/\Lambda$
K	kinetic energy for a particle of mass m: $K = m\,\boldsymbol{V} \cdot \boldsymbol{V}/2$
K	kinetic energy for a system of N particles, $\sum_{n=1}^{N} m^n\,\boldsymbol{V}^n \cdot \boldsymbol{V}^n$
$\mathcal{K}$	kinetic energy per mass of a fluid element arising from macroscopic motion: $\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2$
$\mathcal{K}^{\mathrm{hyd}}$	kinetic energy per mass for an approximate hydrostatic flow: $\mathcal{K}^{\mathrm{hyd}} = \boldsymbol{u} \cdot \boldsymbol{u}/2$
$\mathcal{K}^{\mathrm{sw}}$	kinetic energy per horizontal area for a shallow water layer: $\mathcal{K}^{\mathrm{sw}} = \rho\,h\,\boldsymbol{u} \cdot \boldsymbol{u}/2$
$\mathbb{K}$	diffusivity tensor: positive and symmetric second order tensor parameterizing diffusive mixing
k	integer index to label a layer in a shallow water model with $\mathrm{k} = 1, N$ layers ($\mathrm{k} = 1$ is top layer)
k_{B}	Boltzmann constant: $k_{\mathrm{B}} = 1.3806 \times 10^{-23}$ m^2 kg s^{-2} K^{-1}
k_{R}	Rossby height/depth: $k_{\mathrm{R}} = \vert\boldsymbol{k}\vert\,N/f_0$ with horizontal wavenumber $\vert\boldsymbol{k}\vert = \sqrt{k_x^2 + k_y^2}$

Latin symbols: Part II

SYMBOL	MEANING
L	Lagrangian used in Lagrangian mechanics: kinetic minus potential energies: $L = K - P$
L	length scale for a particular physical feature and commonly used in scale analysis
$\mathcal{L}$	Lagrangian density used in field theory; dimensions energy per volume (when in 3d space)
L_{d}	deformation radius: (a) shallow water $L_{\mathrm{d}} = \sqrt{g\,H}/f$; (b) continuous internal $L_{\mathrm{d}} = H\,N/f$
$\mathbb{M}$	moment of inertia tensor
$\mathcal{M}$	mechanical energy per mass of a fluid element arising from macroscopic motion
$\mathcal{M}^{\mathrm{sw}}$	mechanical energy per area of a shallow water fluid column: $\mathcal{M}^{\mathrm{sw}} = \mathcal{K}^{\mathrm{sw}} + \mathcal{P}^{\mathrm{sw}}$
$\boldsymbol{M}$	potential momentum vector: $\boldsymbol{M} = \boldsymbol{u} + 2\,\boldsymbol{\Omega} \times \boldsymbol{X}$
M	Montgomergy potential for continuously stratified fluid $M = \varphi - b\,z$
$M_{\mathrm{k}}^{\mathrm{dyn}}$	Montgomergy potential for a shallow water layer: $M_{\mathrm{k}}^{\mathrm{dyn}} = \sum_{\mathrm{j}=0}^{\mathrm{k}-1} g_{\mathrm{j}+1/2}^{\mathrm{r}}\,\eta_{\mathrm{j}+1/2}$
M^{air}	mass per mole of air: $M^{\mathrm{air}} = 28.8 \times 10^{-3}$ kg mole^{-1}
N	buoyancy frequency
$\mathcal{O}$	order of magnitude
P	potential energy of a physical system, with corresponding force $\boldsymbol{F} = -\nabla P$
$\mathcal{P}_{\mathrm{k}}^{\mathrm{sw}}$	potential energy per horizontal area for a shallow water fluid: $\mathcal{P}_{\mathrm{k}}^{\mathrm{sw}} = g\,\rho_{\mathrm{k}} \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} z\,\mathrm{d}z$
$\mathcal{P}$	phase of a wave
$\mathcal{P}_\sigma$	generalized momentum for discrete particle system: $\mathcal{P}_\sigma = \partial L/\partial \dot{\xi}^\sigma$
$\mathcal{P}$	generalized momentum density for continuous media: $\mathcal{P} = \partial \mathcal{L}/\partial(\partial_t \psi)$
$\boldsymbol{P}$	linear momentum of a physical system
p	pressure at a point in the fluid
p_{a}	pressure applied to the ocean surface from the atmosphere or cryosphere
p_{b}	pressure at the bottom of a fluid column, at the fluid-solid earth interface
p_{slp}	sea level pressure with an area average, $\langle p_{\mathrm{slp}} \rangle = 101.325 \times 10^3$ N m^{-2}
$p_{\mathrm{k}-1/2}$	hydrostatic pressure at the layer interface with vertical position $z = \eta_{\mathrm{k}-1/2}$
$p_{\mathrm{k}}^{\mathrm{dyn}}$	dynamic pressure in a shallow water layer: $p_{\mathrm{k}}^{\mathrm{dyn}} = \rho_{\mathrm{ref}} \sum_{\mathrm{j}=0}^{\mathrm{k}-1} g_{\mathrm{j}+1/2}^{\mathrm{r}}\,\eta_{\mathrm{j}+1/2}$
P_{k}	pressure integrated over a shallow water layer: $P_{\mathrm{k}} \equiv \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} p_{\mathrm{k}}(z)\,\mathrm{d}z = h_{\mathrm{k}}\,(g\,\rho_{\mathrm{k}}\,h_{\mathrm{k}}/2 + p_{\mathrm{k}-1/2})$
Q	potential vorticity for continuously stratified (Ertel PV) or shallow water (Rossby PV)
q	quasi-geostrophic potential vorticity either for a continuous fluid or shallow water fluid
Q_{m}	mass flux (mass per horizontal area per time) across ocean surface: $Q_{\mathrm{m}} > 0$ enters ocean
$\mathcal{Q}_{\mathrm{m}}$	mass flux (mass per surface area per time) across ocean surface: $\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S} = Q_{\mathrm{m}}\,\mathrm{d}A$
Q_C	turbulent tracer flux (tracer per horiz area per time) across ocean surface: $Q_C > 0$ enters ocean
$\mathcal{Q}_C$	turbulent tracer flux (tracer per surface area per time) across ocean surface: $\mathcal{Q}_C\,\mathrm{d}\mathcal{S} = Q_C\,\mathrm{d}A$
r	radial distance of a point relative to an origin
$\mathbb{R}$	rotation tensor: $2\,\mathbb{R}_{mn} = \partial_n v_m - \partial_m v_n = -2\,\mathbb{R}_{nm}$
$\mathbb{R}^1$	real number line
$\mathbb{R}^2$	two-dimensional space of real numbers
$\mathbb{R}^3$	three-dimensional space of real numbers
R	radius of a sphere
R_{e}	radius of sphere whose volume approximates that of the earth: $R_{\mathrm{e}} = 6.371 \times 10^6$ m
R^{g}	universal gas constant: $R^{\mathrm{g}} = 8.314$ J mole^{-1} K^{-1} $= 8.314$ kg m^2 s^{-2} mole^{-1} K^{-1}
R^{air}	specific gas constant for air: $R^{\mathrm{air}} = R^{\mathrm{g}}/M^{\mathrm{air}} = 2.938 \times 10^2$ m^2 s^{-2} K^{-1}
$\mathcal{R}$	arbitrary region or manifold
Re[ ]	real part of a complex number; e.g., $\mathrm{Re}[e^{-\mathrm{i}\,\omega\,t}] = \cos(\omega\,t)$
$\mathcal{S}$	entropy per mass of a fluid element
$\mathcal{S}$	action: time integral of the Lagrangian: $\mathcal{S} = \int_{t_A}^{t_B} L\,\mathrm{d}t$
$\mathbb{S}$	strain rate tensor: $2\,\mathbb{S}_{mn} = \partial_n v_m + \partial_m v_n$
$\mathbb{S}^{\mathrm{dev}}$	deviatoric strain rate tensor: $\mathbb{S}_{mn}^{\mathrm{dev}} = \mathbb{S}_{mn} - \delta_{mn}\,\mathbb{S}_{qq}/3$
S	salt concentration = mass of salt in a fluid element per mass of seawater
S	Absolute Salinity, generically referred to as salinity: $S = 1000\,\mathsf{S}$
s	expression for a generic surface: $s = s(x, y, z, t)$.
s	arc-length along a curve $\boldsymbol{x}(s)$ with infinitesimal increment $\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x}}$
$\hat{\boldsymbol{s}}$	unit tangent vector to a curve, also written as $\hat{\boldsymbol{s}} = \hat{\boldsymbol{t}}$ (see below)
sgn	sign function related to Heaviside step function via $\mathrm{sgn}(x) = 2\,\mathcal{H}(x) - 1$

Latin symbols: Part III

SYMBOL	MEANING
T	absolute thermodynamic *in situ* temperature (Kelvin if in a thermodynamic equation)
T	time scale for a particular physical process and commonly used in scale analysis
$\mathbb{T}$	stress tensor
$\mathbb{T}^{\text{kinetic}}$	kinetic stress tensor: $\mathbb{T}^{\text{kinetic}} = -\rho\, \boldsymbol{v} \otimes \boldsymbol{v}$
$\mathbb{T}^{\text{sw kinetic}}$	kinetic stress tensor for shallow water fluid: $\mathbb{T}^{\text{sw kinetic}} = -\rho\, \boldsymbol{u} \otimes \boldsymbol{u}$
t	time (universal Newtonian time)
$\hat{\boldsymbol{t}}$	unit tangent vector to a curve: $\hat{\boldsymbol{t}} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$, where s is the arc-length so that $\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x}}$
$\boldsymbol{u}$	horizontal velocity of a fluid particle: $\boldsymbol{u} = \hat{\boldsymbol{x}}\, u + \hat{\boldsymbol{y}}\, v$
U	horizontal velocity scale of the flow under consideration
$\boldsymbol{U}$	depth integrated horizontal velocity: $\boldsymbol{U} = \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u}\, \mathrm{d}z$
$\boldsymbol{v}$	velocity of a fluid particle: $\boldsymbol{v} = \mathrm{D}\boldsymbol{x}/\mathrm{D}t$ with Cartesian component $\boldsymbol{v} = \hat{\boldsymbol{x}}\, u + \hat{\boldsymbol{y}}\, v + \hat{\boldsymbol{z}}\, w$
$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T)$	Lagrangian velocity of a fluid particle: $\boldsymbol{\varsigma}(\boldsymbol{a}, T)$ so that $\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) = \boldsymbol{v}[\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T), t = T]$
$\boldsymbol{v}_{\mathrm{a}}$	velocity of a fluid particle measured in the inertial or absolute reference frame: $\boldsymbol{v}_{\mathrm{a}} = \boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}$
W	vertical velocity scale of the flow under consideration
w	vertical component to the velocity: $w = \mathrm{D}z/\mathrm{D}t$
w^{dia}	dia-surface flux = volume per *horizontal area* per time across a σ-surface: $w^{\text{dia}} = (1/\lvert\nabla\sigma\rvert)\, \dot{\sigma}$
$w^{(\dot{\sigma})}$	dia-surface velocity = volume per *horizontal area* per time across a σ surface: $w^{(\dot{\sigma})} = (\partial z/\partial\sigma)\, \dot{\sigma}$
(x, y, z)	triplet of Cartesian coordinates
$\boldsymbol{x}$	spatial position using a Cartesian representation: $\boldsymbol{x} = \hat{\boldsymbol{x}}\, x + \hat{\boldsymbol{y}}\, y + \hat{\boldsymbol{z}}\, z$
$(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$	triplet of Cartesian unit vectors oriented in a righthand sense
$\boldsymbol{X}(t)$	trajectory of a point particle
$\boldsymbol{X}(\boldsymbol{a}, T)$	position of a material fluid particle, which is the same as the motion field: $\boldsymbol{\varsigma}(\boldsymbol{a}, T) = \boldsymbol{X}(\boldsymbol{a}, T)$
z_σ	specific thickness for a generalized vertical coordinate: $z_\sigma = \partial z/\partial\sigma = \hbar$

Greek symbols: Part I

SYMBOL	MEANING
α	thermal expansion: $\alpha = -\rho^{-1}\,\partial\rho/\partial\theta$ or $\alpha = -\rho^{-1}\,\partial\rho/\partial\Theta$ or $\alpha = -\rho^{-1}\,\partial\rho/\partial T$
α_T	thermal expansion in terms of *in situ* temp: $\alpha = -\rho^{-1}\,\partial\rho/\partial T$
$\alpha^{(\Theta)}$	thermal expansion in terms of Conservative Temperature: $\alpha^{(\Theta)} = -\rho^{-1}\,\partial\rho/\partial\Theta$
α_{aspect}	aspect ratio; ratio of vertical to horizonal scales of the flow: $\alpha_{\text{aspect}} = H/L$
$\beta, \beta^{(\text{S})}$	saline contraction coefficient: $\beta = \beta^{(\text{S})} = \rho^{-1}\,\partial\rho/\partial S$
β	meridional derivative of planetary vorticity: $\beta = \partial_y f$
$\hat{\boldsymbol{\gamma}}$	dianeutral unit vector pointing perpendicular to the neutral tangent plane
δ_{ab}	components to the Kronecker tensor in Cartesian coordinates
δ^a_b	components to the Kronecker tensor in general coordinates
ϵ	kinetic energy dissipation from viscosity (energy per time per mass)
ϵ_{ab}	components to the permutation symbol in two space dimensions
ϵ_{abc}	components to the permutation symbol in three space dimensions
ε_{abc}	components to the Levi-Civita symbol in three space dimensions: $\varepsilon_{abc} = \sqrt{\det(\mathcal{G})}\,\epsilon_{abc}$
η	vertical position of the free upper surface of a fluid domain: $z = \eta(x, y, t)$
$\eta_{\text{k}-1/2}$	vertical position of the top interface of the shallow water layer k
$\eta_{\text{k}+1/2}$	vertical position of the lower interface of the shallow water layer k
$\eta_{\text{b}} = -H$	vertical position of static solid-earth boundary: $z = \eta_{\text{b}}(x, y) = -H(x, y)$
Λ	wavelength of a wave: $\Lambda = 2\,\pi/\lvert\boldsymbol{k}\rvert$, where $\boldsymbol{k}$ is the wavevector and $\lvert\boldsymbol{k}\rvert$ the wavenumber.
$\lambda\!\!\!^{-}$	reduced wavelength of a wave: $\lambda\!\!\!^{-} = \Lambda/(2\pi) = 1/\lvert\boldsymbol{k}\rvert$.
λ	longitude on the sphere: $0 \le \lambda \le 2\pi$
κ	molecular kinematic diffusivity
κ_T	molecular diffusivity for *in situ* temperature in water: $\kappa_T = 1.4 \times 10^{-7}\ \text{m}^2\ \text{s}^{-1}$
κ_S	molecular diffusivity for salt in water: $\kappa_S = 1.5 \times 10^{-9}\ \text{m}^2\ \text{s}^{-1}$
κ_{eddy}	kinematic eddy diffusivity: $\kappa_{\text{eddy}} \gg \kappa$
μ_n	chemical potential for constituent n within a fluid (energy per mass)
$\tilde{\mu}_n$	chemical potential for constituent n within a fluid (energy per mole number)
μ	relative chemical potential for a binary fluid
μ	chemical potential for seawater: $\mu = \mu_{\text{salt}} - \mu_{\text{water}}$
μ_{vsc}	dynamic viscosity $= \rho\,\nu$
ν_{s}	specific volume: $\nu_{\text{s}} = \rho^{-1}$
ν	molecular kinematic viscosity
ν_{air}	molecular kinematic viscosity of air: $\nu_{\text{air}} \approx 1.3 \times 10^{-5}\ \text{m}^2\ \text{s}^{-1}$
ν_{water}	molecular kinematic viscosity of fresh water: $\nu_{\text{water}} \approx 10^{-6}\ \text{m}^2\ \text{s}^{-1}$
ν_{eddy}	eddy viscosity: $\nu_{\text{eddy}} \gg \nu$
ϕ	latitude on the sphere: $-\pi/2 \le \phi \le \phi/2$

Greek symbols: Part II

SYMBOL	MEANING
ξ^a	a'th component to a generalized coordinate
$\boldsymbol{\omega}$	the relative vorticity axial vector: $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$
ω	angular frequency for a wave so that the wave period is $2\pi/\lvert\omega\rvert$
ϖ	dispersion relation for linear waves, relating angular frequency to the wavevector: $\omega = \varpi(\boldsymbol{k})$
$\boldsymbol{\Omega}$	angular velocity vector for a rotating reference frame
$\boldsymbol{\Omega}$	earth's angular velocity vector oriented through the north pole: $\Omega = 7.2921 \times 10^{-5}\ \mathrm{s}^{-1}$
Φ_{e}	gravitational potential from a spherical and homogeneous earth
Φ	geopotential from central gravity plus planetary centrifugal; also, potential energy per mass
Π	Exner function
Π	Boussinesq dynamic enthalpy
ψ	streamfunction for two-dimensional non-divergent flow: $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$
$\boldsymbol{\Psi}$	vector streamfunction for three-dimensional non-divergent flow: $\boldsymbol{v} = \nabla \times \boldsymbol{\Psi}$
ρ	*in situ* density (mass per volume) of a fluid element
ϱ	potential density referenced to a specified pressure
ρ_0	constant reference density used for the oceanic Boussinesq fluid
ρ_{ref}	constant reference density used for the shallow water fluid
σ	generalized vertical coordinate surface with $\sigma(x, y, z, t) =$ constant
$\boldsymbol{\Sigma}$	inverse motion field that generates an inverse mapping of the fluid continuum: $\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T)$
$\boldsymbol{\varsigma}$	motion field that generates a mapping of the fluid continuum as time evolves: $\boldsymbol{a} = \boldsymbol{\Sigma}(\boldsymbol{x}, t)$
$\boldsymbol{\tau}$	stress vector
θ	potential temperature
Θ	Conservative Temperature
ζ	vertical component to the relative vorticity; e.g., $\zeta = \partial_x v - \partial_y u$
ζ_{a}	vertical component to the absolute vorticity; .e.g., $\zeta_{\mathrm{a}} = f + \zeta = f + \partial_x v - \partial_y u$

Mathematical operations and relations

SYMBOL	MEANING
$[\equiv]$	"has dimensions" for use in referring to the physical dimensions
$\times$	vector cross product
∇	gradient operator
∇_z	horizontal gradient operator: $\nabla_z = \hat{\boldsymbol{x}}\,(\partial/\partial x) + \hat{\boldsymbol{y}}\,(\partial/\partial y) = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y$
$\nabla\cdot$	divergence operator that acts on a vector to produce a scalar
$\nabla\times$	curl operator
∇_σ	horizontal gradient on constant σ-surface: $\nabla_\sigma = \hat{\boldsymbol{x}}\,(\partial/\partial x)_\sigma + \hat{\boldsymbol{y}}\,(\partial/\partial y)_\sigma$
∂_σ	vertical partial derivative with general vertical coordinate: $\partial_\sigma = \partial/\partial\sigma = (\partial z/\partial\sigma)\,\partial/\partial z$
$\partial/\partial t$	Eulerian time derivative acting at a fixed spatial position, $\boldsymbol{x}$
$[\partial/\partial t]_\sigma$	time derivative computed on constant σ-surface
$\mathrm{D}/\mathrm{D}t$	material, Lagrangian, or substantial time derivative following a fluid particle
$\mathrm{D}^{\mathrm{g}}/\mathrm{D}t$	time derivative following a ray (integral lines of the group velocity): $\mathrm{D}^{\mathrm{g}}/\mathrm{D}t = \partial/\partial t + \boldsymbol{c}_{\mathrm{g}}\cdot\nabla$
$đ$	inexact differential operator commonly found in thermodynamics
δ	virtual displacement for Lagrangian mechanics and Hamilton's principle
δ	differential increment that is often written when following the fluid flow
$\delta(x)$	one-dimensional Dirac delta with dimensions of inverse length
$\delta^{(2)}(\boldsymbol{x})$	two-dimensional Dirac delta with dimensions of inverse area
$\delta(\boldsymbol{x})$	three-dimensional Dirac delta with dimensions of inverse volume
$\delta(t)$	temporal Dirac delta with dimensions of inverse time
Δ	finite difference increment in space: $\Delta_x, \Delta_y, \Delta_z, \Delta_\sigma$
$\mathrm{d}A$	infinitesimal horizontal area element: $\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y$
$\mathrm{d}\mathcal{S}$	infinitesimal area element on a surface
$\mathrm{d}V$	infinitesimal volume element, sometimes written $\mathrm{d}V = \mathrm{d}\boldsymbol{x}$
$\mathrm{d}\boldsymbol{x}$	infinitesimal volume element, with Cartesian expression $\mathrm{d}\boldsymbol{x} = \mathrm{d}V = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$
δV	infinitesimal volume for a region moving with the fluid (Lagrangian region)
$\int_{\mathcal{R}} \mathrm{d}V$	volume integral over an arbitrary region, $\mathcal{R}$
$\int_{\mathcal{R}(\boldsymbol{v})} \mathrm{d}V$	volume integral over a region following the fluid flow (Lagrangian integral)
$\int_{\mathcal{S}} \mathrm{d}\mathcal{S}$	surface integral over an arbitrary surface $\mathcal{S}$
$\oint_{\partial\mathcal{R}} \mathrm{d}\mathcal{S}$	surface integral over a closed surface $\partial\mathcal{R}$ that bounds the volume $\mathcal{R}$
$\oint \mathrm{d}\ell$	closed line integral over a periodic domain
$\oint_{\partial\mathcal{S}} \mathrm{d}\ell$	counter-clockwise closed line integral over the boundary of a surface, $\partial\mathcal{S}$
$\sim$	"similar to" or "scales as"
$\approx$	approximately equal to
$\dot{\Psi}$	time derivative following a trajectory; for fluid particle trajectories then, $\dot{\Psi} = \mathrm{D}\Psi/\mathrm{D}t$

Part I

Mathematical methods

Fluid mechanics is a classical field theory based on the laws of mechanics and quasi-equilibrium thermodynamics as applied to a continuous fluid media. Geophysical fluid mechanics is concerned with gravitationally stratified fluids with multiple matter constituents moving on a rotating sphere. The speed for all motion is small relative to the speed of light so that relativistic effects are negligible, thus enabling the use of universal *Newtonian time* for all observers. Our goal for this part of the book is to review mathematical topics for use in our study of geophysical fluid mechanics. Depending on the reader's background and interests, this material can be readily skipped on first reading and/or accessed later to fill gaps.

Concerning the value and importance of maths

When considering the impressive skill of numerical simulations, the analytical training received by a theoretical scientist and engineer in the 20th century may seem like a relic of the day when theorists routinely knew how to derive and/or solve many of the key equations of mathematical physics. Indeed, there is (arguably) less need today to be proficient with the methods and tricks built up during the 19th and 20th centuries to analytically derive and solve mathematical physics equations. However, to ignore the wealth of fundamental understanding that arises from such exercises risks missing a huge opportunity to grok the physics. For this book, the study of waves and instabilities (Parts IX and X) provides a particular case in point where solution methods and physical insights are intimately woven. Further insights arise from the use of vector and tensor analysis to expose the physical and geometrical meaning of a physics equation, even if the equation cannot be analytically solved. In general, there is a growing (not declining) need in the atmospheric and oceanic sciences for practitioners to understand the physical principles and mathematical methods at the heart of pictures generated by ever-increasingly powerful computers, satellites, and *in situ* measures. This part of the book offers resources in support of mathematical methods.

physics provides relations between geometric objects

Mathematical objects of use for the study of fluid mechanics include scalar fields (e.g., temperature, mass density, specific entropy), vector fields (e.g., velocity, vorticity), and second order tensor fields (e.g., diffusion tensor, stress tensor, moment of inertia tensor). These and other fields have a value at each point in the continuous space and time used in continuum mechanics. Furthermore, their existence is independent of the arbitrary coordinate choices used for the mathematical description. Abstractly, we can consider these physical fields as geometric objects such as points, vectors, surfaces, volumes, etc. In the study of geophysical fluid mechanics, we use physical principles to develop differential equations relating geometric objects. Mathematical tools of analysis are then used to compute the numbers required to compare with experiments and field measurements, and to formulate discrete equations for numerical simulations.

Our perspective can be summarized by "physics as geometry", which forms a foundation to theoretical physics such as that detailed in *Thorne and Blandford* (2017). This perspective has both conceptual and practical use for our study throughlut this book. In this part of the book we develop mathematical tools of geometry and analysis that are later used to formulate a variety of theoretical geophysical fluid models. Our aim is to develop maths to help both pack and unpack the physics encapsulated by equations, pictures, and words. This aim extends to those cases where closed form analytical solutions are unavailable, which is the norm for nonlinear field theories such as fluid mechanics or even in many cases when the equations are linearized. Such qualitative and conceptual tools are of great value for the analysis of numerical simulations and field measurements.

tensor analysis and geophysical fluid mechanics

There are many occasions where a geophysical fluid system is more physically transparent when using a particular coordinate description or reference frame. However, there is no *a priori* coordinate choice that fits all cases. Thus, being adept at transforming from one mathematical description to another eases the study and pays huge dividends to the practioner. Tensor analysis is the proven means for systematically performing such transformations, thus motivating its use in fluid mechanics and other areas of continuum mechanics. In its more abstract realization via differential (or exterior) forms (not pursued in this book), tensor analysis provides the means to mathematically express physical ideas without any display of coordinate artefacts, thus exposing the underlying physical and mathematical essence.

The following offers an incomplete list of geophysical fluid systems where various coordinate descriptions or reference frames are encountered, and thus where tensor analysis can be put to use. Granted, each system listed here can be studied without the formalism of tensor analysis. However, by doing so one often encounters clumsy manipulations that can obfuscate the underlying physical concepts. Indeed, imagine the tedium required to write continuous field equations in multiple dimensions prior to vector analysis.[3] That situation is akin to the tedium and awkward nature required to work across multiple coordinate systems and reference frames absent the formalism of tensor analysis. Hence, an adept use of vector analysis and its generalization to tensor analysis reveals how maths can inform the physics and how physics can be transparently embodied by the maths.

- RELATING EULERIAN AND LAGRANGIAN KINEMATICS: There is a duality in fluid kinematics between Eulerian and Lagrangian descriptions of fluid motion. To develop an understanding of this duality we make use of tensor analysis to facilitate the transformation between the two kinematic descriptions. For many purposes in continuum mechanics, one can pursue a description of motion without the choice of an origin, thus making use of some general results from differential geometry and tensor analysis. Our pursuit is less ambitious since we always have in mind a fluid system on a rotating planet in a background Euclidean space with universal Newtonian time. So for our puposes we acknowledge that the planet's origin offers the natural origin for a spatial description, and that the rotation axis breaks spherical symmetry down to axial symmetry.

- APPROXIMATELY SPHERICAL PLANET: Geophysical fluids move on an approximately spherical planet, making spherical coordinates the preferred choice for studying planetary flows.[4] The surface of a sphere is non-Euclidean object that is embedded in a background Euclidean space. We make use of tensor methods to transform between planetary Cartesian coordinates (origin at the center of the planet) and spherical coordinates. Notably, spherical coordinates are locally orthogonal, so that one can, if desired, make use of spherical coordinates without the machinery of tensor analysis. Even so, having two ways to develop the spherical equations provides useful pedagogy when learning tensor analysis since results are readily checked with prior experience.

- ROTATING TANK: Rotating laboratory fluids move in a circular tank, with cylindrical polar coordinates of use to respect symmetry of the domain. We make use of tensor methods to transform between Cartesian and cylindrical polar coordinates when considering rotating tank systems. Cylindrical polar coordinates are locally orthogonal, so that our comments above about spherical coordinates holds also here.

[3] The original treatment of electrodynamics by Maxwell was before the notations of vector analysis were invented by Gibbs and others. Hence, reading Maxwell's original maths is, by today's standards, rather tedious and very challenging.

[4] *Staniforth* (2022) provides compelling arguments for moving beyond spherical coordinates for realistic atmospheric and oceanic modeling.

- rotating reference frame: Geophysical fluids move around a rotating earth and the fluid maintains a nearly rigid-body motion. Terrestrial observers also move in near rigid-body motion with the planet. We are thus motivated to study geophysical fluids from a rotating reference frame. We use rudimentary tensor methods to transform between a fixed inertial frame and the non-inertial rotating reference frame, with this transformation revealing non-inertial accelerations (planetary Coriolis and planetary centrifugal) that impact on the observed fluid flow.

- Galilean transformations: Geophysical fluids move in a space-time defined by universal *Newtonian time* (all clocks measure same time) and Euclidean space, with the product of these two defining *Galilean space-time*. When studying fluid motion it can be convenient to move from one Galilean reference frame to another, with the movement referred to as a *Galilean transformation*. Tensor methods are quite useful to develop the mathematical relations between two Galilean reference frames.

- stratified fluids and generalized vertical coordinates: Geophysical fluids move in a gravitational field that acts to stratify the fluid according to its local buoyancy (high buoyancy fluid sit above low buoyancy fluid). When there is a one-to-one invertible relation between the height and the buoyancy, then it can be useful to describe the vertical position of a fluid element according to its buoyancy rather than its height. This buoyancy or "isopycnal" vertical coordinate choice leads to a non-orthogonal coordinate description of the fluid motion. There are other vertical coordinates that can be of use for other situations, such as the terrain following coordinates commonly used for atmospheric simulations and coastal ocean models. Transforming between Cartesian coordinates and such *generalized vertical coordinates* is greatly facilitated by the use of general tensor analysis.

In general, our use of tensor analysis is minimized both to reduce the necessary mathematical overhead for the reader, and because much of the physics in this book is suitably displayed with Cartesian coordinates, in which case tensor analysis and vector calculus are nearly identical. Furthermore, even in those cases where tensor analysis is an obvious benefit, such as the generalized vertical coordinates of Part XI, we do not pursue the full power of tensor analysis since doing so requires more development of the mathematical formalism than warranted for this book.

summary of the math chapters

Some of the chapters in this part of the book are essential for nearly all subsequent chapters (e.g., Chapters 1 and 2), with the bulk of this book accessible to those with a strong undergraduate training in multivariate calculus and the rudiments of analytic geometry. Other chapters target those interested in penetrating various special topics presented in this book. Readers are encouraged to take a close look at each chapter if only to know where to find topics of use later in the book or later in one's career.

- cartesian tensor algebra: Chapter 1 is a synopsis of Cartesian tensor analysis. This topic provides a systematization of ideas from Cartesian geometry and linear algebra. Material in this chapter is essential for nearly every topic in this book.

- cartesian tensor calculus: Chapter 2 extends the algebraic ideas from Chapter 1 to differential and integral calculus. This chapter provides a resume of multivariate or vector calculus of use for fluid mechanics. Material in this chapter is essential for nearly every topic in this book.

- partial differential equations: Chapter 3 provides a summary of linear partial differential equations (PDEs) commonly encountered in mathematical physics. Even though the equations of fluid mechanics are nonlinear, their linear counterparts offer much insight into fluid behavior, with particular applications to the study of waves, instabilities, and tracer transport.

- fourier analysis: Chapter 4 summarizes salient points about Fourier series and Fourier transforms. We make particular use of Fourier analysis in the study of wave mechanics in Part IX of this book.

- green's functions: Chapter 5 provides a survey of Green's function methods used to solve linear partial differential equations of mathematical physics. We study the Green's function method since it facilitates rather general insights into both the mathematical and physical content of fluid equations. Furthermore, Green's function methods are commonly used across various areas of the geophysical sciences, thus making it quite useful to be familiar with the method.

- variational calculus: Chapter 6 offers an introduction to the calculus of variations, which proves of great use for our study of mechanics via Hamilton's Principle.

- geometry of curves and surfaces: Chapter 7 introduces rudimentary differential geometry used to characterize curves (such as fluid particle trajectories) and surfaces (such as isopycnals) embedded in a background Euclidean space. Here we encounter such notions as normal and tangent directions and curvature.

- general tensor introduction: Chapter 8 provides an introduction to general tensor analysis and its applications to geophysical fluids. The discussion is accessible to anyone who has read Chapter 1, and is recommended for all readers of this book, even for those who do not wish to study the details of general tensors in Chapter 9.

- general tensor analysis: Chapter 9 extends the Cartesian tensor algebra and calculus from Chapters 1 and 2 to allow for arbitrary, or general, coordinates. This chapter is essential to understand the mathematics underlying non-Cartesian coordinates, such as spherical coordinates and generalized vertical coordinates.[5] Note that we retain the assumption that all tensors are embedded within a background Euclidean space.

- orthogonal coordinates: Chapter 10 offers a reference for the three locally orthogonal coordinate systems (Cartesian, spherical, cylindrical) used in this book and how various mathematical objects appear when written in these coordinates.

[5] In Part XI of this book, we dive deeply into the mathematical physics enabled by generalized vertical coordinates.

Chapter 1

Cartesian tensor algebra

An isomorphism from Euclidean space to the space of three-dimensional real numbers, $\mathbb{R}^3$, associates to each point of Euclidean space the *Cartesian coordinates* of that point. In this chapter we introduce the formalism of Cartesian tensor analysis with a focus on linear algebraic relations. The study of Cartesian tensors restricts attention to geometric objects described by Cartesian coordinates on a flat Euclidean space. Furthermore, all Cartesian reference frames (of equivalent handedness) are related by rotations as realized by orthogonal transformations.[1] Notably, Cartesian tensors gives us nearly all of the formalism necessary to employ general tensors for applications in geophysical fluid mechanics. So there is nontrivial payoff for diving deep into this chapter as well as the Cartesian tensor calculus treated in Chapter 2

A mathematical study of geophysical fluid motions makes use of *Galilean relativity*, which is built from the *Newtonian universal time* and flat *Euclidean space*. This space and time structure induces the familiar Euclidean norm or *metric* when measuring the spatial distance between two points, whether the points are on a plane, a sphere, or an arbitrary surface within the fluid such as a surface of constant Archimedean buoyancy. We can thus make use of Cartesian coordinates as the starting point for a mathematical formulation of geophysical fluid mechanics. Transformations to alternative coordinates are made when they lend insight to the symmetry of the flow and/or the geometry of the space on which the flow occurs.

CHAPTER GUIDE

We follow standard treatments of Cartesian tensors such as that in Chapter 2 of *Aris* (1962), Chapter 1 of *Segel* (1987), and Chapter 2 of *Lovelock and Rund* (1989) (where they use the term *affine tensors* rather than *Cartesian tensors*). The discussion should be accessible to those having studied undergraduate calculus and linear algebra. For geophysical fluid mechanics, mastery of Cartesian tensors is nearly sufficient for mastery of general tensors. This chapter is basic to all of the maths in this book.

1.1 Scalar fields **8**
1.2 Points and vectors **9**
1.3 Distance and the scalar product **10**
1.3.1 Distance between points 11
1.3.2 Magnitude of a vector and the scalar product 11
1.4 Vector product **12**
1.4.1 Basis vector orientation and the Levi-Civita tensor 12
1.4.2 Axial (or pseudo) vector 13

[1] Such orientation preserving transformations are all that we consider in this book.

1.4.3 Orthogonality relations between cross products 13
1.4.4 Vector product of arbitrary vectors 14
1.4.5 Geometric interpretation of the vector product 14
1.4.6 Generalization to arbitrary vectors 16
1.5 Measuring volume 16
1.5.1 Volume defined by three vectors 16
1.5.2 Cartesian volume element for integration 17
1.5.3 $n-$space volumes and the Levi-Civita tensor 17
1.6 Example vector identities using the Levi-Civita tensor 18
1.6.1 Double vector product 18
1.6.2 Scalar product of two vector products 18

1.9 Irreducible parts of a second order tensor 23
1.10 Exercises 24

1.1 Scalar fields

A scalar field provides a number at each point in space and time, and a physical scalar field provides a number with a physical dimension at each point in space and time. Example physical scalar fields include temperature, mass density, entropy, salinity, humidity, and mechanical energy.

To add a bit of mathematical formalism to these ideas, let Π be a physical scalar field and $\mathscr{P}$ be a space point within the fluid. At time t and point $\mathscr{P}$ the property Π has a value written

$$\Pi(\mathscr{P}, t) = \text{property } \Pi \text{ measured at space point } \mathscr{P} \text{ and time instance } t. \tag{1.1}$$

Now lay down a set of coordinates, $\boldsymbol{x}$. The property Π sampled at a spatial point represented by coordinates $\boldsymbol{x}$ is specified by evaluating a function

$$A(\boldsymbol{x}, t) = \text{property } \Pi \text{ measured using coordinates } \boldsymbol{x} \text{ and time } t. \tag{1.2}$$

If $\boldsymbol{x}$ is the Cartesian coordinate for the point $\mathscr{P}$, then

$$A(\boldsymbol{x}, t) = \Pi(\mathscr{P}, t) \quad \text{with } \boldsymbol{x} \text{ the coordinate representation for } \mathscr{P}. \tag{1.3}$$

If we instead choose another set of coordinates, called $\boldsymbol{x}'$, then property Π sampled at a spatial point represented by coordinates $\boldsymbol{x}'$ is specified by evaluating another function

$$B(\boldsymbol{x}', t) = \text{property } \Pi \text{ representated by coordinates } \boldsymbol{x}' \text{ and time } t. \tag{1.4}$$

That is, B is a function of the spatial coordinates $\boldsymbol{x}'$ used to measure the property Π, whereas A is a generally distinct function of $\boldsymbol{x}$ and t that also measures the property Π. Now if the two sets

FIGURE 1.1: An arbitrary point in space, $\mathscr{P}$, has an objective existence independent of our subjective choice of coordinate system used to describe its position. We here represent its position with respect to the origin of a right-handed Cartesian coordinate system. The Cartesian representation of the position vector is $\mathscr{P} \mapsto \vec{P} = \boldsymbol{P} = \hat{\boldsymbol{x}}\, P_1 + \hat{\boldsymbol{y}}\, P_2 + \hat{\boldsymbol{z}}\, P_3$, with the Cartesian basis vectors the normalized triplet of unit vectors $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$ and the triplet of Cartesian coordinates given by (P_1, P_2, P_3). There is a continuous infinity of possible Cartesian coordinate systems that are rotated and/or translated with respect to the one shown here.

of coordinates are those for the point $\mathscr{P}$, then

$$A(\boldsymbol{x}, t) = B(\boldsymbol{x}', t) = \Pi(\mathscr{P}, t). \tag{1.5}$$

We generally need two functions since a particular point in space, $\mathscr{P}$, will generally have distinct values for the coordinates, $\boldsymbol{x}$ and $\boldsymbol{x}'$.

The above treatment is precise mathematically and necessary for practical applications where details of a function used to represent the scalar field depends on what set of coordinates are chosen. Even so, this mathematically precise treatment is sometimes clumsy for certain physical considertions, in which case it is sufficient to know that Π is a scalar physical property. As a scalar, we know that Π provides a physical property measured at each point in space, with the measured value independent of the chosen coordinates used to represent the space point. Correspondingly, details concerning what function is used to represent the scalar property are uninteresting from a physics perspective, in which case we are motivated to simply write $\Pi(\boldsymbol{x}, t)$ for a scalar field. In this manner, $\Pi(\boldsymbol{x}, t)$ is an overloaded symbol that represents both a physical property measured at $(\boldsymbol{x}, t)$, as well as the mathematical function representing that property.

1.2 Points and vectors

Consider a point, $\mathscr{P} \in \mathbb{R}^3$, as represented by its Cartesian coordinates relative to an arbitrary origin. As such, the position is a vector whose tail is at the origin and head at the point, with Figure 1.1 sketching an example. We write this coordinate representation as

$$\mathscr{P} \mapsto \vec{P} = \hat{\boldsymbol{x}}\, P_1 + \hat{\boldsymbol{y}}\, P_2 + \hat{\boldsymbol{z}}\, P_3, \tag{1.6}$$

with the arrow over a symbol commonly used for vectors. The right hand side of equation (1.6) provides the *coordinate representation* of the position vector through the ordered triplet of numbers, (P_1, P_2, P_2). Each element of the triplet measures the coordinate distance along the axes defined by their corresponding Cartesian unit vectors, $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$. The Cartesian unit vectors form a right-handed basis for three dimensional Euclidean space.[2] Hence, the position vector for any point in Euclidean space can be represented in terms of these three basis vectors.

[2]The unit vectors are sometimes denoted $(\hat{\boldsymbol{\imath}}, \hat{\boldsymbol{\jmath}}, \hat{\boldsymbol{k}})$ in the literature. We generally avoid that notation in this book.

On occasions we find it useful to make use of alternative notations in which the position vector is written

$$\vec{P} = \boldsymbol{P} \tag{1.7a}$$
$$= \hat{\boldsymbol{x}}\, P_1 + \hat{\boldsymbol{y}}\, P_2 + \hat{\boldsymbol{z}}\, P_3 \tag{1.7b}$$
$$= \sum_{a=1}^{3} \vec{e}_a\, P_a \tag{1.7c}$$
$$= \vec{e}_a\, P_a. \tag{1.7d}$$

The first equality introduced the boldface notation, which we commonly use for the representation of vectors in Cartesian coordinates. Indeed, although less convenient when moving to the general tensors of Chapter 8, we still maintain the boldface in this book given its common usage in the literature and since much of this book makes use of Cartesian tensors. Equation (1.7d) introduced the Einstein summation convention in which repeated indices are summed over their range, thus allowing us to drop the summation symbol. Equation (1.7c) introduced a generic notation for the basis vectors

$$\vec{e}_1 = \hat{\boldsymbol{x}} \quad \text{and} \quad \vec{e}_2 = \hat{\boldsymbol{y}} \quad \text{and} \quad \vec{e}_3 = \hat{\boldsymbol{z}}. \tag{1.8}$$

The Cartesian basis vectors each have unit magnitude (normalized), meaning that their scalar products yield[3]

$$\hat{\boldsymbol{x}} \cdot \hat{\boldsymbol{x}} = \hat{\boldsymbol{y}} \cdot \hat{\boldsymbol{y}} = \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{z}} = 1. \tag{1.9}$$

Use of a hat or carot symbol over a vector signifies that the vector is normalized to unity. For Cartesian coordinates we generally work with the normalized basis vectors (1.8). Furthermore, a normalized vector can change only through rotation since by definition it remains of unit norm and so cannot change its magnitude (see Section 2.1.4). For the general tensors of Chapters 8, 10 and 59, we sometimes find it more convenient to work with unnormalized basis vectors. Hence, the basis vectors, $\vec{e}_a$, retain the arrow symbol rather than the carot since they are not always normalized.

We emphasize that the tensor labels denote components of a specific coordinate representation, P_a, as well as members from the set of basis vectors, $\vec{e}_a$. These labels are not to be confused with partial derivative operations.[4] Finally, we sometimes write the vector components and basis vectors in the form of a list or triplet

$$P_a = (P_1, P_2, P_3) \qquad \text{and} \qquad \vec{e}_a = (\vec{e}_1, \vec{e}_2, \vec{e}_3) = (\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}}). \tag{1.10}$$

1.3 Distance and the scalar product

In defining a vector to have unit magnitude, we are assuming we know how to measure the magnitude of a vector. We here make this notion precise.

[3] The Cartesian scalar (or dot or inner) product is discussed more formally in Section 1.3.

[4] In this book we generally eschew the notation where partial derivatives are denoted by a subscript. One exception occurs in our discussion of the density evolution in Sections 67.2 and 67.3.

1.3.1 Distance between points

Consider two points in Euclidean space, $\mathscr{P}$ and $\mathscr{P}+\mathrm{d}\mathscr{P}$, separated by a small distance and specified by their respective position vectors

$$\mathscr{P} \mapsto \vec{P} = \vec{e}_a\, P_a \tag{1.11a}$$

$$\mathscr{P} + \mathrm{d}\mathscr{P} \mapsto \vec{P} + \mathrm{d}\vec{x} = \vec{e}_a\,(P_a + \mathrm{d}x_a). \tag{1.11b}$$

Euclidean space is afforded a metric whereby the squared distance between two points is measured via *Pythagoras' theorem*

$$\begin{aligned}
[\mathrm{distance}(\mathscr{P}, \mathscr{P}+\mathrm{d}\mathscr{P})]^2 &= (\vec{P} + \mathrm{d}\vec{x} - \vec{P}) \cdot (\vec{P} + \mathrm{d}\vec{x} - \vec{P}) && \text{definition of distance} && (1.12a)\\
&= (\boldsymbol{P} + \mathrm{d}\boldsymbol{x} - \boldsymbol{P}) \cdot (\boldsymbol{P} + \mathrm{d}\boldsymbol{x} - \boldsymbol{P}) && \text{boldface notation} && (1.12b)\\
&= \mathrm{d}x_a\, \mathrm{d}x_b\, (\vec{e}_a \cdot \vec{e}_b) && \text{expose tensor indices} && (1.12c)\\
&= \mathrm{d}x_a\, \mathrm{d}x_b\, \delta_{ab} && \text{basis vector orthonormality} && (1.12d)\\
&= \mathrm{d}x_a\, \mathrm{d}x_a && \text{contraction of tensor indices} && (1.12e)\\
&= (\mathrm{d}x_1)^2 + (\mathrm{d}x_2)^2 + (\mathrm{d}x_3)^2 && \text{expanding the sum.} && (1.12f)
\end{aligned}$$

To reach this result we introduced the components to the *Kronecker delta* tensor, which can be represented by the 3×3 identity matrix

$$\vec{e}_a \cdot \vec{e}_b = \delta_{ab} = \begin{bmatrix} \delta_{11} & \delta_{12} & \delta_{13} \\ \delta_{21} & \delta_{22} & \delta_{23} \\ \delta_{31} & \delta_{32} & \delta_{33} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{1.13}$$

The Kronecker tensor provides the Cartesian coordinate representation of the *metric tensor* for Euclidean space. The metric provides the means to measure the distance between points in space, and thus how to measure the length of a vector. It also allows us to *normalize* a vector to have unit magnitude, motivating the often used term *norm* rather than metric. In Section 9.1 we introduce alternative representations for the metric based on the use of non-Cartesian coordinates and non-Euclidean manifolds.

1.3.2 Magnitude of a vector and the scalar product

FIGURE 1.2: Illustrating the geometry of the scalar product (also known as the dot product or inner product) between two vectors, $\boldsymbol{P} \cdot \boldsymbol{Q} = |\boldsymbol{P}|\,|\boldsymbol{Q}|\,\cos\vartheta$.

By defining the distance between two points, we in turn have a prescription for defining the squared magnitude of a vector

$$|\boldsymbol{P}|^2 = \boldsymbol{P} \cdot \boldsymbol{P} = P_a\, P_b\, (\vec{e}_a \cdot \vec{e}_b) = P_a\, P_b\, \delta_{ab} = P_a\, P_a = (P_1)^2 + (P_2)^2 + (P_3)^2. \tag{1.14}$$

Correspondingly, we have the *scalar product* between two arbitrary vectors

$$\boldsymbol{P} \cdot \boldsymbol{Q} = P_a \, Q_b \, (\vec{e}_a \cdot \vec{e}_b) = P_a \, Q_a, \tag{1.15}$$

which also goes by the name *dot product* or *inner product*. Given our expression for the scalar product and the magnitude of vectors, we can introduce a geometrical interpretation by defining the angle between the vectors according to

$$\cos \vartheta \equiv \frac{\boldsymbol{P} \cdot \boldsymbol{Q}}{|\boldsymbol{P}| \, |\boldsymbol{Q}|} = \frac{P_a \, Q_a}{\sqrt{P_b \, P_b} \, \sqrt{Q_c \, Q_c}}. \tag{1.16}$$

We illustrate this equation in Figure 1.2. It is useful to convince oneself that this definition is consistent with $-1 \leq \cos \vartheta \leq 1$. Furthermore, note that this definition of an angle between two vectors makes use of the metric tensor, so that angles on a manifold, just as distance, require a metric.[5]

1.4 Vector product

The scalar product provides a means to measure the magnitude of a vector and the distance between two points. We here introduce the vector (or cross) product, which provides a means to measure area associated with two vectors and to specify the *orientation* of that area.

1.4.1 Basis vector orientation and the Levi-Civita tensor

Consider a flat plane defined by any two of the Cartesian basis vectors, $\vec{e}_a$ and $\vec{e}_b$. We seek a means to specify what side of the plane is up and what side is down. Doing so allows us to orient objects within space.[6] Notably, there is no objective means for this specification, since "up" and "down" are subject to our chosen orientation. Therefore, we must choose a convention. For that purpose, we follow the *right hand rule*, in which the out-stretched thumb, index, and middle fingers of the right hand orient the three Cartesian basis vectors.

We algebraically specify the right hand rule for the basis vectors through the relation

$$\vec{e}_a \times \vec{e}_b = \epsilon_{abc} \, \vec{e}_c. \tag{1.17}$$

The left hand side introduces the *vector (or cross) product* of two basis vectors. The right hand side algebrically defines the vector product as the *contraction* of the Levi-Civita tensor with another basis vector. Here, the term contraction can be considered a generalization of the inner product. The Cartesian components of the Levi-Civita tensor are given by the totally anti-symmetric

[5] This point about the need for a metric tensor might seem pedantic to those having only worked with Euclidean space, where the formalism of linear algebra and calculus generally builds in the Kronecker metric from the start. However, the study of calculus can be generalized to differential manifolds that have no metric, with *Nurser et al.* (2022) offering an example use of this formalism for studies of fluid motion in continuous property spaces rather than Euclidean space.

[6] There are surfaces, such as the Möbius strip, that are not orientable. We only consider orientiable surfaces in this book.

permutation symbol

$$\epsilon_{123} = 1 \tag{1.18a}$$

$$\epsilon_{abc} = \begin{cases} 1, \text{ even permutation of } abc \ (123, 312, 231) \\ -1, \text{ odd permutation of } abc \ (321, 132, 213) \\ 0, \text{ all other } abc. \end{cases} \tag{1.18b}$$

Exchanging indices (an odd permutation) flips the sign of the permutation symbol

$$\epsilon_{abc} = -\epsilon_{bac} = -\epsilon_{acb} \Longrightarrow \epsilon_{123} = -\epsilon_{213}, \tag{1.19}$$

whereas cycling indices (an even permutation) preserves the sign

$$\epsilon_{abc} = \epsilon_{cab} = \epsilon_{bca} \Longrightarrow \epsilon_{123} = \epsilon_{312} = \epsilon_{231}. \tag{1.20}$$

Correspondingly, the vector cross product changes sign when its elements are commuted

$$\vec{e}_a \times \vec{e}_b = \epsilon_{abc}\, \vec{e}_c = -\vec{e}_b \times \vec{e}_a. \tag{1.21}$$

1.4.2 Axial (or pseudo) vector

The vector cross product defines a vector whose coordinate representation changes its sign upon changing from a right handed to left handed orientation of the coordinate system. Such vectors are known as *axial vectors* or *pseudo vectors*. Example axial vectors that we encounter in this book include the angular velocity for the planet as well as the vorticity vector of fluid motion.

1.4.3 Orthogonality relations between cross products

As defined, the permutation symbol ensures that $\vec{e}_a \times \vec{e}_b$ is orthogonal to both $\vec{e}_a$ and $\vec{e}_b$

$$\begin{aligned}
\vec{e}_a \cdot (\vec{e}_a \times \vec{e}_b) &= \vec{e}_a \cdot \epsilon_{abc}\, \vec{e}_c && \text{definition} && (1.22a)\\
&= \epsilon_{abc}\, \vec{e}_a \cdot \vec{e}_c && \text{rearrangement} && (1.22b)\\
&= \epsilon_{cba}\, \vec{e}_c \cdot \vec{e}_a && \text{relabel } a \text{ to } c \text{ and } c \text{ to } a && (1.22c)\\
&= -\epsilon_{abc}\, \vec{e}_c \cdot \vec{e}_a && cba \text{ is an odd permutation of } abc && (1.22d)\\
&= -\epsilon_{abc}\, \vec{e}_a \cdot \vec{e}_c && \text{scalar product commutes} && (1.22e)\\
&\Rightarrow \vec{e}_a \cdot (\vec{e}_a \times \vec{e}_b) = 0. && && (1.22f)
\end{aligned}$$

We made the final conclusion since equation (1.22b) has the opposite sign to equation (1.22e), which can only be satisfied by zero. To help digest step (1.22c), reintroduce the summation symbol

$$\begin{aligned}
\epsilon_{abc}\, \vec{e}_a \cdot \vec{e}_c &= \sum_{a=1}^{3} \sum_{c=1}^{3} \epsilon_{abc}\, \vec{e}_a \cdot \vec{e}_c && \text{summation symbols reintroduced} && (1.23a)\\
&= \sum_{c=1}^{3} \sum_{a=1}^{3} \epsilon_{cba}\, \vec{e}_c \cdot \vec{e}_a && \text{swap } a \text{ and } c && (1.23b)\\
&= \epsilon_{cba}\, \vec{e}_c \cdot \vec{e}_a && \text{reintroduce summation convention.} && (1.23c)
\end{aligned}$$

Additionally, to digest step (1.22d) we step through the permutations

$$\epsilon_{cba} = -\epsilon_{bca} \qquad \text{swap } c \text{ with } b \text{ to pick up a minus sign} \tag{1.24a}$$
$$= \epsilon_{bac} \qquad \text{swap } c \text{ with } a \text{ to pick up a minus sign} \tag{1.24b}$$
$$= -\epsilon_{abc} \qquad \text{swap } b \text{ with } a \text{ to pick up a minus sign.} \tag{1.24c}$$

The same procedure shows that $\vec{e}_b \cdot (\vec{e}_a \times \vec{e}_b) = 0$. Hence, the vector product is orthogonal to the plane specified by any two of the basis vectors. That is, the vector product points orthogonal to that plane and in a direction determined by the right hand rule. We note that this proof reveals a general property. Namely, the contraction of a symmetric tensor (e.g., the scalar product $\vec{e}_c \cdot \vec{e}_a = \vec{e}_a \cdot \vec{e}_c$) with an anti-symmetric tensor results in zero. We further illustrate this property in Exercise 1.2.

1.4.4 Vector product of arbitrary vectors

The expression (1.17) for the vector product of two basis vectors renders the vector product of arbitrary vectors.

$$\boldsymbol{P} \times \boldsymbol{Q} = P_a\, \vec{e}_a \times Q_b\, \vec{e}_b \tag{1.25a}$$
$$= P_a\, Q_b\, \vec{e}_a \times \vec{e}_b \tag{1.25b}$$
$$= P_a\, Q_b\, \epsilon_{abc}\, \vec{e}_c \tag{1.25c}$$
$$= (P_2\, Q_3 - P_3\, Q_2)\, \vec{e}_1 + (P_3\, Q_1 - P_1\, Q_3)\, \vec{e}_2 + (P_1\, Q_2 - P_2\, Q_1)\, \vec{e}_3. \tag{1.25d}$$

We can write the vector product as a determinant

$$\boldsymbol{P} \times \boldsymbol{Q} = \det \begin{bmatrix} \vec{e}_1 & \vec{e}_2 & \vec{e}_3 \\ P_1 & P_2 & P_3 \\ Q_1 & Q_2 & Q_3 \end{bmatrix}. \tag{1.26}$$

As with the basis vectors, the vector product is orthogonal to both of the individual vectors, such as

$$\boldsymbol{P} \cdot (\boldsymbol{P} \times \boldsymbol{Q}) = (P_d\, \vec{e}_d) \cdot (P_a\, Q_b\, \epsilon_{abc}\, \vec{e}_c) \tag{1.27a}$$
$$= P_c\, P_a\, Q_b\, \epsilon_{abc} \tag{1.27b}$$
$$= 0, \tag{1.27c}$$

where the final equality follows since the product $P_c\, P_a$ is symmetric on the labels ac ($P_c\, P_a = P_a\, P_c$), whereas ϵ_{abc} is anti-symmetric.

1.4.5 Geometric interpretation of the vector product

The expression (1.25d) leads to the identity

$$|\boldsymbol{P} \times \boldsymbol{Q}|^2 = |\boldsymbol{P}|^2\, |\boldsymbol{Q}|^2 - (\boldsymbol{P} \cdot \boldsymbol{Q})^2 \tag{1.28a}$$
$$= |\boldsymbol{P}|^2\, |\boldsymbol{Q}|^2\, (1 - \cos^2 \vartheta) \tag{1.28b}$$
$$= |\boldsymbol{P}|^2\, |\boldsymbol{Q}|^2 \sin^2 \vartheta, \tag{1.28c}$$

where we used the scalar product expression (1.16) to introduce the angle subtended by the two vectors. Trigonometry indicates that the area of the parallelogram defined by $\boldsymbol{P}$ and $\boldsymbol{Q}$ is given

FIGURE 1.3: The magnitude of the vector product between two vectors is given by the product of their magnitudes and the sine of the angle between them, $|\boldsymbol{P} \times \boldsymbol{Q}| = |\boldsymbol{P}|\,|\boldsymbol{Q}| \sin\vartheta$. This magnitude equals to the area of the parallelogram formed by the two vectors. The vector product is directed perpendicular to the plane determined by the two vectors and oriented according to the right hand rule. The right hand rule is followed by placing the fingers of the right hand along the first vector, $\boldsymbol{P}$. Closing the fingers in the direction of the second vector, $\boldsymbol{Q}$ (as here depicted by the arrow on the arc for the angle ϑ), then ensures that the thumb orients the vector product, $\boldsymbol{P} \times \boldsymbol{Q}$.

by $|\boldsymbol{P}|\,|\boldsymbol{Q}| \sin\vartheta$. Hence, the vector product has a magnitude given by this area

$$\text{area}(\boldsymbol{P}, \boldsymbol{Q}) = |\boldsymbol{P}|\,|\boldsymbol{Q}| \sin\vartheta = |\boldsymbol{P} \times \boldsymbol{Q}|. \tag{1.29}$$

Since $\boldsymbol{P} \times \boldsymbol{Q}$ is orthogonal to the plane defined by $\boldsymbol{P}$ and $\boldsymbol{Q}$, we can write the vector product in the purely geometric manner

$$\boldsymbol{P} \times \boldsymbol{Q} = \hat{\boldsymbol{n}}\,\text{area}(\boldsymbol{P}, \boldsymbol{Q}) = \hat{\boldsymbol{n}}\,|\boldsymbol{P}|\,|\boldsymbol{Q}| \sin\vartheta, \tag{1.30}$$

where $\hat{\boldsymbol{n}}$ is a unit vector pointing normal to the area and in a direction given by the right hand rule. This formula is illustrated in Figure 1.3.

To further emphasize the geometric interpretation, let $\boldsymbol{P}$ equal to the vertical direction, $\boldsymbol{P} = \hat{\boldsymbol{z}}$. The vector cross product then defines a vector,

$$\begin{aligned}
\boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp} &= \hat{\boldsymbol{z}} \times \boldsymbol{Q} && (1.31a)\\
&= \hat{\boldsymbol{z}} \times [\boldsymbol{Q} - (\hat{\boldsymbol{z}} \cdot \boldsymbol{Q})\,\hat{\boldsymbol{z}}] && (1.31b)\\
&= (\hat{\boldsymbol{z}} \times \hat{\boldsymbol{x}})\,(\hat{\boldsymbol{x}} \cdot \boldsymbol{Q}) + (\hat{\boldsymbol{z}} \times \hat{\boldsymbol{y}})\,(\hat{\boldsymbol{y}} \cdot \boldsymbol{Q}) && (1.31c)\\
&= \hat{\boldsymbol{y}}\,(\hat{\boldsymbol{x}} \cdot \boldsymbol{Q}) - \hat{\boldsymbol{x}}\,(\hat{\boldsymbol{y}} \cdot \boldsymbol{Q}). && (1.31d)
\end{aligned}$$

By construction, $\boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp}$ is in the horizontal plane and it is perpendicular to the horizontal projection of $\boldsymbol{Q}$

$$\boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp} \cdot \hat{\boldsymbol{z}} = 0 \quad \text{and} \quad \boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp} \cdot \boldsymbol{Q} = 0 \Longrightarrow \boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp} \cdot [\boldsymbol{Q} - (\hat{\boldsymbol{z}} \cdot \boldsymbol{Q})\,\hat{\boldsymbol{z}}] = 0. \tag{1.32}$$

Hence, the vector $\boldsymbol{Q}^{\hat{\boldsymbol{z}}\perp}$ is geometrically computed by rotating the horizontal component of $\boldsymbol{Q}$ by $\pi/2$ radians counter-clockwise about the $\hat{\boldsymbol{z}}$ axis. That interpretation holds for all coordinate directions so that

$$\hat{\boldsymbol{x}} \times \boldsymbol{Q} = \hat{\boldsymbol{z}}\,(\hat{\boldsymbol{y}} \cdot \boldsymbol{Q}) - \hat{\boldsymbol{y}}\,(\hat{\boldsymbol{z}} \cdot \boldsymbol{Q}) = \text{project } \boldsymbol{Q} \text{ to y-z plane + rotate } \pi/2 \text{ CCW around } \hat{\boldsymbol{x}} \tag{1.33a}$$
$$\hat{\boldsymbol{y}} \times \boldsymbol{Q} = \hat{\boldsymbol{x}}\,(\hat{\boldsymbol{z}} \cdot \boldsymbol{Q}) - \hat{\boldsymbol{z}}\,(\hat{\boldsymbol{x}} \cdot \boldsymbol{Q}) = \text{project } \boldsymbol{Q} \text{ to z-x plane + rotate } \pi/2 \text{ CCW around } \hat{\boldsymbol{y}} \tag{1.33b}$$
$$\hat{\boldsymbol{z}} \times \boldsymbol{Q} = \hat{\boldsymbol{y}}\,(\hat{\boldsymbol{x}} \cdot \boldsymbol{Q}) - \hat{\boldsymbol{x}}\,(\hat{\boldsymbol{y}} \cdot \boldsymbol{Q}) = \text{project } \boldsymbol{Q} \text{ to x-y plane + rotate } \pi/2 \text{ CCW around } \hat{\boldsymbol{z}}. \tag{1.33c}$$

This geometric interpretation may appear a bit arcane. However, it serves to couple the analytical to the geometrical. This couplinig generally results in a deeper understanding of both the maths and the corresponding physics.

1.4.6 Generalization to arbitrary vectors

Thus far the discussion has considered vectors to represent the position of a point in space. As such, the vectors have the physical dimensions of length and area($\boldsymbol{P}, \boldsymbol{Q}$) has dimensions of squared length. However, the vector analysis is general, so that the above notions extend to vectors of arbitrary physical dimensions. In these more general cases the physical dimensions are adjusted accordingly.

1.5 Measuring volume

The vector product offers a means to measure area defined by two vectors. We now extend that result to measure the volume determined by three non-parallel vectors. This result has particular relevance to the volume element used for integration over space.

1.5.1 Volume defined by three vectors

Consider the scalar product of an arbitrary vector with the vector product, $(\boldsymbol{P} \times \boldsymbol{Q}) \cdot \boldsymbol{R}$. This scalar product projects that portion of the vector, $\boldsymbol{R}$, onto the direction parallel to the normal to the plane defined by $\boldsymbol{P} \times \boldsymbol{Q}$. Given that $|(\boldsymbol{P} \times \boldsymbol{Q})|$ is the area of the parallelogram defined by $\boldsymbol{P}$ and $\boldsymbol{Q}$, we conclude that $(\boldsymbol{P} \times \boldsymbol{Q}) \cdot \boldsymbol{R}$ is the volume of the parallelepiped defined by the three vectors. However, note that this volume is not guaranteed to be positive definite since the sign depends on the relative orientation of $\boldsymbol{P} \times \boldsymbol{Q}$ and $\boldsymbol{R}$. So more precisely, we need to apply an absolute value around the triple product to get a positive volume.

FIGURE 1.4: Three linearly independent position vectors determine a volume given by $|(\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R}| = |(\boldsymbol{R}\times\boldsymbol{P})\cdot\boldsymbol{Q}| = |(\boldsymbol{Q} \times \boldsymbol{R}) \cdot \boldsymbol{P}|$. We see this identity geometrically by noting that the area of the base is given by $|\boldsymbol{P} \times \boldsymbol{Q}|$, so that the volume of the parallelepiped is given by the base area times the height, $|(\boldsymbol{P} \times \boldsymbol{Q}) \cdot \boldsymbol{R}|$. Cyclic permutation then leads to the equality with the other two expressions.

We can prove cyclic symmetry of $(\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R}$ through the following manipulations

$$
\begin{aligned}
(\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R} &= (P_a\,\vec{e}_a\times Q_b\,\vec{e}_b)\cdot R_d\,\vec{e}_d && \text{expose coordinates and basis vectors} && (1.34a)\\
&= P_a\,Q_b\,(\vec{e}_a\times\vec{e}_b)\cdot R_d\,\vec{e}_d && \text{rearrange} && (1.34b)\\
&= P_a\,Q_b\,(\epsilon_{abc}\,\vec{e}_c)\cdot\vec{e}_d\,R_d && \text{vector product as per equation (1.17)} && (1.34c)\\
&= P_a\,Q_b\,\epsilon_{abc}\,(\vec{e}_c\cdot\vec{e}_d)\,R_d && \text{rearrange} && (1.34d)\\
&= P_a\,Q_b\,\epsilon_{abc}\,\delta_{cd}\,R_d && \text{orthonormality: } \vec{e}_c\cdot\vec{e}_d=\delta_{cd} && (1.34e)\\
&= P_a\,Q_b\,\epsilon_{abc}\,R_c && \text{perform contraction on index } d\text{: } \delta_{cd}\,R_d=R_c && (1.34f)\\
&= R_c\,P_a\,Q_b\,\epsilon_{abc} && \text{rearrange} && (1.34g)\\
&= R_a\,P_b\,Q_c\,\epsilon_{bca} && \text{relabel: } a\to b \text{ and } b\to c \text{ and } c\to a && (1.34h)\\
&= R_a\,P_b\,Q_c\,\epsilon_{abc} && \text{even permutation: } \epsilon_{bca}=\epsilon_{abc} && (1.34i)\\
&= (\boldsymbol{R}\times\boldsymbol{P})\cdot\boldsymbol{Q} && \text{redintroduce boldface notation.} && (1.34j)
\end{aligned}
$$

This identity yields the geometric result illustrated in Figure 1.4

$$\text{volume}(\boldsymbol{P},\boldsymbol{Q},\boldsymbol{R}) = |(\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R}| = |(\boldsymbol{R}\times\boldsymbol{P})\cdot\boldsymbol{Q}| = |(\boldsymbol{Q}\times\boldsymbol{R})\cdot\boldsymbol{P}|. \tag{1.35}$$

1.5.2 Cartesian volume element for integration

We need the volume of an infinitesimal region when performing an integration over space. When making use of Cartesian coordinates we need the volume of a rectangular prism defined by infinitesimal distances along each of the axes. We thus set

$$\boldsymbol{P}=\hat{\boldsymbol{x}}\,\mathrm{d}x \qquad \text{and} \qquad \boldsymbol{Q}=\hat{\boldsymbol{y}}\,\mathrm{d}y \qquad \text{and} \qquad \boldsymbol{R}=\hat{\boldsymbol{z}}\,\mathrm{d}z, \tag{1.36}$$

in which case the volume element is

$$\mathrm{d}V = (\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R} = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\,(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{y}})\cdot\hat{\boldsymbol{z}} = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z. \tag{1.37}$$

This expression for the volume element could have been written down without the formalism of a vector triple product. However, in Chapter 8 we find the general relation $(\boldsymbol{P}\times\boldsymbol{Q})\cdot\boldsymbol{R}$ provides a useful starting point for deriving the volume element with arbitrary coordinates.

1.5.3 $n-$space volumes and the Levi-Civita tensor

We combine the geometric specification (1.30) of the vector product as a means to measure area, with the algebraic specification (1.25d) by writing

$$\text{2-volume} = \epsilon(\boldsymbol{P},\boldsymbol{Q}) = \epsilon_{ab}\,P_a\,Q_b = \det\begin{bmatrix} P_1 & Q_1 \\ P_2 & Q_2 \end{bmatrix}. \tag{1.38}$$

In this equation, ϵ_{ab} is the totally anti-symmetric 2×2 tensor. It has Cartesian components that can be organized as a matrix according to

$$\begin{bmatrix} \epsilon_{11} & \epsilon_{12} \\ \epsilon_{21} & \epsilon_{22} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}. \tag{1.39}$$

In words, the first equality in equation (1.38) states that the ϵ-tensor in two dimensions takes two vectors as its argument and produces a 2-volume (i.e., an area). The three dimensional

generalization yields

$$\text{3-volume} = \epsilon(\boldsymbol{P}, \boldsymbol{Q}, \boldsymbol{R}) = \epsilon_{abc}\, P_a\, Q_b\, R_c = \det \begin{bmatrix} P_1 & Q_1 & R_1 \\ P_2 & Q_2 & R_2 \\ P_3 & Q_3 & R_3 \end{bmatrix}. \tag{1.40}$$

Suppressing the first vector argument in the 3-volume produces a vectorial surface area defined by the other two vectors

$$\text{surface area} = \epsilon(\ \ , \boldsymbol{Q}, \boldsymbol{R}). \tag{1.41}$$

By construction, the vectorial surface area is orthogonal to both $\boldsymbol{Q}$ and $\boldsymbol{R}$.

1.6 Example vector identities using the Levi-Civita tensor

The Levi-Civita tensor is a versatile tool for deriving vector identities. We illustrated some of these features in the previous discussion and here illustrate two more. These examples, and others in this chapter, generally expose many of the *index gymnastics* involved with tensor manipulations. A bit of practice readily allows one to skip many of the steps exposed in the following.

1.6.1 Double vector product

Consider the double vector product

$$\begin{aligned}
\boldsymbol{P} \times (\boldsymbol{Q} \times \boldsymbol{R}) &= P_a\, Q_b\, R_c\, \vec{e}_a \times (\vec{e}_b \times \vec{e}_c) && \text{expose coordinates and basis vectors} && (1.42a)\\
&= P_a\, Q_b\, R_c\, \vec{e}_a \times (\epsilon_{bcd}\, \vec{e}_d) && \text{vector product as per equation (1.17)} && (1.42b)\\
&= P_a\, Q_b\, R_c\, \epsilon_{bcd}\, \epsilon_{ade}\, \vec{e}_e && \text{again, vector product as per equation (1.17)} && (1.42c)\\
&= -P_a\, Q_b\, R_c\, \epsilon_{bcd}\, \epsilon_{aed}\, \vec{e}_e && \text{permute } a, d \text{ and pick up a minus sign.} && (1.42d)
\end{aligned}$$

Explicit substitution verifies that the contraction $\epsilon_{bcd}\, \epsilon_{aed}$ equals to

$$\epsilon_{bcd}\, \epsilon_{aed} = \delta_{ba}\, \delta_{ce} - \delta_{be}\, \delta_{ca}, \tag{1.43}$$

which is a very useful identity for Cartesian tensor analysis. It then leads to

$$\epsilon_{bcd}\, \epsilon_{aed}\, \vec{e}_e = \delta_{ba}\, \vec{e}_c - \delta_{ca}\, \vec{e}_b \tag{1.44}$$

so that

$$\begin{aligned}
\boldsymbol{P} \times (\boldsymbol{Q} \times \boldsymbol{R}) &= -P_a\, Q_b\, R_c\, (\delta_{ba}\, \vec{e}_c - \delta_{ca}\, \vec{e}_b) && (1.45a)\\
&= -(\boldsymbol{P} \cdot \boldsymbol{Q})\, \boldsymbol{R} + (\boldsymbol{P} \cdot \boldsymbol{R})\, \boldsymbol{Q}. && (1.45b)
\end{aligned}$$

1.6.2 Scalar product of two vector products

We make further use of the Levi-Civita identity (1.43) to write

$$\begin{aligned}
(\boldsymbol{P} \times \boldsymbol{Q}) \cdot (\boldsymbol{R} \times \boldsymbol{S}) &= (\epsilon_{abc}\, p_a\, q_b)\, (\epsilon_{dec}\, R_d\, s_e) && \text{expand two vector products} && (1.46a)\\
&= p_a\, q_b\, R_d\, s_e\, \epsilon_{abc}\, \epsilon_{dec} && \text{rearrange} && (1.46b)\\
&= p_a\, q_b\, R_d\, s_e\, (\delta_{ad}\, \delta_{be} - \delta_{ae}\, \delta_{bd}) && \epsilon\text{-tensor identity (1.43)} && (1.46c)\\
&= (\boldsymbol{P} \cdot \boldsymbol{R})\, (\boldsymbol{Q} \cdot \boldsymbol{S}) - (\boldsymbol{P} \cdot \boldsymbol{S})\, (\boldsymbol{Q} \cdot \boldsymbol{R}) && \text{reintroduce boldface notation.} && (1.46d)
\end{aligned}$$

1.7 Transforming the coordinate representations

The Cartesian basis vectors are mutually orthogonal and fixed in space. However, the orientation of the basis vectors is arbitrary. We thus consider an alternative specification to the basis vectors by performing a linear transformation

$$\vec{e}_{\bar{a}} = \mathcal{R}_{\bar{a}b}\,\vec{e}_b. \tag{1.47}$$

This expression introduced components to the transformation matrix moving between the unbarred and the barred Cartesian coordinates

$$\mathcal{R}_{\bar{a}b} = \begin{bmatrix} \mathcal{R}_{\bar{1}1} & \mathcal{R}_{\bar{1}2} & \mathcal{R}_{\bar{1}3} \\ \mathcal{R}_{\bar{2}1} & \mathcal{R}_{\bar{2}2} & \mathcal{R}_{\bar{2}3} \\ \mathcal{R}_{\bar{3}1} & \mathcal{R}_{\bar{3}2} & \mathcal{R}_{\bar{3}3} \end{bmatrix}. \tag{1.48}$$

In Cartesian tensor analysis studied in this chapter, the transformation matrix is assumed to be independent of space.[7] Although the transformation matrix carries two indices, it is not a tensor. Instead, it is a matrix operator used to transform from one set of basis vectors to another.[8] We now deduce some constraints on this transformation matrix.

1.7.1 Inverse transformation

Assuming the transformation is invertible leads to the inverse transformation

$$\vec{e}_a = (\mathcal{R}^{-1})_{a\bar{b}}\,\vec{e}_{\bar{b}}. \tag{1.49}$$

As a self-consistency check we combine this relation with equation (1.47) thus rendering

$$\vec{e}_a = (\mathcal{R}^{-1})_{a\bar{b}}\,\vec{e}_{\bar{b}} = (\mathcal{R}^{-1})_{a\bar{b}}\,(\mathcal{R}_{\bar{b}c}\,\vec{e}_c). \tag{1.50}$$

This relation holds since

$$(\mathcal{R}^{-1})_{a\bar{b}}\,\mathcal{R}_{\bar{b}c} = \delta_{ac}, \tag{1.51}$$

or as a matrix identity

$$\mathcal{R}^{-1}\,\mathcal{R} = I. \tag{1.52}$$

1.7.2 Orthogonal transformation

We now assume that the two sets of Cartesian basis vectors are orthonormal. That assumption leads to the following constraint on the transformation matrix

$$\begin{aligned}
\delta_{\bar{a}\bar{b}} &= \vec{e}_{\bar{a}} \cdot \vec{e}_{\bar{b}} && && (1.53a)\\
&= \mathcal{R}_{\bar{a}a}\vec{e}_a \cdot \mathcal{R}_{\bar{b}b}\vec{e}_b && \text{relate barred to unbarred basis vectors} && (1.53b)\\
&= \mathcal{R}_{\bar{a}a}\,\mathcal{R}_{\bar{b}b}\,\vec{e}_a \cdot \vec{e}_b && \text{rearrange} && (1.53c)\\
&= \mathcal{R}_{\bar{a}a}\,\mathcal{R}_{\bar{b}b}\,\delta_{ab} && \text{orthonormality of basis vectors} && (1.53d)\\
&= \mathcal{R}_{\bar{a}a}\,\mathcal{R}_{\bar{b}a} && \text{perform contraction } \mathcal{R}_{\bar{b}b}\,\delta_{ab} = \mathcal{R}_{\bar{b}a} && (1.53e)\\
&= \mathcal{R}_{\bar{a}a}\,(\mathcal{R}^T)_{a\bar{b}} && \text{introduce transpose matrix,} && (1.53f)
\end{aligned}$$

[7] The transformation matrix is a function of space and time for the general tensors considered in Chapter 9.
[8] We have more to say about the distinction between a matrix and tensor in Section 1.7.7.

FIGURE 1.5: Counter-clockwise rotation through an angle ϑ of a right-handed horizontal Cartesian axes.

where $\mathcal{R}^T$ is the transpose of the rotation matrix whose components are

$$(\mathcal{R}^T)_{a\bar{b}} = \mathcal{R}_{\bar{b}a}. \tag{1.54}$$

Written as a matrix equation we see that

$$\mathcal{R}\,\mathcal{R}^T = I. \tag{1.55}$$

This relation defines an *orthogonal transformation*, whereby the inverse matrix equals to the matrix transpose

$$\mathcal{R}^{-1} = \mathcal{R}^T. \tag{1.56}$$

1.7.3 Geometric interpretation of orthogonal transformations

Orthogonal transformations convert one set of Cartesian coordinates to another. Geometrically, an orthogonal transformation corresponds to a rotation so long as the determinant of the transformation is +1, with Figure 1.5 illustrating this axis rotation in two dimensions.[9] For this two dimensional example, the rotation matrix can be written in terms of the cosine of the angles between the unit vectors; i.e., the *direction cosines*

$$\mathcal{R}_{\bar{a}a} = \begin{bmatrix} \cos\vartheta & \sin\vartheta \\ -\sin\vartheta & \cos\vartheta \end{bmatrix} = \begin{bmatrix} \cos\vartheta & \cos(\pi/2-\vartheta) \\ \cos(\pi/2+\vartheta) & \cos\vartheta \end{bmatrix} = \begin{bmatrix} \vec{e}_{\bar{1}}\cdot\vec{e}_1 & \vec{e}_{\bar{1}}\cdot\vec{e}_2 \\ \vec{e}_{\bar{2}}\cdot\vec{e}_1 & \vec{e}_{\bar{2}}\cdot\vec{e}_2 \end{bmatrix}. \tag{1.57}$$

The final form of the rotation matrix reveals that it is built from the projection of the rotated basis vectors onto the original basis vectors. This result holds for rotations in three dimensions as well, thus leading to

$$\mathcal{R}_{\bar{a}a} = \begin{bmatrix} \vec{e}_{\bar{1}}\cdot\vec{e}_1 & \vec{e}_{\bar{1}}\cdot\vec{e}_2 & \vec{e}_{\bar{1}}\cdot\vec{e}_3 \\ \vec{e}_{\bar{2}}\cdot\vec{e}_1 & \vec{e}_{\bar{2}}\cdot\vec{e}_2 & \vec{e}_{\bar{2}}\cdot\vec{e}_3 \\ \vec{e}_{\bar{3}}\cdot\vec{e}_1 & \vec{e}_{\bar{3}}\cdot\vec{e}_2 & \vec{e}_{\bar{3}}\cdot\vec{e}_3 \end{bmatrix}. \tag{1.58}$$

[9] If the determinant of the transformation is −1, then the transformation involves a reflection in addition to a rotation, with the reflection changing the handedness of the basis vectors. We only consider right handed basis vectors in this book, so that the transformation of Cartesian tensors is orthogonal.

With the basis vectors all normalized, elements of the rotation matrix have magnitude less than or equal to unity and are given by the cosine of the angle between the respective basis vectors. As such, one sometimes refers to this rotation matrix as the *direction cosines* matrix.

1.7.4 Transforming the coordinate representation of a vector

We introduced the transformation (1.49) according to how it acts on the basis vectors. Now consider how it acts on the coordinate representation of an arbitrary vector by moving brackets

$$\boldsymbol{P} = P_a\,\vec{e}_a = P_a\,(\mathcal{R}^T)_{a\bar{a}}\,\vec{e}_{\bar{a}} \equiv P_{\bar{a}}\,\vec{e}_{\bar{a}}, \tag{1.59}$$

where we defined the transformation of the vector components

$$P_{\bar{a}} = P_a\,(\mathcal{R}^T)_{a\bar{a}} = \mathcal{R}_{\bar{a}a}\,P_a. \tag{1.60}$$

1.7.5 Invariance of the scalar product

The above properties of an orthogonal transformation ensure that the scalar product

$$\boldsymbol{P}\cdot\boldsymbol{Q} = P_a\,Q_a \tag{1.61}$$

is the same regardless the choice of Cartesian coordinates

$$\begin{aligned}
\boldsymbol{P}\cdot\boldsymbol{Q} &= P_a\,Q_a && \text{expose tensor indices} && (1.62a)\\
&= P_a\,Q_b\,\delta_{ab} && \text{introduce Kronecker delta} && (1.62b)\\
&= P_a\,Q_b\,\vec{e}_a\cdot\vec{e}_b && \text{orthonormal basis vectors: } \vec{e}_a\cdot\vec{e}_b = \delta_{ab} && (1.62c)\\
&= P_a\,Q_b\,(\mathcal{R}^T)_{a\bar{a}}\,\vec{e}_{\bar{a}}\cdot(\mathcal{R}^T)_{b\bar{b}}\,\vec{e}_{\bar{b}} && \text{rotate basis vectors to barred frame} && (1.62d)\\
&= P_a\,(\mathcal{R}^T)_{a\bar{a}}\,Q_b\,(\mathcal{R}^T)_{b\bar{b}}\,\vec{e}_{\bar{a}}\cdot\vec{e}_{\bar{b}} && \text{rearrange} && (1.62e)\\
&= P_{\bar{a}}\,Q_{\bar{b}}\,\vec{e}_{\bar{a}}\cdot\vec{e}_{\bar{b}} && \text{transform vector components (1.59)} && (1.62f)\\
&= P_{\bar{a}}\,Q_{\bar{b}}\,\delta_{\bar{a}\bar{b}} && \text{orthonormal basis vectors: } \vec{e}_{\bar{a}}\cdot\vec{e}_{\bar{b}} = \delta_{\bar{a}\bar{b}} && (1.62g)\\
&= P_{\bar{a}}\,Q_{\bar{b}} && \text{perform the contraction.} && (1.62h)
\end{aligned}$$

1.7.6 Transforming the coordinate representation of a second order tensor

The stress tensor in Chapter 25; the moment of inertia tensor in Section 38.9.4; and the diffusion tensor in Chapter 64 are examples of second order tensors. Second order tensors have a coordinate representation given by

$$\mathbb{T} = T_{ab}\,\vec{e}_a\otimes\vec{e}_b, \tag{1.63}$$

with T_{ab} the Cartesian coordinates that can be organized as a matrix. Notably, there is not a scalar product between the basis vectors in equation (1.63). Instead, the $\otimes$ symbol represents the *outer product* of the two basis vectors. For our purposes the outer product simply provides a formal means for two vectors to be positioned next to one another. For many purposes we drop the $\otimes$ symbol for brevity.

We determine how the Cartesian coordinate components T_{ab} transform by following the now familiar procedure for transforming the basis vectors. The key new facet is that now we have two

basis vectors to carry around

$$\begin{aligned}
\mathbb{T} &= T_{ab}\,\vec{e}_a\,\vec{e}_b && \text{expose indices and basis vectors} && (1.64a)\\
&= T_{ab}\,(\mathcal{R}^T)_{a\bar{a}}\,\vec{e}_{\bar{a}}\,(\mathcal{R}^T)_{b\bar{b}}\,\vec{e}_{\bar{b}} && \text{rotate basis vectors to barred frame} && (1.64b)\\
&= T_{ab}\,(\mathcal{R}^T)_{a\bar{a}}\,(\mathcal{R}^T)_{b\bar{b}}\,\vec{e}_{\bar{a}}\,\vec{e}_{\bar{b}} && \text{rerrange} && (1.64c)\\
&\equiv T_{\bar{a}\bar{b}}\,\vec{e}_{\bar{a}}\,\vec{e}_{\bar{b}} && \text{define transformed tensor components.} && (1.64d)
\end{aligned}$$

The final equality introduced the transformed components to the second order tensor

$$T_{\bar{a}\bar{b}} = T_{ab}\,(\mathcal{R}^T)_{a\bar{a}}\,(\mathcal{R}^T)_{b\bar{b}} = T_{ab}\,\mathcal{R}_{\bar{a}a}\,\mathcal{R}_{\bar{b}b}. \tag{1.65}$$

The transformation of the components to higher order tensors follows analogously simply by carrying around further basis vectors.

1.7.7 Distinguishing between tensors and matrices

Matrices are useful for organizing the coordinate components to a tensor. For example, the coordinate components to a first-order tensor (a vector)

$$\boldsymbol{P} = P_1\,\vec{e}_1 + P_2\,\vec{e}_2 + P_3\,\vec{e}_3, \tag{1.66}$$

can be organized into a *row vector*

$$\boldsymbol{P} = (P_1, P_2, P_3). \tag{1.67}$$

We are justified in assigning the name "vector" in this context since we know that the array elements comprise the coordinate representation of the vector, $\boldsymbol{P}$. However, if we just see an array of numbers, say (Q_1, Q_2, Q_3), on its own, then we generally have no idea whether the elements of that array are related to each other, or if the list is just an ordering of numbers. If the array is merely a list of numbers, then in general nothing changes when we alter coordinates. But if the array is the coordinate representation of a vector (e.g., a row vector), then we know that the elements of the row vector are related, and we know how they are changed when the coordinates are changed.

We now consider two examples of objects that are not tensors. First, consider the rotation matrix, $\mathcal{R}_{\bar{a}a}$, whose elements are built from the direction cosines according to equation (1.58). Although carrying two indices, this matrix is not the coordinate representation of a second order tensor. Rather, it is the matrix used to transform the components of tensors from one coordinate system to another. That is, the rotation matrix is not a geometric object like a vector or tensor, but it is an ordered array that contains information for how a coordinate transformation alters the representation of geometric objects.

Although jumping ahead somewhat, we mention one further example encountered when studying general tensors in Chapter 9. Namely, the *Christoffel symbols* in Section 9.11.1 are built from the spatial derivatives of the basis vectors. Although carrying three indices, the Christoffel symbols are not elements of a third order tensor since they do not transform as elements to a tensor. One way to understand this point is to note that a tensor that vanishes in one coordinate system is zero for all coordinate systems. However, all of the Christoffel symbols vanish for Euclidean space using Cartesian coordinates, because the Cartesian basis vectors are spatially constant. However, there are some nonzero Christoffel symbols when representing Euclidean space with spherical coordinates. By this example, we conclude that the Christoffel symbols cannot be components of a tensor.

The key point we re-emphasize is that a tensor is a geometric object that can be represented

using any arbitrary set of coordinates. Since the tensor has an objective existence independent of coordinates, its coordinate components are constrained to transform in a precise manner when changing coordinates. These properties of tensors are generally not shared with arbitrary matrices, hence the importance of making the distinction between tensors and matrices.

1.8 Homogeneity and isotropy

We have many occasions to consider symmetry properties of tensor fields, with homogeneity and isotropy two such properties.

1.8.1 Homogeneous tensor

A tensor field is *homogeneous* if it possesses the same value at each point in space. For example, a uniform temperature field is homogeneous, as is a uniform velocity field. As defined, a homogeneous tensor field has no spatial dependence and thus it does not provide any means to distinguish points in space. Likewise, a time independent tensor is said to be homogeneous in time.

1.8.2 Isotropic and anisotropic tensors

A tensor field is *isotropic* if its representation remains independent of coordinate basis. A scalar tensor is, by definition, isotropic since it has no information about spatial directions. A nonzero vector field cannot be isotropic since it points in a particular direction and so its representation is dependent on the orientation of the basis vectors.

A second order isotropic tensor, $\mathbb{J}$, has components that are unchanged when undergoing rotation, so that

$$J_{\bar{a}\bar{b}} = J_{ab}\,\mathcal{R}_{\bar{a}a}\,\mathcal{R}_{\bar{b}b} \equiv J_{ab} \tag{1.68}$$

where we used the identity (1.65) for the component transformation. For nonzero tensors, this equation is satisfied by

$$J_{ab} = \lambda\,\delta_{ab}, \tag{1.69}$$

with λ an arbitrary scalar. Hence, the most general second order isotropic tensor is proportional to the Kronecker (identity) tensor.

We often find it useful to decompose an arbitrary second order tensor into its anisotropic and isotropic components according to

$$T_{ab} = \underbrace{T_{ab} - \frac{T_{pp}}{\delta_{pp}}\,\delta_{ab}}_{\text{anisotropic}} + \underbrace{\frac{T_{pp}}{\delta_{pp}}\,\delta_{ab}}_{\text{isotropic}}, \tag{1.70}$$

where

$$T_{pp} = \sum_{p=1}^{N} T_{pp} = \text{trace of } T_{ab} \quad \text{and} \quad \delta_{pp} = \sum_{p=1}^{N} \delta_{pp} = N \tag{1.71}$$

with N the number of space dimensions. We know that $T_{ab} - (T_{pp}/\delta_{pp})\,\delta_{ab}$ is the anisotropic portion of T_{ab} simply because $(T_{pp}/\delta_{pp})\,\delta_{ab}$ is isotropic.

1.9 Irreducible parts of a second order tensor

We encounter many second order tensors in this book, with such tensors having nine degrees of freedom when working in three-dimensional space. It is very useful to decompose these tensors

into their *irreducible tensorial parts* as presented here, since these parts generally represent distinct kinematic properties that help to understand the physical nature of the tensor.

Any second order tensor can be decomposed into its symmetric and anti-symmetric parts,

$$T_{ab} = \underbrace{(T_{ab} + T_{ba})/2}_{\text{symmetric}} + \underbrace{(T_{ab} - T_{ba})/2}_{\text{anti-symmetric}} \equiv S_{ab} + A_{ab}. \tag{1.72}$$

The *symmetric tensor*, S_{ab}, satisfies

$$S_{ab} = S_{ba}, \tag{1.73}$$

and it consequently has six degrees of freedom. The *anti-symmetric tensor* (also called the *skew-symmetric tensor*) satisfies

$$A_{ab} = -A_{ba}, \tag{1.74}$$

which means it has three degrees of freedom and has zero elements along its diagonal

$$A_{11} = A_{22} = A_{33} = 0. \tag{1.75}$$

The final irreducible part of a tensor is the *trace*, which is the sum of the diagonal elements

$$T_{aa} = S_{aa} = T_{11} + T_{22} + T_{33}. \tag{1.76}$$

We are thus led to the irreducible decomposition

$$T_{ab} = S_{qq}\,\delta_{ab}/3 + (S_{ab} - S_{qq}\,\delta_{ab}/3) + A_{ab}. \tag{1.77}$$

The combination

$$S_{ab}^{\text{deviator}} = S_{ab} - S_{qq}\,\delta_{ab}/3 \tag{1.78}$$

is known as the *deviatoric tensor* or *deviator*, which, as defined, has zero trace since $\delta_{aa} = 3$.

1.10 Exercises

EXERCISE 1.1: PRODUCT OF SYMMETRIC MATRICES
Let $A = A^T$ and $B = B^T$ be two symmetric matrices. Under what condition is their product also symmetric: $A\,B = (A\,B)^T$?

EXERCISE 1.2: PRODUCT OF SYMMETRIC AND ANTI-SYMMETRIC MATRICES AND TENSORS
Let $A = -A^T$ be an anti-symmetric matrix, and $S = S^T$ be a symmetric matrix. Show that the trace of their product vanishes: $\mathrm{Tr}(A\,S) = 0$. Alternatively, in terms of tensors, show that the double contraction of an anti-symmetric tensor with a symmetric tensor vanishes: $A_{mn}\,S_{mn} = 0$.

EXERCISE 1.3: PROJECTION OPERATOR
Consider an arbitrary direction in space specified by the unit vector $\hat{\boldsymbol{n}}$ with components $\hat{n}_a$. Define the projection operator

$$P_{ab} = \delta_{ab} - \hat{n}_a\,\hat{n}_b. \tag{1.79}$$

Show that

$$P_{ab}\,T_{bc}\,\hat{n}_a = 0. \tag{1.80}$$

Show that

$$S_{ac} = P_{ab}\,T_{bc} = (\delta_{ab} - \hat{n}_a\,\hat{n}_b)\,T_{bc} = T_{ac} - \hat{n}_a\,(\hat{n}_b\,T_{bc}) \tag{1.81}$$

is the projection of T_{bc} onto the plane perpendicular to the direction $\hat{\boldsymbol{n}}$.

Chapter 2

Cartesian tensor calculus

This chapter presents elements of differential and integral calculus that we later use for the study of geophysical fluid mechanics. We build from the Cartesian tensor algebra of Chapter 1 to develop elements of Cartesian tensor calculus, which is the basis for vector calculus. The material in this chapter is extensively used throughout this book.

CHAPTER GUIDE

The material in this chapter can be found in various forms in nearly all books on calculus with analytic geometry. Particular treatments, with applications to physics, are given in the following.

- Feynman Lectures: Chapters 2 and 3 in Volume II of the Feynman Lectures offers insightful discussions of vector differential calculus. Although written for students of electrodynamics, many of Feynman's examples are drawn from fluid mechanics.
- Div, Grad, Curl and all That (*Schey*, 2004): This text presents the methods and theorems of vector calculus in a manner that greatly assists the development of intuition.
- Chapter 2 in *Segel* (1987) provides a lucid review of vector calculus using Cartesian tensors.
- Theory and Problems of Vector Analysis (*Spiegel*, 1974a): This "Schaum's Outline Series" book has nearly 500 worked exercises and provides a useful resource to develop problem solving in vector calculus. Some of the exercises in Section 2.9 at the end of this chapter are drawn from *Spiegel* (1974a).
- This video from 3Blue1Brown provides some compelling graphics to support intuition for the divergence and curl operators.
- This Youtube channel from Steve Brunton offers some pedagogical lectures on vector calculus.

2.1 Gradient of a scalar field

Consider a real valued scalar field, $\psi(\boldsymbol{x})$, defined on Euclidean space. The argument to his field is the position in space that has a Cartesian coordinate representation

$$\boldsymbol{x} = \sum_{a=1}^{3} x_a \, \vec{e}_a = x_a \, \vec{e}_a, \tag{2.1}$$

where the second equation made use of the Einstein summation convention introduced in Chapter 1. In our applications, we encounter scalar fields such as the temperature, the mass density, and the specific entropy. We can estimate the value of the field at an adjacent point an infinitesimal distance away, $\boldsymbol{x} + \mathrm{d}\boldsymbol{x}$, through use of a truncated Taylor series

$$\psi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}) = \psi(\boldsymbol{x}) + \frac{\partial \psi}{\partial x_1} \, \mathrm{d}x_1 + \frac{\partial \psi}{\partial x_2} \, \mathrm{d}x_2 + \frac{\partial \psi}{\partial x_3} \, \mathrm{d}x_3 + \mathcal{O}\left(\mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x}\right) \tag{2.2a}$$

$$\approx \left[1 + \mathrm{d}x_a \, \partial_a\right] \psi(\boldsymbol{x}), \tag{2.2b}$$

FIGURE 2.1: Contours of a scalar field $\psi(x, y) = -x^2/2 - y^2$. At any point in space, the gradient, $\nabla\psi = -(x\,\hat{\boldsymbol{x}} + 2\,y\,\hat{\boldsymbol{y}})$, points in the direction of steepest increase (ascent) and orients the unit normal vector $\hat{\boldsymbol{n}} = |\nabla\psi|^{-1}\,\nabla\psi$. The unit tangent vector, $\hat{\boldsymbol{s}}$, points in a direction tangent to a ψ isosurface so that it is everywhere orthogonal to the direction of steepest ascent: $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{s}} = 0$. We follow the convention in which the unit normal is oriented to the left of the tangent when facing in the tangent direction.

where we dropped higher order terms to reach the final approximate expression. We also introduced the shorthand notation for the partial derivative operator

$$\partial_a = \frac{\partial}{\partial x_a}, \tag{2.3}$$

which is a notation used throughout this book. We can introduce the Cartesian gradient operator according to

$$\nabla = \vec{e}_a\,\partial_a = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,\partial_z \tag{2.4}$$

in which case

$$\psi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}) \approx (1 + \mathrm{d}\boldsymbol{x} \cdot \nabla)\,\psi(\boldsymbol{x}). \tag{2.5}$$

2.1.1 Direction of steepest ascent

Using the approximate relation (2.5), and the geometric expression (1.16) for the scalar product, renders

$$\psi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}) - \psi(\boldsymbol{x}) \approx |\mathrm{d}\boldsymbol{x}|\,|\nabla\psi|\cos\vartheta, \tag{2.6}$$

where ϑ is the angle between the differential increment, $\mathrm{d}\boldsymbol{x}$, and the gradient, $\nabla\psi$. Orienting the increment $\mathrm{d}\boldsymbol{x}$ so that $\vartheta = 0$ ensures that $\psi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}) - \psi(\boldsymbol{x})$ is maximal. Consequently, $\nabla\psi$ points in the direction of *steepest ascent* across constant ψ isosurfaces (Figure 2.1). The opposite direction is that of *steepest descent*, where $\vartheta = \pi$.

2.1.2 Tangent to an isosurface

Consider a family of isosurfaces defined by points satisfying

$$\psi(\boldsymbol{x}) = \text{constant}. \tag{2.7}$$

Figure 2.1 shows a two dimensional example where the isosurfaces are lines where ψ is a constant. As another example, consider $\psi(\boldsymbol{x}) = \psi(r)$, where $r^2 = \boldsymbol{x} \cdot \boldsymbol{x}$ is the squared radius of a sphere. Isosurfaces for this spherically symmetric function are spherical surfaces of radius r.

In general, moving along an isosurface keeps the scalar field unchanged. Let $\hat{\boldsymbol{s}}$ be a unit vector that points in the direction tangent to the isosurface at any point $\boldsymbol{x}$. By construction[1]

$$\psi(\boldsymbol{x} + \hat{\boldsymbol{s}}\,\mathrm{d}s) - \psi(\boldsymbol{x}) = 0, \tag{2.8}$$

where $\mathrm{d}s$ is an infinitesimal arc length along the tangent direction. In words, this identity says that if we move an infinitesimal distance in the direction tangent to the isosurface, then the function ψ does not change its value. Now expanding this identity in a Taylor series leads to the vanishing of the tangential partial derivative

$$\hat{\boldsymbol{s}} \cdot \nabla\psi = \frac{\partial \psi}{\partial s} = 0. \tag{2.9}$$

That is, isosurfaces of a function ψ are defined by directions along which the partial derivative of the function vanishes. For the spherically symmetric function, $\psi(\boldsymbol{x}) = \psi(r)$, the tangent vector points in either of the two angular directions along the spherical surface.

2.1.3 Normal to an isosurface

We may normalize the direction of maximal ascent, in which case we define the unit normal direction

$$\hat{\boldsymbol{n}} = |\nabla\psi|^{-1}\,\nabla\psi. \tag{2.10}$$

By construction, the gradient computed in the $\hat{\boldsymbol{n}}$ direction yields the maximum change for the function so that the *normal derivative* is given by

$$\hat{\boldsymbol{n}} \cdot \nabla\psi = \frac{\partial \psi}{\partial n} = |\nabla\psi|. \tag{2.11}$$

For the spherically symmetric example,

$$\hat{\boldsymbol{n}} = \frac{\boldsymbol{x}}{|\boldsymbol{x}|} = \hat{\boldsymbol{r}}, \tag{2.12}$$

where $\hat{\boldsymbol{r}}$ is the unit vector pointing radially outward from the origin. In this case the normal derivative is equal to the radial derivative

$$\hat{\boldsymbol{n}} \cdot \nabla\psi = \frac{\partial \psi}{\partial r} \qquad \text{spherically symmetric } \psi. \tag{2.13}$$

2.1.4 Unit vectors change only by rotation

Consider an arbitrary unit vector, $\hat{\boldsymbol{m}}$, that is generally a function of space. The defining feature of a unit vector is that it has unit magnitude,

$$\hat{\boldsymbol{m}} \cdot \hat{\boldsymbol{m}} = 1, \tag{2.14}$$

with this property holding at each point in space. Unit vectors can only be modified through changes in their direction since their magnitude is everywhere fixed at unity. Hence, unit vectors

[1] Sometimes in this book we write $\hat{\boldsymbol{t}}$ for the unit tangent vector.

FIGURE 2.2: The infinitesimal change to a unit vector is itself perpendicular to the unit vector: $\delta\hat{\boldsymbol{m}} \cdot \hat{\boldsymbol{m}} = 0$. The reason is that the unit vector is constrained to retain its unit length, so that the only way that it can change is to change its direction. So in this image we have $|\hat{\boldsymbol{m}} + \delta\hat{\boldsymbol{m}}| = |\hat{\boldsymbol{m}}| = 1$, which requires $\delta\hat{\boldsymbol{m}} \cdot \hat{\boldsymbol{m}} = 0$. In this figure, we can see that $\delta\hat{\boldsymbol{m}}$ is orthogonal to $\hat{\boldsymbol{m}}$ in the limit that $\delta\hat{\boldsymbol{m}}$ gets tiny.

differ in space only through rotations. An important consequence of this property is that the infinitesimal spatial change to a unit vector is perpendicular to unit vector itself (see Figure 2.2). We see this property through considering an arbitrary infinitesimal change, symbolized by δ, in which

$$0 = \delta(1) = \delta\left(\hat{\boldsymbol{m}} \cdot \hat{\boldsymbol{m}}\right) = 2\,\hat{\boldsymbol{m}} \cdot \delta\hat{\boldsymbol{m}}. \tag{2.15}$$

In Section 11.2, we formally show that the constraint

$$\delta\hat{\boldsymbol{m}} \cdot \hat{\boldsymbol{m}} = 0 \tag{2.16}$$

means that unit vector changes can only arise from rotations. Even so, the above assertion should make intuitive sense, with Figure 2.2 illustrating this property.

2.1.5 Showing that $\delta\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{n}} = 0$

As an illustration of the constraint (2.16), we verify that it holds for the special case of a unit normal vector defined according to equation (2.10) for surfaces of constant scalar field

$$\hat{\boldsymbol{n}} = |\nabla\psi|^{-1}\,\nabla\psi. \tag{2.17}$$

The proof follows first by writing

$$\delta\hat{\boldsymbol{n}} = |\nabla\psi|^{-1}\,\left[\delta(\nabla\psi) - \hat{\boldsymbol{n}}\,\delta|\nabla\psi|\right], \tag{2.18}$$

so that

$$|\nabla\psi|\,\hat{\boldsymbol{n}} \cdot \delta\hat{\boldsymbol{n}} = \hat{\boldsymbol{n}} \cdot \delta(\nabla\psi) - \delta(|\nabla\psi|) = \frac{\nabla\psi \cdot \delta(\nabla\psi)}{|\nabla\psi|} - \delta|\nabla\psi|. \tag{2.19}$$

We now make use of the identity

$$\delta(|\nabla\psi|) = \delta(\sqrt{\nabla\psi \cdot \nabla\psi}) = \frac{1}{2\sqrt{\nabla\psi \cdot \nabla\psi}}\delta(\nabla\psi \cdot \nabla\psi) = \frac{\nabla\psi \cdot \delta(\nabla\psi)}{|\nabla\psi|}, \tag{2.20}$$

in which case we have shown that $\delta\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{n}} = 0$.

FIGURE 2.3: Two vector fields with a non-zero horizontal divergence. Left panel: The vector field $\boldsymbol{F} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}$ has a spatially constant positive divergence at each point with $\nabla \cdot \boldsymbol{F} = 2$. We thus say that the vector field is "diverging from each point." Right panel: with the opposite sign, the vector field $\boldsymbol{G} = -\boldsymbol{F} = -x\,\hat{\boldsymbol{x}} - y\,\hat{\boldsymbol{y}}$ has a spatially constant negative divergence at each point with $\nabla \cdot \boldsymbol{G} = -2$. We thus say that the vector field is "converging to each point." Note that these two vector fields have zero curl, $\nabla \times \boldsymbol{F} = \nabla \times \boldsymbol{G} = 0$.

2.2 Divergence of a vector field

The divergence of a vector field, $\boldsymbol{F}$, is the scalar product of the gradient operator with the vector

$$\operatorname{div}(\boldsymbol{F}) = \nabla \cdot \boldsymbol{F} = \partial_a F_a \begin{cases} > 0 \Rightarrow \text{diverging vector field,} \\ < 0 \Rightarrow \text{converging vector field} \\ = 0 \Rightarrow \text{divergence-free (or non-divergent) vector field.} \end{cases} \tag{2.21}$$

If the vector field in the surrounding neighborhood of a point is directed away from that point, then the vector field is diverging as if there is a source at the point (Figure 2.3). In this case the divergence of the vector field is positive. The converse occurs for a vector field converging to a point as if there is a sink.

If the vector field under consideration is the velocity field of a moving fluid, then these considerations are directly related to the conservation of matter that we study in Chapter 20. That discussion motivates us to consider a positive divergence for a vector field as representing the creation of "stuff" at a point where there is a positive divergence. Again for the case of a fluid velocity, there is a net divergence if more fluid leaves a point than enters, and the converse holds if the velocity field is converging. We further discuss these ideas as part of our study of Gauss's divergence theorem in Section 2.7.

2.2.1 Divergence of a scalar field times a vector field

We have many opportunities to make use of properties of the divergence operator following from application of the chain rule. For example, use of the chain rule indicates that the divergence of a scalar field times a vector field is given by

$$\nabla \cdot (\phi\,\boldsymbol{F}) = \partial_a(\phi\,F_a) \tag{2.22a}$$

$$= F_a\,\partial_a\phi + \phi\,\partial_a F_a \tag{2.22b}$$

$$= \boldsymbol{F} \cdot \nabla\phi + \phi\,\nabla \cdot \boldsymbol{F}. \tag{2.22c}$$

FIGURE 2.4: A horizontal vector field with a constant curl and zero divergence. Left panel: $\boldsymbol{F} = -y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}$, $\implies \nabla \times \boldsymbol{F} = 2\,\hat{\boldsymbol{z}}$ and $\nabla \cdot \boldsymbol{F} = 0$. Right panel: $\boldsymbol{G} = -\boldsymbol{F}$ so that $\nabla \times \boldsymbol{G} = -2\,\hat{\boldsymbol{z}}$.

2.2.2 Laplacian of a scalar field

The Laplacian of a scalar field is the divergence of the gradient

$$\nabla^2 \psi = \nabla \cdot \nabla \psi. \tag{2.23}$$

Scalar fields that have a vanishing Laplacian are said to be *harmonic*

$$\nabla^2 \psi = 0 \qquad \text{harmonic function.} \tag{2.24}$$

Familiar examples of harmonic functions are the sines and cosines used for Fourier analysis in Euclidean space (Chapter 4), and the spherical harmonics used for Fourier analysis on the sphere. The name *harmonic* originates from the relation of harmonic functions to characteristic vibrational modes of a taut string such as those found on musical instruments (when played with skill). Furthermore, harmonic functions play a central role in complex analysis.

2.3 Curl of a vector field

The curl characterizes how a vector field spins around each point in space. In fluid mechanics we make great use of the vorticity field, which is the curl of the velocity[2]

2.3.1 Computing the curl

We measure the curl of a vector by computing the cross product of the gradient operator with the vector field. Hence, just like the cross product from Section 1.4, the curl is specified by both a magnitude and a direction

$$\begin{aligned}
\operatorname{curl}(\boldsymbol{F}) &= \nabla \times \boldsymbol{F} && \text{(2.25a)}\\
&= \vec{e}_a\,\partial_a \times \vec{e}_b\,F_b && \text{coordinate representation and basis} \quad \text{(2.25b)}\\
&= \vec{e}_a \times \partial_a\,(\vec{e}_b\,F_b) && \text{move derivative operator onto } \boldsymbol{F} = \vec{e}_b\,F_b \quad \text{(2.25c)}\\
&= (\vec{e}_a \times \vec{e}_b)\,\partial_a F_b + F_b\,(\vec{e}_a \times \partial_a \vec{e}_b) && \text{perform product rule} \quad \text{(2.25d)}\\
&= \epsilon_{abc}\,\vec{e}_c\,\partial_a F_b && \partial_a \vec{e}_b = 0 \text{ for Cartesian coordinates.} \quad \text{(2.25e)}
\end{aligned}$$

[2]We study vorticity in Part VII of this book.

FIGURE 2.5: A horizontal vector field with a zero curl, where $\boldsymbol{F} = -\nabla\psi$ with the scalar potential given by $\psi = \sin(x/10)\,\sin(y/10)$.

To reach this result we set $\partial_a \vec{e}_b = 0$ since the Cartesian basis vectors are fixed in space.[3] We also made use of the relation (1.17) for the cross product of basis vectors. Expanding the final expression leads to

$$\text{curl}(\boldsymbol{F}) = \nabla \times \boldsymbol{F} = \left[\frac{\partial F_3}{\partial x_2} - \frac{\partial F_2}{\partial x_3}\right]\hat{\boldsymbol{x}} + \left[\frac{\partial F_1}{\partial x_3} - \frac{\partial F_3}{\partial x_1}\right]\hat{\boldsymbol{y}} + \left[\frac{\partial F_2}{\partial x_1} - \frac{\partial F_1}{\partial x_2}\right]\hat{\boldsymbol{z}}, \tag{2.26}$$

which can also be written as a determinant

$$\nabla \times \boldsymbol{F} = \det\begin{bmatrix} \vec{e}_1 & \vec{e}_2 & \vec{e}_3 \\ \partial_1 & \partial_2 & \partial_3 \\ F_1 & F_2 & F_3 \end{bmatrix}. \tag{2.27}$$

The horizontal vector field $\boldsymbol{F} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}$ shown in Figure 2.3 has zero curl yet non-zero divergence. Figure 2.4 shows another vector field, $\boldsymbol{F} = -y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}$, with zero divergence yet nonzero curl $\nabla \times \boldsymbol{F} = 2\,\hat{\boldsymbol{z}}$. We encounter this vector again in Section 38.6, where we see that it corresponds to the velocity due to rigid-body motion in a rotating reference frame, and with its curl measuring the vorticity induced by the rotation.

2.3.2 Curl-free vector fields

There are some cases of physically relevant vector fields that have a vanishing curl

$$\nabla \times \boldsymbol{F} = 0. \tag{2.28}$$

We sometimes refer to such curl-free vectors as *irrotational*. In fluid mechanics a curl-free velocity field has zero vorticity, which is a property maintained by linear gravity waves in the absence of rotation (Section 53.5). We illustrate a curl-free vector field in Figure 2.5.

The curl of a gradient vanishes, which follows from

$$\nabla \times \nabla\psi = \vec{e}_a\,\partial_a \times \vec{e}_b\,\partial_b\psi = (\vec{e}_a \times \vec{e}_b)\,\partial_a\partial_b\psi = 0, \tag{2.29}$$

where the final equality follows since $\vec{e}_a \times \vec{e}_b$ is anti-symmetric on the labels ab (i.e., $\vec{e}_a \times \vec{e}_b =$

[3] Basis vectors corresponding to non-Cartesian coordinates are spatially dependent (see Chapters 8 and 9), thus making this step invalid for general tensors. We will find a "fix" for this step in Section 9.17, thus leading to the *covariant curl operator*.

$-\vec{e}_b \times \vec{e}_a)$ whereas $\partial_a \partial_b$ is symmetric (i.e., $\partial_a \, \partial_b = \partial_b \, \partial_a$). This property allows us to introduce a scalar field whose gradient equals to the curl-free vector field

$$\boldsymbol{F} = -\nabla \psi \qquad \text{scalar potential.} \tag{2.30}$$

The scalar ψ is known as the *scalar potential*. We may be familiar with the scalar potential for the gravitational force, in which ψ is called the gravitational potential (see Section 13.10 and Chapter 35).

2.3.3 Curl-free and divergence-free fields

Consider a vector field that has zero curl *and* zero divergence. The curl-free property means that

$$\nabla \times \boldsymbol{F} = 0 \Longrightarrow \boldsymbol{F} = -\nabla \psi. \tag{2.31}$$

The divergence-free property means that ψ is a harmonic function (Section 2.2.2)

$$\nabla \cdot \nabla \psi = \nabla^2 \psi = 0. \tag{2.32}$$

The velocity field arising from a linear non-rotating gravity wave (Section 53.5) in a Boussinesq fluid (Section 30.1) maintains zero vorticity and zero divergence. Furthermore, curl-free and divergence-free velocity fields are commonly encountered in engineering applications such as aerodynamics (e.g., see *Acheson* (1990) for many elementary examples).

2.3.4 Identities involving the curl

We close this section by deriving a suite of identities involving the curl operator. These identities are especially useful when developing dynamical equations for vorticity. Furthermore, by making use of the rules for general tensor analysis developed in Chapters 8 and 9, these identities take on the same form regardless the coordinate choice.

Divergence of the curl vanishes

The divergence of the curl vanishes, as seen through the following

$$\nabla \cdot (\nabla \times \boldsymbol{F}) = \partial_a (\epsilon_{abc} \, \partial_b F_c) = \epsilon_{abc} \, \partial_a \partial_b F_c = 0. \tag{2.33}$$

The final equality holds since $\partial_a \, \partial_b$ is symmetric on ab whereas ϵ_{abc} is anti-symmetric.

Divergence of a cross product

We now derive an expression for the divergence of a cross product through the following manipulations

$$\begin{aligned}
\nabla \cdot (\boldsymbol{F} \times \boldsymbol{E}) &= \vec{e}_a \cdot \partial_a \left(F_b \, \vec{e}_b \times E_c \, \vec{e}_c \right) && \text{expose indices and basis vectors} && (2.34a)\\
&= \vec{e}_a \cdot (\vec{e}_b \times \vec{e}_c) \, \partial_a (F_b \, E_c) && \text{spatially constant Cartesian basis} && (2.34b)\\
&= \vec{e}_a \cdot (\epsilon_{bcd} \, \vec{e}_d) \, \partial_a (F_b \, E_c) && \text{cross product equation (1.17)} && (2.34c)\\
&= \vec{e}_a \cdot \vec{e}_d \, \epsilon_{bcd} \, \partial_a (F_b \, E_c) && \text{rearrange} && (2.34d)\\
&= \epsilon_{abc} \, \partial_a (F_b \, E_c) && \vec{e}_a \cdot \vec{e}_d \, \epsilon_{bcd} = \delta_{ad} \, \epsilon_{bcd} = \epsilon_{bca} = \epsilon_{abc}. && (2.34e)\\
&= F_b \, \epsilon_{abc} \, \partial_a E_c + E_c \, \epsilon_{abc} \, \partial_a F_b && \text{product rule} && (2.34f)\\
&= -\boldsymbol{F} \cdot (\nabla \times \boldsymbol{E}) + \boldsymbol{E} \cdot (\nabla \times \boldsymbol{F}) && \text{boldface notation.} && (2.34g)
\end{aligned}$$

Curl of a scalar times a vector

Following similar logic we compute the curl of a scalar field $\psi\,\boldsymbol{F}$ through the following steps

$$\begin{aligned}
\nabla \times (\psi\,\boldsymbol{F}) &= \vec{e}_a\,\partial_a \times \psi\,\vec{e}_b\,F_b && (2.35a)\\
&= (\vec{e}_a \times \vec{e}_b)\,\partial_a(\psi\,F_b) && (2.35b)\\
&= \epsilon_{abc}\,\vec{e}_c\,(\psi\,\partial_a F_b + F_b\,\partial_a\psi) && (2.35c)\\
&= \psi\,\nabla \times \boldsymbol{F} + \nabla\psi \times \boldsymbol{F}. && (2.35d)
\end{aligned}$$

Curl of a cross product

Likewise, the curl of a cross product of two vectors is given by

$$\begin{aligned}
\nabla \times (\boldsymbol{F} \times \boldsymbol{E}) &= \vec{e}_a\,\partial_a \times (\vec{e}_b\,F_b \times \vec{e}_c\,E_c) && (2.36a)\\
&= \vec{e}_a \times (\vec{e}_b \times \vec{e}_c)\,\partial_a(F_b\,E_c) && (2.36b)\\
&= \vec{e}_a \times (\epsilon_{bcd}\,\vec{e}_d)\,\partial_a(F_b\,E_c) && (2.36c)\\
&= \epsilon_{ade}\,\epsilon_{bcd}\,\vec{e}_e\,\partial_a(F_b\,E_c) && (2.36d)\\
&= -\epsilon_{aed}\,\epsilon_{bcd}\,\vec{e}_e\,\partial_a(F_b\,E_c) && (2.36e)\\
&= -(\delta_{ab}\,\delta_{ec} - \delta_{ac}\,\delta_{eb})\,\vec{e}_e\,\partial_a(F_b\,E_c) && (2.36f)\\
&= (-\delta_{ba}\,\vec{e}_c + \delta_{ca}\,\vec{e}_b)\,\partial_a(F_b\,E_c) && (2.36g)\\
&= \boldsymbol{F}\,(\nabla\cdot\boldsymbol{E}) + (\boldsymbol{E}\cdot\nabla)\,\boldsymbol{F} - \boldsymbol{E}\,(\nabla\cdot\boldsymbol{F}) - (\boldsymbol{F}\cdot\nabla)\,\boldsymbol{E}. && (2.36h)
\end{aligned}$$

Curl of a curl

A special case of the identity (2.36h) allows us to write the curl of a curl as

$$\begin{aligned}
\nabla \times (\nabla \times \boldsymbol{F}) &= \vec{e}_a \times (\vec{e}_b \times \vec{e}_c)\,\partial_a\partial_b\,F_c && (2.37a)\\
&= (-\delta_{ba}\,\vec{e}_c + \delta_{ca}\,\vec{e}_b)\,\partial_a\partial_b\,F_c && (2.37b)\\
&= \nabla(\nabla\cdot\boldsymbol{F}) - \nabla^2\boldsymbol{F}. && (2.37c)
\end{aligned}$$

Relating advection, curl, and kinetic energy

We apply some of the previous manipulations to derive a relation required to derive the vorticity equation (Section 41.3.1). Here, we aim to show that

$$(\boldsymbol{v}\cdot\nabla)\boldsymbol{v} = \boldsymbol{\omega}\times\boldsymbol{v} + \nabla(\boldsymbol{v}\cdot\boldsymbol{v})/2, \tag{2.38}$$

where

$$\boldsymbol{\omega} = \nabla\times\boldsymbol{v} \tag{2.39}$$

is the vorticity, $\boldsymbol{v}\cdot\boldsymbol{v}/2$ is the kinetic energy per mass, and $\boldsymbol{v}$ is the fluid velocity field. We here show all the steps along with their justification

$$\begin{aligned}
\boldsymbol{\omega}\times\boldsymbol{v} &= (\nabla\times\boldsymbol{v})\times\boldsymbol{v} && \text{insert } \boldsymbol{\omega}=\nabla\times\boldsymbol{v} && (2.40a)\\
&= (\vec{e}_a\,\partial_a\times\vec{e}_b\,v_b)\times\vec{e}_c\,v_c && \text{Cartesian representation of } \boldsymbol{v} \text{ and } \nabla && (2.40b)\\
&= (\vec{e}_a\times\vec{e}_b)\times\vec{e}_c\,(\partial_a v_b)\,v_c && \text{rearrange} && (2.40c)\\
&= \epsilon_{abd}\,(\vec{e}_d\times\vec{e}_c)\,(\partial_a v_b)\,v_c && \text{first cross product expanded} && (2.40d)\\
&= \epsilon_{abd}\,\epsilon_{dce}\,\vec{e}_e\,(\partial_a v_b)\,v_c && \text{second cross product expanded} && (2.40e)\\
&= \epsilon_{abd}\,\epsilon_{ced}\,\vec{e}_e\,(\partial_a v_b)\,v_c && \text{arrange indices to prepare for next step} && (2.40f)\\
&= (\delta_{ac}\,\delta_{be}-\delta_{ae}\,\delta_{bc})\,\vec{e}_e\,(\partial_a v_b)\,v_c && \text{use identity (1.43)} && (2.40g)\\
&= \vec{e}_a\,v_c\,\partial_c v_a-\vec{e}_a\,v_c\,\partial_a v_c && \text{contract the Kronecker deltas} && (2.40h)\\
&= \vec{e}_a\,[(\boldsymbol{v}\cdot\nabla)\,v_a-\partial_a\boldsymbol{v}^2/2] && \text{re-express as Cartesian tensor} && (2.40i)\\
&= (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v}-\nabla[\boldsymbol{v}\cdot\boldsymbol{v}/2] && \text{rearrange.} && (2.40j)
\end{aligned}$$

Note that Section 4.4.4 of *Griffies* (2004) exhibits these steps making use of general coordinates rather than Cartesisn.

2.4 Path integral of a scalar function

Consider the integral of a scalar function, ψ, over an arbitrary one-dimensional path in space, $\mathcal{C}$

$$\mathcal{I}=\int_{\varphi_A}^{\varphi_B}\psi(\varphi)\,\mathrm{d}\varphi. \tag{2.41}$$

Since any path is a one-dimensional curve, a point along the path can be specified by a single parameter, denoted here by φ with endpoints φ_A and φ_B.[4] We now consider some explicit examples of how to parameterize a curve to thus enable an explicit evaluation of the integral.[5]

2.4.1 Cartesian coordinates

Lay down a Cartesian coordinate system with an arbitrary origin, in which case the Cartesian coordinate representation of a point along the path is written

$$\boldsymbol{x}(\varphi)=\hat{\boldsymbol{x}}\,x(\varphi)+\hat{\boldsymbol{y}}\,y(\varphi)+\hat{\boldsymbol{z}}\,z(\varphi), \tag{2.42}$$

along with the endpoints along the path

$$\boldsymbol{x}(\varphi_A)=\boldsymbol{x}_A \quad\text{and}\quad \boldsymbol{x}(\varphi_B)=\boldsymbol{x}_B. \tag{2.43}$$

In this way the path integral is written

$$\mathcal{I}=\int_{\varphi_A}^{\varphi_B}\psi(\varphi)\,\mathrm{d}\varphi=\int_{\varphi_A}^{\varphi_B}\psi[\boldsymbol{x}(\varphi)]\,\mathrm{d}\varphi. \tag{2.44}$$

[4] We have more to say about the geometry of paths in Sections 7.1 and 7.2.

[5] In the more general language of differential forms, the evaluation of a path integral requires one to parameterize points along the path so to then write the path integral as a Riemann integral. This process is known as *pulling back* the path integral to a Riemann integral. *Shifrin* (2004) provies a treatment accessible to those having studied undergraduate calculus.

To bring the integral (2.44) fully into a Cartesian parameterized form requires us to perform a coordinate transformation from φ to $\boldsymbol{x}$ along the curve. For this purpose, consider two points on the path that are separated by an infinitesimal parameter difference, in which the difference in their Cartesian coordinates is given by

$$\mathrm{d}\boldsymbol{x} = \boldsymbol{x}(\varphi + \mathrm{d}\varphi) - \boldsymbol{x}(\varphi) = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\varphi}\,\mathrm{d}\varphi. \tag{2.45}$$

We thus have

$$(\mathrm{d}\varphi)^2 = \frac{\mathrm{d}\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{x}}{\mathrm{d}\boldsymbol{x}/\mathrm{d}\varphi\cdot\mathrm{d}\boldsymbol{x}/\mathrm{d}\varphi}. \tag{2.46}$$

Assuming $\mathrm{d}\varphi > 0$ then leads to the integral (2.44) taking on the rather clumsy, but nonetheless general, form

$$\mathcal{I} = \int_{\varphi_A}^{\varphi_B} \psi(\varphi)\,\mathrm{d}\varphi = \int_{\varphi_A}^{\varphi_B} \psi[\boldsymbol{x}(\varphi)]\,\mathrm{d}\varphi = \int_{\boldsymbol{x}_A}^{\boldsymbol{x}_B} \psi[\boldsymbol{x}(\varphi)]\sqrt{\frac{\mathrm{d}\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{x}}{\mathrm{d}\boldsymbol{x}/\mathrm{d}\varphi\cdot\mathrm{d}\boldsymbol{x}/\mathrm{d}\varphi}}. \tag{2.47}$$

2.4.2 Arc length parameterization

We now consider a common special case for path parameterization where $\varphi = s$ is the arc length along the path[6]

$$\mathcal{I} = \int_{\varphi_A}^{\varphi_B} \psi(\varphi)\,\mathrm{d}\varphi = \int_{s_A}^{s_B} \psi[\boldsymbol{x}(s)]\,\mathrm{d}s. \tag{2.48}$$

For Euclidean space using Cartesian coordinates, the differential increment of arc length is given by

$$\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{x}}. \tag{2.49}$$

Inserting $\boldsymbol{x}(s)$ into this expression renders

$$\mathrm{d}s = \sqrt{\mathrm{d}\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{x}} = \mathrm{d}s\sqrt{\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\cdot\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}}. \tag{2.50}$$

This expression is self-consistent if

$$\sqrt{\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\cdot\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}} = 1, \tag{2.51}$$

which is merely a rewrite of the defining expression (2.49). Note that the derivative of the curve with respect to the arc-length, $\mathrm{d}\boldsymbol{x}/\mathrm{d}s$, defines a unit tangent vector to the curve

$$\hat{\boldsymbol{s}} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s} \Longrightarrow \hat{\boldsymbol{s}}\cdot\hat{\boldsymbol{s}} = 1. \tag{2.52}$$

2.4.3 Linear path example

As a specific example, consider a straight line between two points, $\boldsymbol{x}_A$ and $\boldsymbol{x}_B$, as in Figure 2.6. We can parameterize the line using a dimensionless parameter φ according to

$$\boldsymbol{x}(\varphi) = \boldsymbol{x}_A + (\boldsymbol{x}_B - \boldsymbol{x}_A)\,\varphi \qquad \varphi \in [0,1]. \tag{2.53}$$

[6] We offer a more focused discussion of curves and tangents in Section 7.2.1 (see in particular equation (7.9)).

FIGURE 2.6: A linear path, $\boldsymbol{x}(\varphi)$ extending from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$ can be parameterized by a non-dimensional parameter $\varphi \in [0,1]$ via $\boldsymbol{x}(\varphi) = \boldsymbol{x}_A + (\boldsymbol{x}_B - \boldsymbol{x}_A)\,\varphi$. Alternatively, it can be parameterized by the arc-length along the path via $\boldsymbol{x}(s) = \boldsymbol{x}_A + \hat{\boldsymbol{s}}\,s$ with $s \in [0, L]$, $L = |\boldsymbol{x}_B - \boldsymbol{x}_A|$, and $\hat{\boldsymbol{s}}$ the unit tangent vector pointing from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$.

Alternatively, we can parameterize using the arc length

$$\boldsymbol{x}(s) = \boldsymbol{x}_A + \hat{\boldsymbol{s}}\,s \qquad s \in [0, L], \tag{2.54}$$

where $L = \int_A^B \mathrm{d}s = |\boldsymbol{x}_B - \boldsymbol{x}_A|$ is the total arc length of the line, and where $\hat{\boldsymbol{s}}$ is the unit tangent vector pointing along the path from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$

$$\hat{\boldsymbol{s}} = \frac{\boldsymbol{x}'(s)}{|\boldsymbol{x}'(s)|} = \frac{\boldsymbol{x}_B - \boldsymbol{x}_A}{|\boldsymbol{x}_B - \boldsymbol{x}_A|}. \tag{2.55}$$

As defined we have $|\boldsymbol{x}'(s)| = |\hat{\boldsymbol{s}}| = 1$, so that the path integral is given by

$$\mathcal{I} = \int_{\mathcal{C}} \psi(\varphi)\,\mathrm{d}\varphi = \int_0^L \psi[\boldsymbol{x}(s)]\,\mathrm{d}s. \tag{2.56}$$

2.5 Path integral of a vector function

Generalizing to a vector field, $\boldsymbol{F}(\boldsymbol{x})$, we could conceivably integrate each component of the vector along the curve independently, making use of the approach for scalar fields in Section 2.4. In practice, however, that quantity rarely appears in physics.[7] Instead, we more commonly wish to integrate that component of $\boldsymbol{F}(\boldsymbol{x})$ that projects onto a curve

$$\int_{\mathcal{C}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{C}} \boldsymbol{F} \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\,\mathrm{d}s = \int_{\mathcal{C}} \boldsymbol{F} \cdot \hat{\boldsymbol{s}}\,\mathrm{d}s, \tag{2.57}$$

where $\hat{\boldsymbol{s}} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$ is tangent to the curve given by equation (2.52). A common example for the path integral of a vector concerns the work performed by a force field applied to a physical system that is moving along a path (this example is studied in Section 11.1.4).

[7] The mathematical reason it does not appear is that for a general manifold, the addition of vectors is only defined locally within a tangent space. This limitation prevents us from integrating general tensors over a volume.

2.5.1 Circulation

For the case of a closed curve or a circuit (see Section 7.1), we refer to the path integral as the *circulation* and use the convention of putting an arrowed circle on the integral sign

$$\text{circulation of vector field} = \oint_{\mathcal{C}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x}. \tag{2.58}$$

The arrow indicates that we conventionally traverse the closed path in a counter-clockwise (right hand) manner when looking down on the path from above. Note that by choosing a viewpoint as "above", we necessarily allow for an unambiguous definition of "counter-clockwise", thus chosing an *orientation*.

2.5.2 Circulation example

Consider the vector field $\boldsymbol{F} = -y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}$ shown in Figure 2.4. What is the circulation for this field computed around a circle of radius r whose center is the origin? To compute this circulation we make use of plane polar coordinates, in which $x = r\,\cos\varphi$ and $y = r\,\sin\varphi$, with $\varphi \in [0, 2\pi]$ the polar angle measured from the positive x-axis. The position of a point on the circle is thus written $\boldsymbol{x}(\varphi) = r\,(\hat{\boldsymbol{x}}\,\cos\varphi + \hat{\boldsymbol{y}}\,\sin\varphi)$, and the tangent to the circle is $\mathrm{d}\boldsymbol{x}(\varphi)/\mathrm{d}\varphi = r\,(-\hat{\boldsymbol{x}}\,\sin\varphi + \hat{\boldsymbol{y}}\,\cos\varphi)$. The integrand to the circulation (2.57) thus takes the form

$$\boldsymbol{F} \cdot \frac{\mathrm{d}\boldsymbol{x}(\varphi)}{\mathrm{d}\varphi} = r\,(y\,\sin\varphi + x\cos\varphi) = r^2. \tag{2.59}$$

Hence, the circulation around the constant radius circle is given by twice the area of the circle

$$\oint_{\mathcal{C}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = 2\,\pi\,r^2. \tag{2.60}$$

We apply this result in Section 41.6.2 to geophysical fluids when computing the vorticity induced by the rotating planet.

2.5.3 Fundamental theorem of calculus

The special case of $\boldsymbol{F} = -\nabla\psi$ for a scalar field ψ recovers the fundamental theorem of calculus

$$\psi(\boldsymbol{x}_B) - \psi(\boldsymbol{x}_A) = \int_{\boldsymbol{x}_A}^{\boldsymbol{x}_B} \mathrm{d}\psi = \int_{\boldsymbol{x}_A}^{\boldsymbol{x}_B} \nabla\psi \cdot \mathrm{d}\boldsymbol{x}. \tag{2.61}$$

It follows that for any closed curve with $\boldsymbol{x}_A = \boldsymbol{x}_B$, the circulation of $\nabla\psi$ vanishes

$$\oint_{\mathcal{C}} \mathrm{d}\psi = \oint_{\mathcal{C}} \nabla\psi \cdot \mathrm{d}\boldsymbol{x} = 0. \tag{2.62}$$

2.6 Stokes' curl theorem

Stokes' theorem relates the integral of a vector field, projected onto the tangent of a boundary around an orientable surface, to the integral of the unit normal component of the vector field's curl over the area of the surface.[8] This theorem is used extensively in our study of circulation

[8] As noted in a footnote on page 13 of *Truesdell* (1954), Lord Kelvin and later Hankel who independently discovered what we here refer to as Stokes' theorem. Stokes' name became attached to the theorem merely since he included its derivation on an examination question.

FIGURE 2.7: Illustrating the geometry of Stokes' theorem (2.63). The unit outward normal vector, $\hat{\boldsymbol{n}}$, points outward from the surface, $\mathcal{S}$, thus defining the positive or up direction. The integrand $(\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}}$ is the projection of the curl of a vector field onto the surface outward normal. The boundary of the area, $\mathcal{C} = \partial\mathcal{S}$, is traversed counterclockwise following the unit tangent vector, $\hat{\boldsymbol{s}}$, when computing the circulation. Counter-clockwise is oriented relative to the positive side of the surface as defined by the outward normal.

and vorticity in Part VII of this book. The geometry of Stokes' theorem is illustrated in Figure 2.7.

2.6.1 Statement of Stokes' theorem

For an oriented[9] two-dimensional surface, $\mathcal{S}$, with a closed boundary, $\partial\mathcal{S}$, Stokes' theorem says that the circulation around the boundary equals to the area integrated curl projected onto the surface outward unit normal

$$\oint_{\partial\mathcal{S}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} (\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{2.63}$$

In this equation,

$$\mathrm{d}\boldsymbol{x} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s} \, \mathrm{d}s = \hat{\boldsymbol{s}} \, \mathrm{d}s \tag{2.64}$$

is the vector line element along the closed path (circuit), $\hat{\boldsymbol{s}}$ is the unit tangent vector along the path, and s is the arc-distance along the path. For the surface integral we have the outward unit normal vector, $\hat{\boldsymbol{n}}$, and $\mathrm{d}\mathcal{S}$ is the infinitesimal surface area element. The orientation of the outward normal determines, through the right hand rule, the counter-clockwise direction for the path integral.

2.6.2 Stokes' theorem for a rectangular region

To build experience with Stokes' theorem, consider the case of a rectangle in the x-y plane with dimensions L_x and L_y. In this case $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, so that

$$(\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{z}} = \frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y}, \tag{2.65}$$

[9]For a surface to be orientable means that we can unambiguously describe its two sides, thus allowing us to determine a positive (top) side and negative (bottom) side. We are here only concerned with surfaces that are orientable, thus precluding non-orientable surfaces such as the Möbius strip.

FIGURE 2.8: Illustrating the geometry of Gauss's divergence theorem for an ellipsoidal volume, $\mathcal{R}$, with closed boundary surface, $\mathcal{S} = \partial\mathcal{R}$. The outward unit normal along the boundary, $\hat{\boldsymbol{n}}$, is projected onto the vector field, $\boldsymbol{F}$, via the scalar product, $\boldsymbol{F}\cdot\hat{\boldsymbol{n}}$. Gauss's divergence theorem says that integrating $\boldsymbol{F}\cdot\hat{\boldsymbol{n}}$ over the closed boundary surface, $\mathcal{S}$, yields the same answer as computing the volume integral of the divergence, $\nabla\cdot\boldsymbol{F}$, over the closed region, $\mathcal{R}$, bounded by the closed surface $\mathcal{S}$.

in which case the right hand side of Stokes' theorem reduces to

$$\int_{\mathcal{S}} (\nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}S = \int_0^{L_x}\int_0^{L_y}\left(\frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y}\right)\mathrm{d}x\,\mathrm{d}y. \tag{2.66}$$

Integration around the rectangle then leads to a direct verification of Stokes' theorem

$$\int_0^{L_x}\int_0^{L_y}\left(\frac{\partial F_2}{\partial x} - \frac{\partial F_1}{\partial y}\right)\mathrm{d}x\,\mathrm{d}y = \int_0^{L_y} F_2(x,y)\Big|_{x=0}^{x=L_x}\mathrm{d}y - \int_0^{L_x} F_1(x,y)\Big|_{y=0}^{y=L_y}\mathrm{d}x \tag{2.67a}$$

$$= \int_0^{L_x} F_1(x,0)\,\mathrm{d}x + \int_0^{L_y} F_2(L_x,y)\,\mathrm{d}y + \int_{L_x}^{0} F_1(x,L_y)\,\mathrm{d}x + \int_{L_y}^{0} F_2(0,y)\,\mathrm{d}y \tag{2.67b}$$

$$= \oint_{\partial\mathcal{S}} \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{x}. \tag{2.67c}$$

We can generalize this result to verify Stokes' theorem for an arbitrary surface. We do so by breaking the surface into a lattice of tiny rectangles. Integrating around the tiny rectangles and summing their contributions leads to a cancellation of the line integrals over all interior boundaries. The cancellation occurs since an internal edge of a rectangle is integrated once in each direction thus cancelling its contribution. The only nonzero contribution comes from integration over the boundary, $\partial\mathcal{S}$.

2.7 Gauss's divergence theorem

For a continuously differentiable vector field $\boldsymbol{F}$, Gauss's divergence theorem states that

$$\int_{\mathcal{R}} \nabla\cdot\boldsymbol{F}\,\mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{F}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{2.68}$$

where $\hat{\boldsymbol{n}}$ is the outward unit normal to the boundary surface, $\partial\mathcal{R}$, and $\mathrm{d}\mathcal{S}$ is the surface area element on the boundary. In words, the left hand side of Gauss's theorem is the volume integral of the divergence of a continuously differentiable vector field over a connected volume, $\mathcal{R}$. The right hand side is the unit normal projection of the vector field that is area integrated over the closed surface, $\partial\mathcal{R}$, bounding the volume. We follow the convention that $\oint_{\partial\mathcal{R}}$ refers to a surface integral over a closed surface that bounds a volume. This notation contrasts with the surface

integral, $\int_{\mathcal{S}}$, that generally does not enclose a volume. Figure 2.8 illustrates the geometry of Gauss's divergence theorem. In physics jargon, we say that the divergence of a vector field, $\nabla \cdot \boldsymbol{F}$, integrated over a volume equals to the flux of that vector field, $\boldsymbol{F} \cdot \hat{\boldsymbol{n}}$, integrated over the area bounding the volume.

2.7.1 An example rectangular volume

To build intuition for Gauss's divergence theorem, consider a rectangular volume with dimensions L_x, L_y, and L_z. The volume integral on the left hand side of equation (2.68) gives

$$\int_{\mathcal{R}} \left[\frac{\partial F_1}{\partial x} + \frac{\partial F_2}{\partial y} + \frac{\partial F_3}{\partial z} \right] \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z. \tag{2.69}$$

Focusing on just the leftmost term, integration in x gives

$$\int_{\mathcal{R}} \frac{\partial F_1}{\partial x} \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z = \int_{y=0}^{y=L_y} \int_{z=0}^{z=L_z} [F_1(L_x, y, z) - F_1(0, y, z)] \, \mathrm{d}y \, \mathrm{d}z \tag{2.70a}$$

$$= \int_{\mathcal{S}_1 + \mathcal{S}_2} \boldsymbol{F} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{2.70b}$$

where $\mathcal{S}_1$ is the rectangle's face with outward unit normal $\hat{\boldsymbol{n}} = \hat{\boldsymbol{x}}$ and $\mathcal{S}_2$ is the rectangle's face with unit normal $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{x}}$. Repeating this procedure on the other terms in equation (2.69) gives the area integrated flux through the full boundary. To verify the theorem for a general volume V, we take the approach used to prove Stokes' theorem. First, divide the volume into many rectangular sub-volumes. Then apply the above result to each sub-volume and sum up the result. The area integrated fluxes through internal rectangular faces cancel exactly. Therefore, the sum of all the area integrated fluxes equals to just the flux integrated over the external boundary, thus yielding the divergence theorem.

2.7.2 Divergence theorem for scalar fields

We consider two corollaries of the divergence theorem, the first of which arises from the special case of a vector field $\boldsymbol{F} = \phi \, \boldsymbol{c}$ with $\boldsymbol{c}$ an arbitrary *constant* vector. Substitution into the divergence theorem (2.68) yields

$$\oint_{\partial \mathcal{R}} \phi \, \boldsymbol{c} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla \cdot (\phi \, \boldsymbol{c}) \, \mathrm{d}V. \tag{2.71}$$

Pulling the constant vector out of the integrals and rearrangement leads to

$$\boldsymbol{c} \cdot \left[\oint_{\partial \mathcal{R}} \phi \, \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} - \int_{\mathcal{R}} \nabla \phi \, \mathrm{d}V \right] = 0. \tag{2.72}$$

Since $\boldsymbol{c}$ is an arbitrary vector, this equality is generally true if and only if

$$\oint_{\partial \mathcal{R}} \phi \, \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla \phi \, \mathrm{d}V. \tag{2.73}$$

In words, this result says that the integral of a scalar field over the boundary of a closed surface, when weighted by the outward unit normal to the surface, equals to the volume integral of the gradient of the scalar field integrated over the region bounded by the closed surface. We make use of this result in Section 25.2.3 when studying how stresses contribute to the motion of a fluid element, with particular application to the case of pressure.

2.7.3 Surface integral of the outward unit normal

A corollary of equation (2.73) can be found by setting the scalar field, ϕ, to a constant so that $\nabla\phi = 0$. We thus find that the area integral of the outward unit normal vector vanishes when integrated over the surface of a closed volume

$$\oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0. \tag{2.74}$$

An example of this result can be seen by integrating over a closed rectangular volume, whereby the area integrals cancel component-wise. Another example is the sphere, where $\hat{\boldsymbol{n}} = \hat{\boldsymbol{r}}$ is the radial outward unit vector, so that integration of the radial unit vector over the spherical surface identically vanishes. For some purposes we can take equation (2.74) as the definition of a simply closed volume.

2.7.4 Integral of the curl of a vector

Another identity follows from Gauss's theorem by setting

$$\boldsymbol{F} = \boldsymbol{c} \times \boldsymbol{v} \tag{2.75}$$

where $\boldsymbol{c}$ is a constant vector. As a result,

$$\nabla \cdot \boldsymbol{F} = -\boldsymbol{c} \cdot (\nabla \times \boldsymbol{v}), \tag{2.76}$$

which follows from the identity (2.34g), again with $\boldsymbol{c}$ a constant vector. We are thus led to the following identities

$$\int_{\mathcal{R}} \nabla \cdot \boldsymbol{F}\,\mathrm{d}V = -\boldsymbol{c} \cdot \int_{\mathcal{R}} \nabla \times \boldsymbol{v}\,\mathrm{d}V \quad \text{equation (2.76)} \tag{2.77a}$$

$$= \oint_{\partial\mathcal{R}} (\boldsymbol{c} \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \quad \text{divergence theorem (2.68)} \tag{2.77b}$$

$$= \boldsymbol{c} \cdot \oint_{\partial\mathcal{R}} (\boldsymbol{v} \times \hat{\boldsymbol{n}})\,\mathrm{d}\mathcal{S} \quad \text{since } \boldsymbol{c} \text{ is a constant.} \tag{2.77c}$$

Since these identities hold for arbitrary $\boldsymbol{c}$, we are led to

$$\int_{\mathcal{R}} \nabla \times \boldsymbol{v}\,\mathrm{d}V = \oint_{\partial\mathcal{R}} (\hat{\boldsymbol{n}} \times \boldsymbol{v})\,\mathrm{d}\mathcal{S}. \tag{2.78}$$

2.7.5 First and second form of Green's identities

The further corollary to the divergence theorem arises from considering another special vector field

$$\boldsymbol{F} = \psi\,\nabla\phi, \tag{2.79}$$

with ψ and ϕ scalar fields. Substitution into the divergence theorem (2.68) leads to

$$\oint_{\partial\mathcal{R}} \psi\,\frac{\partial\phi}{\partial n}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}} [\nabla\psi \cdot \nabla\phi + \psi\,\nabla^2\phi]\,\mathrm{d}V \qquad \text{Green's first integral identity.} \tag{2.80}$$

FIGURE 2.9: The integral of the unit normal component of the curl of a function vanishes when integrated over an oriented closed surface, $\partial\mathcal{R}$, which forms the boundary to a closed volume, $\mathcal{R}$. This result follows from both Gauss's divergence theorem as well as Stokes' curl theorem. For Gauss's theorem we find $\oint_{\partial\mathcal{R}}(\nabla\times\boldsymbol{\Psi})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}}\nabla\cdot(\nabla\times\boldsymbol{\Psi})\,\mathrm{d}V = 0$, which follows since the divergence of the curl vanishes. For Stokes' theorem we split the closed volume into two so that its boundary surface has also been split into two, $\partial\mathcal{R} = \mathcal{S}_1 + \mathcal{S}_2$. Separately applying Stokes' theorem to $\mathcal{S}_1$ and $\mathcal{S}_2$ leads to the calculation of the circulation around the common boundary along the equatorial plane. Since orientation of the outward unit normal along the equatorial plane is opposite for the two regions, the two circulations exactly cancel since they are computed in opposite directions.

We can make this result more symmetric by swapping ψ and ϕ and then subtracting, thus yielding

$$\oint_{\partial\mathcal{R}}\left[\psi\,\frac{\partial\phi}{\partial n} - \phi\,\frac{\partial\psi}{\partial n}\right]\mathrm{d}\mathcal{S} = \int_{\mathcal{R}}[\psi\,\nabla^2\phi - \phi\,\nabla^2\psi]\,\mathrm{d}V \qquad \text{Green's second integral identity.} \tag{2.81}$$

Finally, setting $\phi = 1$ renders

$$\oint_{\partial\mathcal{R}}\frac{\partial\psi}{\partial n}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}}\nabla^2\psi\,\mathrm{d}V \Longleftrightarrow \oint_{\partial\mathcal{R}}\nabla\psi\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}}\nabla\cdot\nabla\psi\,\mathrm{d}V. \tag{2.82}$$

We make use of these identities in Chapter 5 when studying the Green's function method for solving linear partial differential equations.

2.7.6 Integral of a curl over a closed surface

Application of Gauss's divergence theorem leads us to conclude that the following integral vanishes

$$\oint_{\partial\mathcal{R}}(\nabla\times\boldsymbol{\Psi})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}}\nabla\cdot(\nabla\times\boldsymbol{\Psi})\,\mathrm{d}V = 0, \tag{2.83}$$

where the final equality follows since the divergence of a curl vanishes. Hence, the integral of the unit normal projection of the curl of a vector field, as computed over an oriented closed surface, vanishes. We can understand this result geometrically by splitting the closed volume into two regions and then applying Stokes' theorem separately to the two regions (see Figure 2.9)

$$\oint_{\partial\mathcal{R}}(\nabla\times\boldsymbol{\Psi})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{S}_1}(\nabla\times\boldsymbol{\Psi})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}_1 + \int_{\mathcal{S}_2}(\nabla\times\boldsymbol{\Psi})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}_2 \tag{2.84a}$$

$$= \oint_{\partial\mathcal{S}_1}\boldsymbol{\Psi}\cdot\mathrm{d}\boldsymbol{x} - \oint_{\partial\mathcal{S}_2}\boldsymbol{\Psi}\cdot\mathrm{d}\boldsymbol{x} \tag{2.84b}$$

$$= 0. \tag{2.84c}$$

The minus sign appearing in front of $\oint_{\partial\mathcal{S}_2}$ occurs since the orientation of the circulation integral is opposite that for $\oint_{\partial\mathcal{S}_1}$. We are thus left with a cancellation of the circulations. When applied

to the vorticity of fluid flow (Chapter 38), we see that

$$\oint_{\partial\mathcal{R}} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla\cdot\boldsymbol{\omega}\,\mathrm{d}V = 0, \tag{2.85}$$

where $\boldsymbol{\omega} = \nabla\times\boldsymbol{v}$ is the vorticity and $\boldsymbol{v}$ is the fluid velocity.

2.7.7 The domain integral of a non-divergent field

Consider a vector field that has zero divergence everywhere within a domain, $\mathcal{R}$. Consequently, $\int_{\mathcal{R}} \nabla\cdot\boldsymbol{F}\,\mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{F}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0$. Now what can we say about $\int_{\mathcal{R}} \boldsymbol{F}\,\mathrm{d}V$? One might be tempted to say that it vanishes. But that is generally an incorrect statement as we now show.[10]

Since $\nabla\cdot\boldsymbol{F} = 0$ we know that

$$0 = \int_{\mathcal{R}} x_a\,\nabla\cdot\boldsymbol{F}\,\mathrm{d}V = \int_{\mathcal{R}} [\nabla\cdot(x_a\,\boldsymbol{F}) - F_a]\,\mathrm{d}V, \tag{2.86}$$

where we used $\partial_b x_a = \delta_{ab}$. Use of the divergence theorem leads to

$$\int_{\mathcal{R}} F_a\,\mathrm{d}V = \int_{\mathcal{R}} \nabla\cdot(x_a\,\boldsymbol{F})\,\mathrm{d}V = \oint_{\partial\mathcal{R}} x_a\,(\hat{\boldsymbol{n}}\cdot\boldsymbol{F})\,\mathrm{d}\mathcal{S}. \tag{2.87}$$

The right hand side does not generally vanish since $\hat{\boldsymbol{n}}\cdot\boldsymbol{F}$ does not generally vanish at each point along $\partial\mathcal{R}$. Hence, we find that $\int_{\mathcal{R}} \boldsymbol{F}\,\mathrm{d}V = 0$ only for those domains where $\hat{\boldsymbol{n}}\cdot\boldsymbol{F} = 0$ at each point along $\partial\mathcal{R}$.

2.8 Exact and inexact differentials

Thus far in this chapter all differentials have been exact. However, the thermodynamics discussed in Part IV makes use of both exact and inexact differentials. We here introduce the mathematics of such differentials. Our focus concerns differentials taken between space points, though we note that in some applications it may be appropriate to consider space-time displacements.

2.8.1 Exact differentials

As in Section 2.1, consider an arbitrary function of space, $\Phi(\boldsymbol{x})$. A differential increment for that function, computed between two close points $\boldsymbol{x}$ and $\boldsymbol{x}+\mathrm{d}\boldsymbol{x}$, is given by

$$\mathrm{d}\Phi(\boldsymbol{x}) = \Phi(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}) - \Phi(\boldsymbol{x}) \tag{2.88a}$$

$$= \mathrm{d}\boldsymbol{x}\cdot\nabla\Phi, \tag{2.88b}$$

where we dropped higher order terms due to the infinitesimal nature of the increments. It follows that we can determine the finite increment between two points through integration

$$\Phi(\boldsymbol{x}_B) - \Phi(\boldsymbol{x}_A) = \int_{\boldsymbol{x}_A}^{\boldsymbol{x}_B} \mathrm{d}\Phi(\boldsymbol{x}) = \int_{\boldsymbol{x}_A}^{\boldsymbol{x}_B} \mathrm{d}\boldsymbol{x}\cdot\nabla\Phi. \tag{2.89}$$

These results are familiar from elementary calculus, with the increment $\mathrm{d}\Phi$ given by equation (2.88b) termed an *exact* differential. Importantly, the finite increment, $\Phi(\boldsymbol{x}_B) - \Phi(\boldsymbol{x}_A)$, depends

[10] As a technical note, we observe that the integral of a vector field is generally only well defined in Euclidean space. A general manifold requires us to add extra formalism for the purpose of comparing vectors at two different points.

only on the endpoint values of Φ. It does not depend on the path taken to go from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$. Correspondingly, the integral of an exact differential vanishes when computed around a closed loop

$$\oint \mathrm{d}\Phi = 0. \tag{2.90}$$

2.8.2 Inexact differentials

Consider now a general differential expression written as

$$\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} = A\,\mathrm{d}x + B\,\mathrm{d}y + C\,\mathrm{d}z, \tag{2.91}$$

where $\boldsymbol{A} = A\,\hat{\boldsymbol{x}} + B\,\hat{\boldsymbol{y}} + C\,\hat{\boldsymbol{z}}$ is an arbitrary vector function. If $\nabla \times \boldsymbol{A} = 0$, then $\boldsymbol{A}$ can be written as the gradient of a scalar

$$\nabla \times \boldsymbol{A} = 0 \Longrightarrow \boldsymbol{A} = \nabla\Psi, \tag{2.92}$$

in which case we have an exact differential expression

$$\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} = \nabla\Psi \cdot \mathrm{d}\boldsymbol{x} = \mathrm{d}\Psi. \tag{2.93}$$

That is, the differential $\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x}$ is exact if

$$\nabla \times \boldsymbol{A} = 0 \Longrightarrow \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} \ \text{ exact differential.} \tag{2.94}$$

In the more general case where $\nabla \times \boldsymbol{A} \neq 0$, then $\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x}$ is termed an *inexact differential*. We make use of the following notation for inexact differentials

$$đ\Psi = \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x}. \tag{2.95}$$

Notably, the path integral of an inexact differential depends on the path taken between the endpoints. Correspondingly, the integral of an inexact differential around a closed loop does not generally vanish

$$\oint đ\Psi \neq 0. \tag{2.96}$$

2.8.3 Integrating factors

Consider again the inexact differential $đ\Psi = \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x}$, and assume there exists a function τ so that the product $\tau^{-1}\,đ\Psi$ is an exact differential. For τ to exist it must be such that

$$\nabla \times (\boldsymbol{A}\,\tau^{-1}) = 0. \tag{2.97}$$

Consequently, we can write

$$\boldsymbol{A} = \tau\,\nabla\Phi, \tag{2.98}$$

so that

$$đ\Psi = \boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} = \tau\,\nabla\Phi \cdot \mathrm{d}\boldsymbol{x} = \tau\,\mathrm{d}\Phi. \tag{2.99}$$

The function τ is known as an *integrating factor*. As seen in Section 23.2.3, pressure is the integrating factor for mechanical work, temperature is the integrating factor for heating, and the chemical potential is the integrating factor for chemical work.

2.8.4 An example using the velocity field

Consider the scalar product, $\boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x}$, where $\boldsymbol{v}$ is the velocity field for a fluid and $\mathrm{d}\boldsymbol{x}$ is a differential increment in space directed along a path. Furthermore, introduce the curl of the velocity, which defines the vorticity (Section 38.2) $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$. For cases where the vorticity vanishes, $\boldsymbol{\omega} = 0$, then $\mathrm{d}\Psi = \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x}$ is an exact differential. Consequently, Stokes' theorem means that the circulation vanishes for an irrotational velocity field computed around an arbitrary closed loop (Section 38.4)

$$\mathcal{C} \equiv \oint_{\partial S} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \int_S \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}S = 0. \tag{2.100}$$

Another way to see this result is to note that a vanishing curl means that the velocity field can be expressed as the gradient of a scalar, $\boldsymbol{v} = \nabla\psi$, so that $\mathrm{d}\Psi = \nabla\psi \cdot \mathrm{d}\boldsymbol{x}$, which is manifestly exact.

2.8.5 Heuristic physics of exact and inexact differential operations

Consider a hiker climbing a mountain. The mechanical work, which is force applied over a distance, is a function of the path taken. Some paths are smooth and well marked, whereas others are rough and poorly marked. Likewise, the frictional heating (of the hiker's feet, for example) depend on details of the path (and the shoes!). So although the start and finish points are fixed, the work exerted and heat generated in going between these points is a function of the path.

In contrast, the change in gravitational potential energy between the start and finish points is a function only of the elevation difference between the start and finish points. It does not depend on the path between the points. So the gravitational potential energy increment between the two points is an exact differential, with the potential energy for each point a function of the elevation at the point.

The First Law of thermodynamics, studied in Part IV, states that the sum of path-dependent processes (work and heat) used in going from one thermodynamic state to another equals to the difference in the internal energy between the two states. That is, the sum of the inexact differentials for heat and work equal to the exact differential for internal energy.

2.9 Exercises

Throughout these exercises we consider a point whose Cartesian position vector, relative to an arbitrary origin, is written

$$\boldsymbol{x} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + z\,\hat{\boldsymbol{z}} \tag{2.101}$$

and whose squared distance from the origin is

$$r^2 = \boldsymbol{x} \cdot \boldsymbol{x} = x^2 + y^2 + z^2. \tag{2.102}$$

EXERCISE 2.1: PRACTICE WITH THE GRADIENT OPERATOR
Prove the following identities:

(a) $\nabla(|\boldsymbol{x}|) = \boldsymbol{x}\,|\boldsymbol{x}|^{-1} \equiv \hat{\boldsymbol{r}}$

(b) $\nabla \ln |\boldsymbol{x}| = \boldsymbol{x}\,|\boldsymbol{x}|^{-2} = \hat{\boldsymbol{r}}\,|\boldsymbol{x}|^{-1}$

(c) $\nabla|\boldsymbol{x}|^{-1} = -\boldsymbol{x}\,|\boldsymbol{x}|^{-3} = -\hat{\boldsymbol{r}}\,|\boldsymbol{x}|^{-2}$.

EXERCISE 2.2: PRACTICE WITH THE LAPLACIAN OPERATOR
Show that the Laplacian of the function

$$\psi = \frac{z\,x^2}{r^2} \tag{2.103}$$

is given by

$$\nabla^2\psi = \frac{2\,z\,(r^2 - 5\,x^2)}{r^4}. \tag{2.104}$$

Perform the proof using both Cartesian coordinates as well as spherical coordinates (see Figure 10.1), making use of the following expressions for Laplacian operator acting on a scalar field

$$\nabla^2\psi(x,y,z) = \frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} \tag{2.105a}$$

$$\nabla^2\psi(\lambda,\phi,r) = \frac{1}{r^2\,\cos\phi}\left[\frac{1}{\cos\phi}\frac{\partial^2\psi}{\partial\lambda^2} + \frac{\partial}{\partial\phi}\left(\cos\phi\frac{\partial\psi}{\partial\phi}\right) + \cos\phi\,\frac{\partial}{\partial r}\left(r^2\,\frac{\partial\phi}{\partial r}\right)\right]. \tag{2.105b}$$

EXERCISE 2.3: MORE PRACTICE WITH OPERATORS
Prove the following identities with $r \neq 0$:

(a) $\nabla^2 r^{-1} = 0$

(b) $\nabla\cdot(\boldsymbol{x}/r^3) = 0$

(c) $\nabla\cdot(\boldsymbol{A}\times\boldsymbol{x}) = \boldsymbol{x}\cdot(\nabla\times\boldsymbol{A})$ for an arbitrary vector field $A(\boldsymbol{x})$.

(d) $\nabla\times[\boldsymbol{x}\,f(r)] = 0$ for an arbitrary function $f(r) = f(|\boldsymbol{x}|)$.

EXERCISE 2.4: RIGID-BODY ROTATION
Define a velocity field according to

$$\boldsymbol{v} = \boldsymbol{\Omega}\times\boldsymbol{x} \tag{2.106}$$

with $\boldsymbol{\Omega}$ a spatially constant angular rotation velocity (e.g., rotation of the earth). This velocity field describes rigid-body rotation as discussed in Section 38.6. Show that $2\,\boldsymbol{\Omega} = \nabla\times\boldsymbol{v}$. See also Exercise 38.2.

EXERCISE 2.5: DIVERGENCE-FREE AND IRROTATIONAL VECTOR
Let Φ be a harmonic function so that $\nabla^2\Phi = 0$. Show that $\boldsymbol{v} = -\nabla\Phi$ satisfies

(a) $\nabla\cdot\boldsymbol{v} = 0$

(b) $\nabla\times\boldsymbol{v} = 0$.

In this way we prove that all harmonic scalar fields correspond to a divergence-free and curl-free vector field.

EXERCISE 2.6: CONSERVATIVE VECTOR FIELD AND SCALAR POTENTIAL
Show that the curl, $\nabla\times\boldsymbol{F}$, of the following vector field vanishes

$$\boldsymbol{F} = 2\,x\,z\,\hat{\boldsymbol{x}} + 2\,y\,z^2\,\hat{\boldsymbol{y}} + (x^2 + 2\,y^2\,z - 1)\,\hat{\boldsymbol{z}}. \tag{2.107}$$

Hence, deduce that $\boldsymbol{F}$ is a *conservative vector field*, meaning that it can be written as the gradient of a scalar potential ψ according to $\boldsymbol{F} = -\nabla\psi$, where (to within an arbitrary constant)

$$\psi = -[x^2\,z + (y\,z)^2 - z]. \tag{2.108}$$

EXERCISE 2.7: PRODUCT RULE IDENTITIES
Prove the following identities for vectors in $\mathbb{R}^3$:

(a) $\boldsymbol{F} = \partial_n \left(F_n \, \boldsymbol{x}\right) - \boldsymbol{x} \, \nabla \cdot \boldsymbol{F}$

(b) $2 \, F_m = [\boldsymbol{x} \times (\nabla \times \boldsymbol{F})]_m - \partial_m(\boldsymbol{x} \cdot \boldsymbol{F}) + \nabla \cdot (\boldsymbol{x} \, F_m)$.

Make use of Cartesian tensors and show all relevant steps, including use of the Levi-Civita tensor from Section 1.4.1 for the cross-product.

As discussed in Section 12.4.1 of *Bühler* (2014a), these product rule identities have use for the study of impulses imparted by a body force per volume, $\boldsymbol{F}$, to a fluid on an unbounded domain where the force has compact support (i.e., the force vanishes outside a finite domain). In that case the above product rule identities allow us to make use of the corresponding integral identities

$$\int \boldsymbol{F} \, \mathrm{d}V = -\int \boldsymbol{x} \, \nabla \cdot \boldsymbol{F} \, \mathrm{d}V = \frac{1}{2} \int \boldsymbol{x} \times (\nabla \times \boldsymbol{F}) \, \mathrm{d}V. \tag{2.109}$$

EXERCISE 2.8: BELTRAMI FLOW
Beltrami flow is defined by velocity and vorticity fields satisfying

$$\nabla \cdot \boldsymbol{v} = 0 \tag{2.110a}$$

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} = \lambda \boldsymbol{v} \tag{2.110b}$$

where λ is a constant. Show that the following velocity field is a Beltrami flow

$$\boldsymbol{v} = (A \, \sin z + C \, \cos y) \, \hat{\boldsymbol{x}} + (B \, \sin x + A \, \cos z) \, \hat{\boldsymbol{y}} + (C \, \sin y + B \, \cos x) \, \hat{\boldsymbol{z}}, \tag{2.111}$$

where A, B, C are constants. Hint: the solution follows directly from computing

$$u = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \qquad v = \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \qquad w = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}. \tag{2.112}$$

EXERCISE 2.9: PRACTICE WITH PATH INTEGRALS
Consider the vector field

$$\boldsymbol{F} = x \, y^2 \, \hat{\boldsymbol{x}} + 2 \, \hat{\boldsymbol{y}} + x \, \hat{\boldsymbol{z}}. \tag{2.113}$$

Let $\mathcal{L}$ be a path parameterized by

$$x = c \, t \qquad y = c/t \qquad z = d \qquad t \in [1, 2], \tag{2.114}$$

where c and d are constants. Show that the following identities hold

$$\int_{\mathcal{L}} \boldsymbol{F} \, \mathrm{d}t = c^3 \ln 2 \, \hat{\boldsymbol{x}} + 2 \, \hat{\boldsymbol{y}} + \frac{3 \, c}{2} \, \hat{\boldsymbol{z}} \tag{2.115a}$$

$$\int_{\mathcal{L}} \boldsymbol{F} \, \mathrm{d}y = -\frac{3 \, c^4}{8} \, \hat{\boldsymbol{x}} - c \, \hat{\boldsymbol{y}} - c^2 \, \ln 2 \hat{\boldsymbol{z}} \tag{2.115b}$$

$$\int_{\mathcal{L}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = c^4 \ln 2 - c, \tag{2.115c}$$

where $\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{x}} \, \mathrm{d}x + \hat{\boldsymbol{y}} \, \mathrm{d}y + \hat{\boldsymbol{z}} \, \mathrm{d}z$. Although all three integrals are computed along the same path, they are not necessarily of the same type. In particular, the first two integrals are vector fields, whereas the third integral is a scalar.

EXERCISE 2.10: STOKES' THEOREM ON A PLANE
Show that

$$\mathcal{I} = \oint_{\partial\mathcal{S}} \left[y\,(4\,x^2 + y^2)\,\mathrm{d}x + x\,(2\,x^2 + 3\,y^2)\,\mathrm{d}y \right] = \frac{\pi}{2}\,b\,a^3 \tag{2.116}$$

when integrating around the boundary of an ellipse $\mathcal{S}$ defined by

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \tag{2.117}$$

where a, b are constants. Hint: make use of Stokes' theorem on a plane, otherwise known as Green's Theorem. Also make use of the substitution $x = a\cos\phi$ and the identity

$$\int_{\pi}^{0} \sin^2(2\,\phi)\,\mathrm{d}\phi = -\frac{\pi}{2}. \tag{2.118}$$

EXERCISE 2.11: PRACTICE WITH GAUSS'S DIVERGENCE THEOREM
We here demonstrate the validity of Gauss's divergence theorem for a particular vector field

$$\boldsymbol{F} = \frac{\alpha\,\boldsymbol{x}}{(r^2 + a^2)^{3/2}}, \tag{2.119}$$

where α and a are constants and $r^2 = \boldsymbol{x}\cdot\boldsymbol{x}$ is the squared radial distance to a point. Using fluid mechanics jargon, we think of $\boldsymbol{F}$ as a matter flux with physical dimensions of M L^{-2} T^{-1} (mass length^{-2} time^{-1}). Now compute the transport of $\boldsymbol{F}$ through a spherical surface, $\mathcal{S}$, of radius $|\boldsymbol{x}| = a\sqrt{3}$

$$\Phi = \oint_{|\boldsymbol{x}|=a\sqrt{3}} \boldsymbol{F}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \frac{3\,\pi\,\alpha\,\sqrt{3}}{2}. \tag{2.120}$$

With $\boldsymbol{F}$ a matter flux then Φ has physical dimensions of M T^{-1}, so that it is the *mass transport* through the spherical surface. Next, show that this transport is equal to the integral of the divergence over the volume of the sphere

$$\Phi = \int_{|\boldsymbol{x}|=a\sqrt{3}} \nabla\cdot\boldsymbol{F}\,\mathrm{d}V. \tag{2.121}$$

We thus verify, for this particular vector field, the divergence theorem

$$\int_{\mathcal{R}} \nabla\cdot\boldsymbol{F}\,\mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{F}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{2.122}$$

where $\hat{\boldsymbol{n}}$ is the outward unit normal on the bounding surface $\mathcal{S}$.

EXERCISE 2.12: MORE PRACTICE WITH GAUSS'S DIVERGENCE THEOREM
Prove the following identities, which are readily shown using Gauss's divergence theorem.

(a) $\oint_{\partial\mathcal{R}} \boldsymbol{x}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 3\int_{\mathcal{R}} \mathrm{d}V = 3\,V$, where $\mathcal{R}$ is a closed region bounded by $\partial\mathcal{R}$ and with volume $\int_{\mathcal{R}} \mathrm{d}V = V$.

(b) $\oint_{\partial\mathcal{R}} (\hat{\boldsymbol{n}}\times\boldsymbol{F})\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla\times\boldsymbol{F}\,\mathrm{d}V$, for an arbitrary vector field $\boldsymbol{F}$ and with $\hat{\boldsymbol{n}}$ the outward unit normal on the bounding surface $\partial\mathcal{R}$. Hint: in a manner similar to the result shown in Section 2.7.2, make use of Gauss's theorem with $\boldsymbol{A} = \boldsymbol{F}\times\boldsymbol{C}$ where $\boldsymbol{C}$ is a constant vector.

(c) Let $\partial\mathcal{R}$ be a closed surface bounding a volume $\mathcal{R}$, and let $\boldsymbol{x}$ denote the position vector of a

point measured from an arbitrary origin. Prove the following

$$\oint_{\partial\mathcal{R}} \frac{\hat{\boldsymbol{n}}\cdot\boldsymbol{x}}{r^3}\,\mathrm{d}\mathcal{S} = \begin{cases} 0 & \text{if the origin lies outside of } \partial\mathcal{R} \\ 4\pi & \text{if the origin lies inside of } \partial\mathcal{R}. \end{cases} \tag{2.123}$$

EXERCISE 2.13: HELMHOLTZ DECOMPOSITION FOR CORIOLIS ACCELERATION
Consider a vector field

$$\boldsymbol{F} = 2\,\boldsymbol{\Omega}\times\boldsymbol{v}, \tag{2.124}$$

where $\boldsymbol{\Omega}$ is a spatial constant and $\nabla\cdot\boldsymbol{v}=0$. As seen in Part V of this book, the vector $\boldsymbol{F}$ is minus the Coriolis acceleration in the presence of an incompressible velocity. Since $\boldsymbol{v}$ is non-divergent, there exists a vector potential so that

$$\boldsymbol{v} = \nabla\times\boldsymbol{B}. \tag{2.125}$$

Show that we can perform a Helmholtz decomposition

$$\boldsymbol{F} = 2\,\boldsymbol{\Omega}\times\boldsymbol{v} = -\nabla\Psi + \nabla\times\boldsymbol{A}, \tag{2.126}$$

where

$$-\nabla^2\Psi = -2\,\boldsymbol{\Omega}\cdot(\nabla\times\boldsymbol{v}) \tag{2.127a}$$

$$\nabla\times\boldsymbol{A} = (\boldsymbol{\Omega}\cdot\nabla)\,\boldsymbol{B} + \nabla\lambda, \tag{2.127b}$$

with λ an arbitrary gauge function.

Chapter 3

Partial differential equations

Fluid mechanics is a classical field theory whose mathematical description involves partial differential equations (PDEs). Although most of these partial differential equations are nonlinear, some are linear. Regardless, an understanding of linear partial differential equations provides useful insights into the physics and maths of geophysical fluids. For this purpose, we here explore the rudiments of linear partial differential equations.

CHAPTER GUIDE

One can penetrate much of this book without reading this chapter. What this chapter adds, however, is an appreciation for the mathematical structure and physical behavior of the equations describing geophysical fluid mechanics. Indeed, it is remarkable how useful it is, both mathematically and physically, to develop a basic understanding of linear partial differential equations. Furthermore, those aiming to develop solution methods, either analytical or numerical, should have a working knowledge of this chapter. Additionally, the Green's function method detailed in Chapter 5 assumes a firm understanding of the material in this chapter.

There are many resources devoted to the theory and application of partial differential equations throughout physics, engineering, and applied mathematics. Chapter 8 of *Hildebrand* (1976) offers a pedagogical starting point whereas *Stakgold* (2000a,b) thoroughly develops the theory and methods available for boundary value problems encountered in physics. *Duchateau and Zachmann* (1986) concisely summarize partial differential equations and provide nearly 300 worked exercises, with much of the presentation in this chapter following their treatment.

3.1 The advection equation

Consider a tracer concentration, C, which for present purposes is a scalar field that is a function of space and time. As derived in Section 64.5, the tracer concentration in the absence of diffusion satisfies the advection equation

$$\frac{\partial C}{\partial t} + \boldsymbol{v} \cdot \nabla C = 0. \tag{3.1}$$

The space and time derivatives acting on C are both first order, indicating that the advection equation is a first order partial differential equation. It is a nonlinear partial differential equation for those *active* tracers such as temperature, where active tracers affect the velocity through changes to density and hence to pressure. In contrast, the advection equation is linear for *passive* tracers (e.g., colored dye, dust), which are tracers whose effects on velocity are negligible (Section 21.1.5). We limit the present discussion to passive tracers so that the advection equation is linear.

3.1.1 Constant advection velocity

To expose the gist of the advection equation, consider one space dimension and let the advection velocity be constant in space and time,

$$\frac{\partial C}{\partial t} + U \frac{\partial C}{\partial x} = 0 \tag{3.2}$$

where U is a constant velocity in the $\hat{\boldsymbol{x}}$ direction. An inspired guess reveals that

$$C(x,t) = \Gamma(\alpha) = \Gamma(x - Ut) \tag{3.3}$$

is a general solution to equation (3.2). Here, Γ is an arbitrary differentiable function that is determined by the initial conditions of the tracer field. Furthermore, there is only one argument to Γ, here written as $\alpha = x - Ut$. As discussed in Section 3.2, $\alpha = x - Ut$ is referred to as a *characteristic curve* for the constant speed one-dimensional advection equation.

Verification of the solution (3.3) is readily found by noting

$$\frac{\partial C}{\partial x} = \frac{\mathrm{d}\Gamma(\alpha)}{\mathrm{d}\alpha}\frac{\partial \alpha}{\partial x} = \Gamma'(\alpha)\frac{\partial (x - Ut)}{\partial x} = \Gamma' \tag{3.4a}$$

$$\frac{\partial C}{\partial t} = \frac{\mathrm{d}\Gamma(\alpha)}{\mathrm{d}\alpha}\frac{\partial \alpha}{\partial t} = \Gamma'(\alpha)\frac{\partial (x - Ut)}{\partial t} = -\Gamma' U. \tag{3.4b}$$

We have thus verified that

$$\frac{\partial C}{\partial t} + \boldsymbol{v}\cdot\nabla C = -\Gamma' U + U\Gamma' = 0. \tag{3.5}$$

The functional dependence,

$$C(x,t) = \Gamma(\alpha) = \Gamma(x - Ut), \tag{3.6}$$

reveals that as time progresses with $U > 0$, an observer that moves in the positive $\hat{\boldsymbol{x}}$ direction with a speed U maintains a constant value for the tracer concentration. This behavior means that the tracer concentration is transported by advection with a speed U without changing its structure. We illustrate this behavior in Figure 3.1.

FIGURE 3.1: Illustrating the advection of a scalar field resulting from a constant advection velocity $\boldsymbol{v} = U\hat{\boldsymbol{x}}$ with $U > 0$. The initially square pulse of tracer concentration is translated, unchanged, by the constant advection velocity.

3.1.2 Arbitrary functions resulting from PDEs

As revealed from the above example, the solution to a partial differential equation is typically given in terms of an arbitrary function with a specified dependence on the independent variables. The function itself is unspecified without additional information from initial and/or boundary conditions. For example, consider an initial tracer concentration in the form of a sine-wave

$$C(x, t = 0) = C_0 \sin(k\,x), \tag{3.7}$$

with k a wavenumber (dimensions of inverse length), and allow the domain to be infinite in extent (no boundaries). When advected by a constant advection velocity, the solution to the advection equation is a tracer concentration in the form of a sine-wave moving in the positive $\hat{\boldsymbol{x}}$ direction with speed U

$$C(x,t) = C_0 \sin[k\,(x - Ut)]. \tag{3.8}$$

The arbitrary functional degree of freedom is a generalization of the case with ordinary differential equations, whose solutions are specified up to unknown constants with values set by initial and/or boundary conditions.

3.1.3 Further study

Advection plays a fundamental role in the transport of matter, energy, and momentum within fluids. As seen in our discussion of fluid kinematics in Chapter 18, advection appears in the fluid mechanical equations when viewing the fluid from the fixed laboratory or *Eulerian* reference frame. We thus encounter advection throughout this book, with further development of the mathematics and physics provided in Sections 64.5 and 64.6.

3.2 Characteristic curves for first order PDEs

The advection equation is the canonical first order partial differential equation commonly found in fluid mechanics. A more general form for a first order partial differential equation in one space dimension is given by[1]

$$P(x,t,\psi)\frac{\partial\psi}{\partial x} + Q(x,t,\psi)\frac{\partial\psi}{\partial t} = R(x,t,\psi), \tag{3.9}$$

where P, Q, and R are arbitrary smooth functions. This partial differential equation is linear if P, Q, and R are independent of ψ, and quasi-linear if P and Q are independent of ψ and R is at most a linear function of ψ. In this section we develop a formalism that determines the functional dependence of solutions to these partial differential equations. This *method of characteristics* is quite useful for exposing general properties of the solutions, even for those cases where the solution is not analytically available.

3.2.1 General formulation

In the first order partial differential equation given by equation (3.9), assume there is a functional relation

$$\Upsilon(x,t,\psi) = \text{constant} \tag{3.10}$$

that determines ψ consistent with the PDE (3.9). We refer to Υ as an *integral surface* that specifies a solution to the partial differential equation. For Υ to specify an integral surface it must satisfy

$$\mathrm{d}\Upsilon = 0, \tag{3.11}$$

since the differential of a constant vanishes. This condition then leads to the differential constraints

$$\frac{\mathrm{d}\Upsilon}{\mathrm{d}t} = 0 = \frac{\partial\Upsilon}{\partial\psi}\frac{\partial\psi}{\partial t} + \frac{\partial\Upsilon}{\partial t} \tag{3.12a}$$

$$\frac{\mathrm{d}\Upsilon}{\mathrm{d}x} = 0 = \frac{\partial\Upsilon}{\partial\psi}\frac{\partial\psi}{\partial x} + \frac{\partial\Upsilon}{\partial x}. \tag{3.12b}$$

Assuming $\partial\Upsilon/\partial\psi \neq 0$ allows us to write

$$\frac{\partial\psi}{\partial t} = -\frac{\partial\Upsilon/\partial t}{\partial\Upsilon/\partial\psi} \quad \text{and} \quad \frac{\partial\psi}{\partial x} = -\frac{\partial\Upsilon/\partial x}{\partial\Upsilon/\partial\psi} \tag{3.13}$$

so that the first order partial differential equation (3.9) takes on the equivalent form

$$P\,\frac{\partial\Upsilon}{\partial x} + Q\,\frac{\partial\Upsilon}{\partial t} + R\,\frac{\partial\Upsilon}{\partial\psi} = 0. \tag{3.14}$$

[1] Much from this section is taken from Section 8.2 of *Hildebrand* (1976).

Through this construct we have brought the functions P, Q, R into a symmetric form. Consistency of equation (3.14) with

$$\mathrm{d}\Upsilon = \frac{\partial \Upsilon}{\partial x}\,\mathrm{d}x + \frac{\partial \Upsilon}{\partial t}\,\mathrm{d}t + \frac{\partial \Upsilon}{\partial \psi}\,\mathrm{d}\psi = 0, \tag{3.15}$$

requires

$$P = \rho\,\mathrm{d}x \quad \text{and} \quad Q = \rho\,\mathrm{d}t \quad \text{and} \quad R = \rho\,\mathrm{d}\psi, \tag{3.16}$$

for some non-dimensional function, $\rho(x, t, \psi)$. Eliminating the unknown function ρ renders the ordinary differential equations

$$\frac{\mathrm{d}x}{P} = \frac{\mathrm{d}t}{Q} = \frac{\mathrm{d}\psi}{R}. \tag{3.17}$$

Paths in (x, t, ψ) space that satisfy these differential equations are known as *characteristic curves*. Note that if any one of the functions P, Q, or R vanish, then we merely remove that term from these relations.

3.2.2 Examples

We now determine characteristic curves for some specific examples. First consider the linear homogeneous advection equation with constant advection speed

$$U\,\frac{\partial \psi}{\partial x} + \frac{\partial \psi}{\partial t} = 0, \tag{3.18}$$

in which we identify $P = U$, $Q = 1$, and $R = 0$. The single ordinarly differential equation defining the characteristic curve is given by

$$\frac{\mathrm{d}x}{U} = \frac{\mathrm{d}t}{1}, \tag{3.19}$$

so that characteristics are given by the family of space-time lines

$$x - U\,t = \alpha \tag{3.20}$$

with α an arbitrary constant. These lines determine the paths in space-time along which advective signals are transmitted.

Now add a constant source to the linear advection equation

$$U\,\frac{\partial \psi}{\partial x} + \frac{\partial \psi}{\partial t} = R. \tag{3.21}$$

The two ordinary differential equations defining the characteristic curve are

$$\frac{\mathrm{d}x}{U} = \frac{\mathrm{d}t}{1} = \frac{\mathrm{d}\psi}{R}. \tag{3.22}$$

In addition to the relation $x - U\,t = \alpha_1$ determined from the homogeneous case, we also have $\psi - R\,t = \alpha_2$ for α_2 an arbitrary constant. Hence, the characteristic equations render the general solution of the form

$$\Gamma[x - U\,t, \psi - R\,t] = \text{constant}, \tag{3.23}$$

for Γ an arbitrary function. One example solution is given by

$$\psi = f(x - U\,t) + R\,to \tag{3.24}$$

for an arbitrary smooth function, f. This solution has the form of a traveling signal, $f(x - U\,t)$,

plus a growing source, $R\,t$.

For the final example, consider the linear advection equation with non-constant coefficients and non-constant source

$$x\,\frac{\partial\psi}{\partial x} + t\,\frac{\partial\psi}{\partial t} = \psi, \tag{3.25}$$

d in which the ordinary differential equations determining the characteristics are given by

$$\frac{\mathrm{d}x}{x} = \frac{\mathrm{d}t}{t} = \frac{\mathrm{d}\psi}{\psi}. \tag{3.26}$$

We are thus led to the relations

$$\frac{t}{x} = \alpha_1 \qquad \frac{\psi}{x} = \alpha_2. \tag{3.27}$$

Hence, the general solution of the partial differential equation (3.25) is given by e

$$\Gamma(t/x, \psi/x) = 0 \Rightarrow \psi = x\,F(t/x) \tag{3.28}$$

for an arbitrary smooth function F.

3.3 Classifying second order partial differential equations

There are many second order partial differential equations appearing in fluid mechanics, a general form of which in one space dimension is given by

$$A\,\frac{\partial^2\psi}{\partial x^2} + B\frac{\partial^2\psi}{\partial x\,\partial t} + C\frac{\partial^2\psi}{\partial t^2} = \Lambda. \tag{3.29}$$

For linear partial differential equations, A, B, C are arbitrary functions of space and time that are independent of ψ. Furthermore, Λ is a function of space and time and at most a linear function of ψ and its derivatives. The most general solution to a linear partial differential equation consists of the sum of any *particular solution* and a solution to the homogeneous problem (where $\Lambda = 0$).

The terms involving second derivatives in equation (3.29) are of principle importance for determining the character of the solutions, with importance placed on the sign of the discriminant $B^2 - 4\,A\,C$. By analogy with conic sections we classify 2nd order partial differential equations as follows

$$\text{PDE form} = \begin{cases} \text{hyperbolic} & B^2 - 4\,A\,C > 0 \\ \text{elliptic} & B^2 - 4\,A\,C < 0 \\ \text{parabolic} & B^2 - 4\,A\,C = 0. \end{cases} \tag{3.30}$$

We can further motivate this terminology by considering the case of a homogeneous constant coefficient partial differential equation and an assumed solution of the form

$$\psi(x,t) = f(m\,x + t). \tag{3.31}$$

Plugging into the 2nd order partial differential equation (3.29) with $\Lambda = 0$ leads to

$$A\,m^2 + B\,m + C = 0. \tag{3.32}$$

The two solutions m_1 and m_2 are both real for the hyperbolic case, conjugate complex for the elliptic case, and a perfect square for the parabolic case.

3.4 Elliptic partial differential equations

The elliptic case from Section 3.3 has discriminant $B^2 - 4\,A\,C < 0$, in which case there are two imaginary characteristics. The canonical example elliptic equation is *Laplace's equation*

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0, \tag{3.33}$$

where we converted from t as an independent variable to the space coordinate y. Formally, this transition is realized by setting $t = \mathrm{i}\,y$, where $\mathrm{i} = \sqrt{-1}$. Laplace's equation is satisfied by time-independent (i.e., *steady state*) solutions to the heat/diffusion equation (Section 3.5). Another common elliptic equation is *Poisson's equation*, which results from adding a source to Laplace's equation

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = \Lambda. \tag{3.34}$$

As there is no time present in the Laplace and Poisson equations, information is transmitted instantaneously so that the structure of the solution is determined by boundary conditions or boundary *data*. Strictly speaking, instantaneous information transfer is not physical since all physical signals have a finite propagation speed no greater than the speed of light. However, an infinite speed can be a useful mathematical construct. For example, acoustic signals in fluids propagate much faster than other waves and particle speeds, and they carry a very small energy.[2] For many purposes it is thus suitable to assume acoustic speeds are infinite, and in so doing we *filter* or remove acoustic modes from of the dynamical equations. In the process, the hyperbolic equation describing acoustic signals is converted into an elliptic equation. We consider acoustic signals in Chapter 49.

3.4.1 Some general properties of Laplace's equation

Solutions to Laplace's equation, $\nabla^2 \psi = 0$, are known as *harmonic functions*. Here are some example harmonic functions for two space dimensions:

$$\psi = x^3 - 3\,x\,y^2 \qquad \psi = \ln(x^2 + y^2) \qquad \psi = e^{\gamma\,x}\cos(\gamma\,y) \qquad \psi = a\,x + b\,y, \tag{3.35}$$

for arbitrary constants a, b, γ. Furthermore, with

$$\nabla^2(\psi\,\phi) = \psi\,\nabla^2\phi + 2\,\nabla\phi\cdot\nabla\psi + \phi\,\nabla^2\psi, \tag{3.36}$$

we see that the product of two harmonic functions ($\nabla^2\psi = \nabla^2\phi = 0$) is itself harmonic if and only if their gradients are orthogonal, $\nabla\psi\cdot\nabla\phi = 0$. In the remainder of this section we present, without proof, some general properties of harmonic functions and develop self-consistency for the boundary data appearing in the Laplacian boundary value problem defined by equations (3.39a)-(3.39b) stated below.

3.4.2 Mean-value property of harmonic functions

Harmonic functions possess a remarkable *mean-value* property. This property says that the value of a harmonic function, ψ, at a point $\boldsymbol{x}_o$ within an open region of $\mathcal{R}$ equals to the average of ψ

[2] A scuba diver feeling the beat of a ship underwater, or an audience member at a rock concert may question this statement. However, acoustic energy is in fact tiny relative to planetary waves and gravity waves, and utterly negligible for studies of large scale geophysical fluid motions.

taken over the surface of a sphere within $\mathcal{R}$ that is centered at $\boldsymbol{x}_o$. In equations this property states that

$$\psi(\boldsymbol{x}_o) = \frac{\oint_{\mathcal{S}_R} \psi(\boldsymbol{x})\, \mathrm{d}\mathcal{S}}{\oint_{\mathcal{S}_R} \mathrm{d}\mathcal{S}}, \tag{3.37}$$

where $\mathcal{S}_R$ is a sphere with radius R centered at $\boldsymbol{x}_o$ with "area" given by

$$\oint_{\mathcal{S}_R} \mathrm{d}\mathcal{S} = \begin{cases} 2\pi R & n = 2 \text{ space dimensions} \\ 4\pi R^2 & n = 3 \text{ space dimensions.} \end{cases} \tag{3.38}$$

We illustrate this property in Figure 3.2.

The mean-value property of harmonic functions holds anywhere within the domain where $\nabla^2\psi = 0$, so long as the sphere is fully contained within that domain. It implies that there can be no extrema of ψ within the domain, since if there was an extrema then it could not satisfy the mean-value property. Hence, all extrema of harmonic functions must exist on the domain boundary. These properties lend mathematical support for considering harmonic functions to be solutions to continuous physical systems that are in equilibrium or a steady state. As a physical example, consider a temperature field, $T(\boldsymbol{x})$, in a region with zero heat sources and zero fluid flow. As shown in Section 64.3.4, the steady state temperature satisfies $\nabla^2 T = 0$, and as such it is harmonic and hence has no extrema within the domain.

FIGURE 3.2: The value of a harmonic function at a point $\boldsymbol{x}_o$ equals to the area average of the function over a sphere centered at $\boldsymbol{x}_o$. We here illustrate this property for 3-dimensions, but it holds for arbitrary space dimensions.

3.4.3 Laplace's boundary value problem

Laplace's equation requires boundary conditions to fully specify the harmonic function. We here consider the Laplacian *boundary value problem* in the form

$$\nabla^2\psi = 0 \qquad \boldsymbol{x} \in \mathcal{R} \tag{3.39a}$$

$$\alpha\,\psi + \beta\,\hat{\boldsymbol{n}} \cdot \nabla\psi = \sigma \qquad \boldsymbol{x} \in \partial\mathcal{R}, \tag{3.39b}$$

where $\mathcal{R}$ is a smooth and simply connected volume, $\partial\mathcal{R}$ is the boundary surface enclosing $\mathcal{R}$ with outward unit normal, $\hat{\boldsymbol{n}}$, and with α, β, and σ given boundary data functions.

We can establish constraints on the boundary conditions that lead to a self-consistent Laplacian boundary value problem (3.39a)-(3.39b). We do so through the use of Gauss's divergence theorem (Section 2.7) in which integration over the full domain leads to

$$0 = \int_{\mathcal{R}} \nabla^2\psi\, \mathrm{d}V = \oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}} \cdot \nabla\psi\, \mathrm{d}\mathcal{S}. \tag{3.40}$$

In physical applications the boundary condition (3.39b) usually appears with either $\alpha = 0$ or $\beta = 0$, and these two cases are associated with distinct self-consistency constraints.

Dirichlet boundary condition

The case with $\beta = 0$ is referred to as a *Dirichlet boundary condition* whereby

$$\psi = \sigma \qquad \boldsymbol{x} \in \partial\mathcal{R}, \tag{3.41}$$

where we set $\alpha = 1$ without loss of generality. In this case all boundary data result in a self-consistent Laplacian boundary value problem so there is no constraint on σ. Thinking again about temperature, this boundary condition specifies the temperature on the domain boundary to equal $T = \sigma$, with all boundary functions σ consistent with a harmonic temperature distribution within the domain interior.

Neumann boundary condition

The case with $\alpha = 0$ results in a *Neumann boundary condition*. Without loss of generality we set $\beta = 1$ and reach the following self-consistency condition

$$\oint_{\partial\mathcal{R}} \sigma \, \mathrm{d}\mathcal{S} = 0. \tag{3.42}$$

A self-consistent boundary condition for Laplace's equation with the Neumann boundary condition must satisfy this surface integral constraint. For the temperature example, this boundary condition says that to realize a steady state harmonic temperature distribution within a region, we can at most apply a zero area averaged boundary heating. If the boundary constraint (3.42) is not satisfied, then the interior temperature field cannot be harmonic so that it will not be in a steady state.

3.4.4 Poisson's equation

The generic boundary value problem for Poisson's equation takes on the form

$$\nabla^2\psi = \Lambda \qquad \boldsymbol{x} \in \mathcal{R} \tag{3.43a}$$

$$\alpha\,\psi + \beta\,\hat{\boldsymbol{n}} \cdot \nabla\psi = \sigma \qquad \boldsymbol{x} \in \partial\mathcal{R}, \tag{3.43b}$$

where $\Lambda(\boldsymbol{x})$ is a specified source function. We here present, without proof, some general properties of solutions to Poisson's equation and develop self-consistency conditions for the boundary data appearing in equation (3.43b).

3.4.5 Extended max-min principle for Poisson's equation

A subharmonic function is one where

$$\nabla^2\psi = \Lambda \geq 0 \qquad \boldsymbol{x} \in \mathcal{R}. \tag{3.44}$$

Here, the source function makes the curvature of a subharmonic function positive. Correspondingly, every point within $\mathcal{R}$ satisfies the minimum principle

$$\psi(\boldsymbol{x}_o) \leq \frac{\oint_{\mathcal{S}_R} \psi(\boldsymbol{x}) \, \mathrm{d}\mathcal{S}}{\oint_{\mathcal{S}_R} \mathrm{d}\mathcal{S}}, \tag{3.45}$$

for spheres, $\mathcal{S}_R$, that are fully within $\mathcal{R}$. The signs switch for superharmonic functions whereby $\nabla^2\psi \leq 0$ for $\boldsymbol{x} \in \mathcal{R}$

Returning to the temperature example, consider a temperature field in a region with a positive heat source, $\Lambda > 0$. The steady state temperature in the presence of zero fluid flow satisfies Poisson's equation $\nabla^2 T = \Lambda \geq 0$ for regions with the heat source. The minimum principle (3.45) means that the temperature at any point within the heating region is less than the temperature averaged over a sphere centered on the point, so long as the sphere remains within the region of heating. It is only in the absence of a heat source or sink, where $\nabla^2 T = 0$, that we recover the mean-value property of harmonic functions given by equation (3.37).

3.4.6 Poisson's boundary value problem

We follow the method in Section 3.4.3 to develop constraints on the boundary conditions applied as part of the Poisson boundary value problem (3.43a)-(3.43b). Use of Gauss's divergence theorem leads to the constraint

$$\oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}} \cdot \nabla\psi \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \Lambda \, \mathrm{d}V. \tag{3.46}$$

We separately consider the Dirichlet and Neumann cases.

Dirichlet boundary condition

The Dirichlet condition with $\beta = 0$ leads to

$$\psi = \sigma \qquad \boldsymbol{x} \in \partial\mathcal{R}. \tag{3.47}$$

Just as for Laplace's boundary value problem, all boundary data result in a self-consistent Poisson boundary value problem so there is no constraint on σ. Thinking again about temperature, this boundary condition specifies the temperature on the domain boundary to equal $T = \sigma$, with all boundary functions σ consistent with the interior heating Λ and a temperature field satisfying $\nabla^2 T = \Lambda$ within the interior.

Self-consistent Neumann boundary condition

The *Neumann* boundary condition leads to the following self-consistency condition

$$\oint_{\partial\mathcal{R}} \sigma \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \Lambda \, \mathrm{d}V. \tag{3.48}$$

A self-consistent boundary condition for Poisson's equation with a Neumann boundary condition must satisfy this surface integral constraint. For the temperature example, this boundary condition says that the area integrated boundary data must be consistent with the volume integrated source function in order for the temperature to satisfy Poisson's equation. Otherwise, the temperature field will evolve in time and thus not be in a steady state. Compatibility of the boundary conditions ensures the existence of a solution to the Poisson equation that is unique up to an arbitrary constant.

3.5 Parabolic partial differential equations

The parabolic case from Section 3.3, $B^2 - 4\,A\,C = 0$, contains a single real characteristic. The canonical example is the *heat equation*, which is also known as the *diffusion equation*

$$\frac{\partial \psi}{\partial t} = \kappa\,\frac{\partial^2 \psi}{\partial x^2}, \tag{3.49}$$

where $\kappa > 0$ is the kinematic diffusivity with dimensions of squared length per time.

3.5.1 Initial and initial-boundary value problems

The *Cauchy Problem* is the name given to the initial value problem for the heat equation over all space, here given by Euclidean space

$$\frac{\partial \psi}{\partial t} = \kappa\,\nabla^2 \psi \qquad \boldsymbol{x} \in \mathbb{R}^n, t > 0 \tag{3.50a}$$

$$\psi(\boldsymbol{x}, t = 0) = \sigma(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathbb{R}^n \tag{3.50b}$$

$$|\psi(\boldsymbol{x}, t)| < \infty \qquad \boldsymbol{x} \in \mathbb{R}^n, t > 0. \tag{3.50c}$$

The general initial-boundary value problem over a finite domain $\mathcal{R}$ takes the form

$$\frac{\partial \psi}{\partial t} = \kappa\,\nabla^2 \psi \qquad \boldsymbol{x} \in \mathcal{R}, t > 0 \tag{3.51a}$$

$$\psi(\boldsymbol{x}, t = 0) = \sigma(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R} \tag{3.51b}$$

$$\alpha(\boldsymbol{x})\,\psi(\boldsymbol{x}, t) + \beta(\boldsymbol{x})\,\hat{\boldsymbol{n}} \cdot \nabla\psi(\boldsymbol{x}, t) = g(\boldsymbol{x}, t) \qquad \boldsymbol{x} \in \partial\mathcal{R}, t > 0, \alpha\,\beta \geq 0. \tag{3.51c}$$

Following from the discussion of Laplace's and Poisson's boundary value problems, choices for the boundary functions α and β impact on the character of the boundary conditions. The Neumann condition is most commonly applied to set the flux of a tracer or temperature at the boundaries. The alternative use of the Dirichlet condition is commonly applied for idealized "diagnostic" tracers in geophysical fluid applications (see *Haine et al.* (2024) for a review of such idealized ocean tracers).

3.5.2 Smoothing property

The extended max-min principle from Section 3.4.5 holds also for the heat equation, which is consistent with solutions to the heat equation generally decaying their initial condition towards zero by reducing the amplitude of all extrema. Hence, no extrema are introduced in the interior of the domain by the heat equation; extrema only arise via boundary and/or initial conditions. Furthermore, the steady state limit of the heat equation is a harmonic function, and so solves Laplace's equation whereby the mean-value property holds (Section 3.4.2). These characteristics of the heat equation are generally shared by all linear parabolic partial differential equations.

Illustrating the smoothing property in a finite domain

We illustrate the smoothing property for the specific case of the one-dimensional initial-boundary value problem with homogeneous Dirichlet boundary conditions

$$\frac{\partial \psi}{\partial t} = \kappa \frac{\partial^2 \psi}{\partial x^2} \qquad 0 < x < L,\ t > 0 \tag{3.52a}$$

$$\psi(x,t) = I(x) \qquad 0 < x < L,\ t = 0 \tag{3.52b}$$

$$\psi(0,t) = \psi(L,t) = 0 \qquad t > 0. \tag{3.52c}$$

A variety of methods, such as separation of variables, can be used to derive the following Fourier series solution

$$\psi(x,t) = \sum_{n=1}^{\infty} I_n \, e^{-\kappa\, t\, (n\pi/L)^2} \sin(n\,\pi\, x/L) \qquad \text{with} \qquad I_n = \frac{2}{L}\int_0^L I(x) \sin(n\,\pi\, x/L)\, \mathrm{d}x. \tag{3.53}$$

As per the smoothing property of diffusion, note how the amplitude of each Fourier mode decays exponentially in time.

Smoothing property for an initial value problem on the real line

Now consider the one-dimensional heat equation on the real line, with the only boundary conditions being regularity at infinity

$$\frac{\partial \psi}{\partial t} = \kappa \frac{\partial^2 \psi}{\partial x^2} \qquad -\infty < x < \infty,\ t > 0 \tag{3.54a}$$

$$\psi(x,t) = I(x) \qquad -\infty < x < \infty,\ t = 0. \tag{3.54b}$$

One can show by direct differentiation that the following Gaussian is a solution

$$\psi(x,t) = \frac{1}{\sqrt{4\,\pi\,\kappa\, t}} \int_{-\infty}^{\infty} I(\xi)\, \exp\left[-\frac{(x-\xi)^2}{4\,\kappa\, t}\right] \mathrm{d}\xi. \tag{3.55}$$

Again, this function smooths/damps the initial condition function $I(x)$ as time increases.

3.5.3 Duhamel's superposition integral for the heat equation

Consider a scalar field that starts from zero initial conditions and evolves according to the heat equation in the presence of a source

$$\frac{\partial \Psi}{\partial t} = \kappa\, \nabla^2 \Psi + f(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathbb{R}^n,\ t > 0 \tag{3.56a}$$

$$\Psi(\boldsymbol{x},t) = 0 \qquad \boldsymbol{x} \in \mathbb{R}^n,\ t = 0. \tag{3.56b}$$

Now consider the converse, in which another scalar field evolves without a source and yet is initialized according to the source

$$\frac{\partial \psi}{\partial t} = \kappa\, \nabla^2 \psi \qquad \boldsymbol{x} \in \mathbb{R}^n,\ t > 0 \tag{3.57a}$$

$$\psi(\boldsymbol{x},t) = f(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathbb{R}^n,\ t = 0. \tag{3.57b}$$

Remarkably, these two scalar fields are related by *Duhamel's superposition integral*

$$\Psi(\boldsymbol{x},t) = \int_0^t \psi(\boldsymbol{x},t-\tau)\,\mathrm{d}\tau. \tag{3.58}$$

We verify the connection by direct differentiation

$$\frac{\partial \Psi(\boldsymbol{x},t)}{\partial t} = \psi(\boldsymbol{x},0) + \int_0^t \frac{\partial \psi(\boldsymbol{x},t-\tau)}{\partial t}\,\mathrm{d}\tau = f(\boldsymbol{x}) + \kappa\,\nabla^2\,\Psi(\boldsymbol{x},t). \tag{3.59}$$

Duhamel's superposition integral allows us to move the source between the partial differential operator and the initial conditions. It says that the forced solution, $\Psi(\boldsymbol{x},t)$, is built by time integrating the "retarded" values of the unforced solution, ψ, from the initial time, $t=0$, to the current time, t. Note that a more general presentation allows for the source function to be a function of time, $f(\boldsymbol{x},t)$, in which case we must develop a family of solutions, $\psi_f(\boldsymbol{x},t;\tau)$, generated by reinitializing $\psi_f(\boldsymbol{x},t=\tau;\tau) = f(\boldsymbol{x},\tau)$ and then superposing the members of this family to generate $\Psi(\boldsymbol{x},t)$.

As an example, consider the initial value problem for the heat equation on a line as given by equations (3.54a)-(3.54b)

$$\frac{\partial \psi}{\partial t} = \kappa\,\frac{\partial^2 \psi}{\partial x^2} \qquad -\infty < x < \infty,\ t > 0 \tag{3.60a}$$

$$\psi(x,t) = f(x) \qquad -\infty < x < \infty,\ t = 0, \tag{3.60b}$$

whose solution is given by the Gaussian function in equation (3.55). Duhamel's superposition integral (3.58) says that

$$\Psi(x,t) = \int_0^t \psi(x,t-\tau)\,\mathrm{d}\tau = \int_0^t \frac{1}{\sqrt{4\,\pi\,\kappa\,(t-\tau)}} \int_{-\infty}^{\infty} f(\xi)\,\exp\left[-\frac{(x-\xi)^2}{4\,\kappa\,(t-\tau)}\right]\,\mathrm{d}\tau\,\mathrm{d}\xi \tag{3.61}$$

satisfies the forced (inhomogeneous) initial value problem with zero initial condition

$$\frac{\partial \Psi}{\partial t} = \kappa\,\frac{\partial^2 \Psi}{\partial x^2} + f(x) \qquad -\infty < x < \infty,\ t > 0 \tag{3.62a}$$

$$\Psi(x,t) = 0 \qquad -\infty < x < \infty,\ t = 0. \tag{3.62b}$$

We make use of this result in our discussion of Green's functions in Chapter 5.

3.5.4 Further study

We examine physical and mathematical properties of the heat/diffusion equation in Sections 64.3 and 64.4. Section 9.11 of *Hildebrand* (1976) offers a lucid discussion of Duhamel's superposition integral.

3.6 Hyperbolic partial differential equations

The hyperbolic case from Section 3.3 has $B^2 - 4\,A\,C > 0$ and thus contains two real characteristics. The canonical example of a hyperbolic partial differential equation is the linear homogeneous wave equation

$$(\partial_{tt} - U^2\,\partial_{xx})\psi = 0. \tag{3.63}$$

Solutions have the form of a moving wave in both directions (the two wave characteristics)

$$\psi(x,t) = \mathcal{F}(x - Ut) + \mathcal{G}(x + U\,t), \tag{3.64}$$

where $\mathcal{F}$ and $\mathcal{G}$ are differentiable functions whose form is determined by the initial conditions. Note that we can factor the differential operator into the form

$$(\partial_t - U\,\partial_x)\,(\partial_t + U\,\partial_x)\psi = 0. \tag{3.65}$$

Consequently, if either one of the linear first-order partial differential equations are satisfied

$$(\partial_t - U\,\partial_x)\psi = 0 \tag{3.66a}$$
$$(\partial_t + U\,\partial_x)\psi = 0 \tag{3.66b}$$

then ψ will satisfy the full wave equation. These first-order partial differential equations are the one-dimensional advection equations considered in Section 3.2 with opposite advection direction, and each of which has a single characteristic. In this manner, we can think of advection by constant velocity as the square root of the wave equation. Similarly, some disciplines refer to the linear advection equation (3.2), with constant advection speed, as the *one-way wave equation*. It represents the simplest of the hyperbolic partial differential equations.

3.6.1 Initial value problem for the infinite-domain wave equation

Since there are two time derivatives, specification of a solution requires initial conditions for the field and its first time derivative. To illustrate the structure of a solution to the wave equation, we develop a solution to the *Cauchy problem*, which is the initial value problem for the one-dimensional wave equation on the real line (infinite spatial domain so no boundary conditions)

$$\partial_{tt}\psi = c^2\,\partial_{xx}\psi \qquad -\infty < x < \infty,\ t > 0 \qquad \text{wave equation on a line} \tag{3.67a}$$
$$\psi = F(x) \qquad -\infty < x < \infty,\ t = 0 \qquad \text{initial condition} \tag{3.67b}$$
$$\partial_t\psi = G(x) \qquad -\infty < x < \infty,\ t = 0 \qquad \text{initial tendency,} \tag{3.67c}$$

where the initial condition data, F, G, are arbitrary functions of space and c is a constant wave speed. Following from the discussion of characteristics in Section 3.2, we are motivated to transform the wave equation into wave characteristic coordinates

$$\xi = x + c\,t \qquad \text{and} \qquad \eta = x - c\,t \Longrightarrow (\xi + \eta)/2 = x \qquad \text{and} \qquad (\xi - \eta)/(2c) = t. \tag{3.68}$$

Wave signals propagate in directions defined by constant ξ and η, so that these coordinates isolate the signal transmission. Furthermore, as we will see, this coordinate transformation facilitates a direct integration of the wave equation.

Transformation to characteristic coordinates

To help organize the transformation to characteristic coordinates, write equation (3.68) as a matrix-vector equation

$$\begin{bmatrix} \xi \\ \eta \end{bmatrix} = \begin{bmatrix} c & 1 \\ -c & 1 \end{bmatrix} \begin{bmatrix} t \\ x \end{bmatrix} \Longleftrightarrow \begin{bmatrix} t \\ x \end{bmatrix} = \frac{1}{2} \begin{bmatrix} c^{-1} & -c^{-1} \\ 1 & 1 \end{bmatrix} \begin{bmatrix} \xi \\ \eta \end{bmatrix}. \tag{3.69}$$

Furthermore, introduce tensor indices (see Chapter 1)

$$\mu = (0, 1) \quad \text{and} \quad \overline{\mu} = (\overline{0}, \overline{1}), \tag{3.70}$$

where indices 0 and $\overline{0}$ represent time and indices 1 and $\overline{1}$ represent space, in which case the time and space coordinates are written

$$x^{\mu} = (x^0, x^1) = (t, x) \quad \text{and} \quad x^{\overline{\mu}} = (x^{\overline{0}}, x^{\overline{1}}) = (\xi, \eta). \tag{3.71}$$

Use of this index notation brings the transformation (3.69) into the tidy form

$$x^{\overline{\mu}} = \Lambda^{\overline{\mu}}{}_{\nu}\, x^{\nu} \Longleftrightarrow x^{\mu} = \Lambda^{\mu}{}_{\overline{\nu}}\, x^{\overline{\nu}}, \tag{3.72}$$

where the transformation matrices are given by

$$\Lambda^{\overline{\mu}}{}_{\nu} = \begin{bmatrix} \partial x^{\overline{1}}/\partial x^1 & \partial x^{\overline{1}}/\partial x^2 \\ \partial x^{\overline{1}}/\partial x^2 & \partial x^{\overline{2}}/\partial x^2 \end{bmatrix} = \begin{bmatrix} c & 1 \\ -c & 1 \end{bmatrix} \tag{3.73}$$

and

$$\Lambda^{\mu}{}_{\overline{\nu}} = \begin{bmatrix} \partial x^1/\partial x^{\overline{1}} & \partial x^1/\partial x^{\overline{2}} \\ \partial x^2/\partial x^{\overline{1}} & \partial x^2/\partial x^{\overline{2}} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} c^{-1} & -c^{-1} \\ 1 & 1 \end{bmatrix}. \tag{3.74}$$

Note the use of an upstairs position for the row index on the transformation matrix, which conforms to the use with general tensors from Chapter 8. The coordinate transformation (3.72) and the transformation matrices (3.73)-(3.74) then lead to the partial derivative relationship

$$\partial_{\overline{\nu}} = \Lambda^{\mu}{}_{\overline{\nu}}\, \partial_{\mu} \Longleftrightarrow \partial_{\nu} = \Lambda^{\overline{\mu}}{}_{\nu}\, x_{\overline{\mu}}, \tag{3.75}$$

so that

$$\frac{\partial^2}{\partial x^2} = \left[\frac{\partial}{\partial \xi} + \frac{\partial}{\partial \eta}\right]^2 = \frac{\partial^2}{\partial \xi^2} + 2\,\frac{\partial}{\partial \xi}\,\frac{\partial}{\partial \eta} + \frac{\partial^2}{\partial \eta^2} \tag{3.76a}$$

$$c^{-2}\,\frac{\partial^2}{\partial t^2} = \left[\frac{\partial}{\partial \xi} - \frac{\partial}{\partial \eta}\right]^2 = \frac{\partial^2}{\partial \xi^2} - 2\,\frac{\partial}{\partial \xi}\,\frac{\partial}{\partial \eta} + \frac{\partial^2}{\partial \eta^2}. \tag{3.76b}$$

General solution for the initial value problem

The operator transformations (3.76a) and (3.76b) bring the initial value problem (3.67a)-(3.67c) into the form

$$\frac{\partial^2 \psi}{\partial \xi \partial \eta} = 0 \qquad -\infty < \eta < \xi < \infty \tag{3.77a}$$

$$\psi(\xi, \eta) = F(\xi) \qquad -\infty < \xi < \infty,\ \xi = \eta \tag{3.77b}$$

$$\frac{\partial \psi}{\partial \xi} - \frac{\partial \psi}{\partial \eta} = c^{-1}\, G(\xi) \qquad -\infty < \xi < \infty,\ \xi = \eta. \tag{3.77c}$$

Integrating equation (3.77a) in two steps leads to $\partial_{\xi}\psi = \theta(\xi)$ so that

$$\psi(\xi, \eta) = \Phi(\eta) + \int^{\xi} \theta(s)\, \mathrm{d}s \equiv \Phi(\eta) + \Theta(\xi), \tag{3.78}$$

for two functions $\Phi(\eta)$ and $\Theta(\xi)$. The initial conditions (3.77b) and (3.77c) determine relations between $\Phi(\eta)$ and $\Theta(\xi)$ and the initial data

$$\Theta(\xi) = \frac{1}{2}\left[F(\xi) + \frac{1}{c}\int^{\xi} G(s)\,\mathrm{d}s\right] \tag{3.79a}$$

$$\Phi(\eta) = \frac{1}{2}\left[F(\eta) - \frac{1}{c}\int^{\eta} G(s)\,\mathrm{d}s\right], \tag{3.79b}$$

in which case the general solution to the initial value problem (3.67a)-(3.67c) takes the form

$$\psi(x,t) = \frac{1}{2}\left[F(x+c\,t) + F(x-c\,t)\right] + \frac{1}{2c}\int_{x-c\,t}^{x+c\,t} G(s)\,\mathrm{d}s, \tag{3.80}$$

where we reintroduced the variables (x,t). This solution is known as the *D'Alembert formula* for the wave equation. Note how the initial profile, $F(x)$, is propagated along the two characteristics, $\xi = x + c\,t$ and $\eta = x - c\,t$, without any change. In contrast, the initial tendency, $\partial_t\psi(x,t=0) = G(x)$, is smoothed through the time integration. This behavior contrasts to the heat equation in Section 3.5, with its single time derivative resulting in a smoothing of the full solution.

FIGURE 3.3: Equation (3.80) is the general solution to the wave equation initial value problem on a line, in which case an arbitrary space-time point, (x_0, t_0), is causally connected via wave signals to all space-time points within the shaded region in its past. This *domain of influence* is bounded by the two wave characteristics, $\xi_0 = x_0 + c\,t_0$ and $\eta_0 = x_0 - c\,t_0$, with these characteristics the pathway for propagating information about the initial wave profile, $\psi(x, t=0) = F(x)$. Points in between the characteristics are causally connected via the initial time tendency, $\partial_t\psi(x,t=0) = G(x)$, which is integrated over the region $x_0 - c\,t_0 \le x \le x_0 + c\,t_0$. Points outside the domain of influence are causally disconnected from the point (x_0, t_0).

3.6.2 Domain of influence for wave signals

The wave solution (3.80) at a point in space time, (x_0, t_0), depends on data to its past within a causality triangle, or *domain of influence*, as shown in Figure 3.3. The domain of influence is bounded by the two wave characteristics, $\xi_0 = x_0 + c\,t_0$ and $\eta_0 = x_0 - c\,t_0$. These characteristics are the pathways for propagating information about the initial wave profile, $\psi(x, t=0) = F(x)$. Points in between the characteristics are causally connected via the initial time tendency, $\partial_t\psi(x,t=0) = G(x)$, which is integrated over the region $x_0 - c\,t_0 \le x \le x_0 + c\,t_0$. Points outside the domain of influence are causally disconnected from the point (x_0, t_0).

3.6.3 Helmholtz equation

Consider the wave equation with a constant wave speed

$$\partial_{tt}\psi - c^2\nabla^2\psi = 0. \tag{3.81}$$

Assuming a monochromatic periodic time dependence ansatz[3] of the form

$$\psi(\boldsymbol{x}, t) = e^{-\mathrm{i}\,\omega\, t}\,\Psi(\boldsymbol{x}) \tag{3.82}$$

results in the *Helmholtz equation* for the amplitude function

$$[\nabla^2 + (\omega/c)^2]\,\Psi = 0. \tag{3.83}$$

The Helmholtz equation thus plays a central role in wave theory. In Exercise 49.1, we encounter this equation when deriving the standing acoustic modes in a rectangular cavity.

3.6.4 Duhamel's superposition integral for the wave equation

We here present Duhamel's superposition integral for the wave equation, following from the similar discussion for the heat equation in Section 3.5.3. For this purpose, consider the forced wave equation with time independent forcing

$$\frac{\partial^2\Psi}{\partial t^2} = c^2\,\nabla^2\Psi + G(\boldsymbol{x}) \qquad \boldsymbol{x}\in\mathbb{R}^n,\ t>0 \tag{3.84a}$$

$$\Psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x}\in\mathbb{R}^n,\ t=0, \tag{3.84b}$$

and the corresponding unforced wave equation with inhomogenous initial time tendency

$$\frac{\partial^2\psi}{\partial t^2} = c^2\,\nabla^2\psi \qquad \boldsymbol{x}\in\mathbb{R}^n, t>0 \tag{3.85a}$$

$$\psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x}\in\mathbb{R}^n,\ t=0. \tag{3.85b}$$

$$\frac{\partial\psi(\boldsymbol{x}, t)}{\partial t} = G(\boldsymbol{x}) \qquad \boldsymbol{x}\in\mathbb{R}^n,\ t=0. \tag{3.85c}$$

The two scalar fields are related by Duhamel's superposition integral

$$\Psi(\boldsymbol{x}, t) = \int_0^t \psi(\boldsymbol{x}, t-\tau)\,\mathrm{d}\tau. \tag{3.86}$$

We can verify this formula through direct differentiation

$$\frac{\partial\Psi(\boldsymbol{x}, t)}{\partial t} = \int_0^t \frac{\partial\psi(\boldsymbol{x}, t-\tau)}{\partial t}\,\mathrm{d}\tau \tag{3.87a}$$

$$\frac{\partial^2\Psi(\boldsymbol{x}, t)}{\partial t^2} = \frac{\partial\psi(\boldsymbol{x}, 0)}{\partial t} + \int_0^t \frac{\partial^2\psi(\boldsymbol{x}, t-\tau)}{\partial t^2}\,\mathrm{d}\tau = G(\boldsymbol{x}) + c^2\,\nabla^2\Psi(\boldsymbol{x}, t). \tag{3.87b}$$

As an example, consider the initial value problem for wave equation on a line with time

[3] *Ansatz* is a German word meaning an educated guess for the form of the solution. Monochromatic refers to the refers to the time dependence where each portion of the wave oscillates with the same angular frequency, ω. We study wave kinematics in Chapter 47.

independent forcing

$$\frac{\partial^2 \Psi}{\partial t^2} = c^2 \frac{\partial^2 \Psi}{\partial x^2} + G(x) \qquad -\infty < x < \infty,\ t > 0 \tag{3.88a}$$

$$\Psi(x,t) = 0 \qquad -\infty < x < \infty,\ t = 0 \tag{3.88b}$$

$$\frac{\partial \Psi(x,t)}{\partial t} = 0 \qquad -\infty < x < \infty,\ t = 0. \tag{3.88c}$$

Duhamel's superposition integral says that Ψ is related to the solution of the unforced wave equation with initial time tendency given by the forcing

$$\frac{\partial^2 \psi}{\partial t^2} = c^2 \frac{\partial^2 \psi}{\partial x^2} \qquad -\infty < x < \infty,\ t > 0 \tag{3.89a}$$

$$\psi(x,t) = 0 \qquad -\infty < x < \infty, t = \tau \tag{3.89b}$$

$$\frac{\partial \psi(x,t)}{\partial t} = G(x) \qquad -\infty < x < \infty,\ t = \tau > 0. \tag{3.89c}$$

We know from Section 3.6.1 that the solution ψ is given by the D'Alembert formula in equation (3.80), only here with the initial condition function set to zero

$$\psi(x,t) = \frac{1}{2c} \int_{x-c\,t}^{x+c\,t} G(s)\,\mathrm{d}s. \tag{3.90}$$

Hence, D'Alembert's formula says that the solution to the forced wave equation (3.88a)-(3.88c) is given by the superposition integral

$$\Psi(x,t) = \frac{1}{2c} \int_0^t \int_{x-c\,(t-\tau)}^{x+c\,(t-\tau)} G(s)\,\mathrm{d}s. \tag{3.91}$$

Introducing the *antiderivative* function via

$$\mathcal{G}(s) = \int^s G(s')\,\mathrm{d}s' \Longleftrightarrow \frac{\partial \mathcal{G}(s)}{\partial s} = G(s) \tag{3.92}$$

allows us to interpret the solution (3.91) as the superposition of two oppositely traveling waves

$$\Psi(x,t) = \frac{1}{2c} \int_0^t \Big[\mathcal{G}[x + c\,(t-\tau)] - \mathcal{G}[x - c\,(t-\tau)]\Big] \mathrm{d}\tau. \tag{3.93}$$

3.6.5 Further study

Stakgold (2000a,b) provides a thorough discussion of the wave equation and the related Helmholtz equation. We further our understanding of wave maths and physics in Part IX of this book, where we refer to the hyperbolic waves of this section as *non-dispersive waves*. For non-dispersive waves, the linear superposition of many waves retains its integrity since each wave travels with the same speed. However, most waves of interest for geophysical fluid mechanics are *dispersive*, so that waves mix among themselves; i.e., they change wavelengths as they interact. Dispersive waves are described by partial differential equations that are not necessarily hyperbolic. For example, surface gravity waves of Chapter 50 satisfy an elliptic equation, with time dependence arising from boundary conditions. The dispersion of surface gravity waves leads to the familiar spreading of waves on the surface of a pond whereby longer waves travel faster than shorter waves.

3.7 Helmholtz decomposition

In characterizing the kinematic properties of vector fields, such as the velocity vector for a moving fluid, *Helmholtz* (1867) introduced a method to decompose any vector into two distinct components whose properties are readily analyzed: one component vector has a zero divergence and the second vector has a zero curl. This *Helmholtz decomposition* has extensive applications throughout fluid mechanics. See also *Bhatia et al.* (2013) for a review, as well as an earlier treatment in Section 26 of *Serrin* (1959). We make particular use of the Helmholtz decomposition when introducing a scalar or vector potential for studying the kinematics of non-divergent fluid flows (Chapter 22). In this section we provide further insights into features of the Helmholtz decomposition, with much of the discussion following *Denaro* (2003) and *Bhatia et al.* (2013). Note that our treatment makes use of Cartesian vector analysis, with more general treatments, such as Chapter 14 of *Frankel* (2012), outside our scope.

To introduce the Helmholtz decomposition, consider a vector field, $\boldsymbol{F}$, in free space (i.e., no boundaries) that decays to zero outside of a finite domain. In this case we can decompose $\boldsymbol{F}$ into

$$\boldsymbol{F} = -\nabla D + \nabla \times \boldsymbol{R}, \tag{3.94}$$

where

$$D(\boldsymbol{x}) = \frac{1}{4\pi} \int_{\mathcal{R}} \frac{\nabla \cdot \boldsymbol{F}(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} \, \mathrm{d}V' \tag{3.95a}$$

$$\boldsymbol{R}(\boldsymbol{x}) = \frac{1}{4\pi} \int_{\mathcal{R}} \frac{\nabla \times \boldsymbol{F}(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|} \, \mathrm{d}V'. \tag{3.95b}$$

The scalar potential, D, and vector potential, $\boldsymbol{R}$, are here given by the Green's function solutions derived in Section 5.6.5.

The Helmholtz decomposition (3.95a) and (3.95b) is both elegant and straightforward. It offers motivation to seek a similar decomposition for domains of relevance to geophysical fluids, where boundaries play a fundamental role. However, there are many mathematical nuances associated with Helmholtz decompositions in more general situations, each depending on the domain topology and nature of the prescribed boundary conditions. Our goal in this section is to explore the mathematics for a few common boundary conditions for a fluid on simply connected manifolds.[4] We offer rather brief comments for the more general non-simply connected case as the mathematics is beyond our scope.[5]

3.7.1 Summarizing the Helmholtz decomposition

The Helmholtz decomposition on a simply connected manifold, $\mathcal{R}$, states that a vector field, $\boldsymbol{F}$, is fully determined by specifying its divergence, $\nabla \cdot \boldsymbol{F}$, and curl, $\nabla \times \boldsymbol{F}$, for points $\boldsymbol{x} \in \mathcal{R}$, along with the normal component, $\hat{\boldsymbol{n}} \cdot \boldsymbol{F}$, or the tangential component[6], $\hat{\boldsymbol{n}} \times \boldsymbol{F}$, along the domain boundary, $\partial\mathcal{R}$. Here, $\hat{\boldsymbol{n}}$ is the outward normal along the boundary. Expressed with equations, the Helmholtz

[4] A manifold is simply connected if a closed curve can be continuously shrunk to a point while remaining on the manifold. For example, the domain of the global ocean on a water covered planet is a simply connected manifold. Adding land masses in the form of islands or continents makes the ocean domain non-simply connected.

[5] Section 5.2 of *Bhatia et al.* (2013) provides a few comments on the non-simply connected case, whereas chapter 14 of *Frankel* (2012) provides details for the mathematically experienced reader.

[6] *Helmholtz* (1867) only considered vector fields with a specified normal component along boundaries. This situation is most common in fluid mechanical applications. *Denaro* (2003) showed how specification of the tangential component along the boundary also allows for a Helmholtz decomposition. We explore both boundary conditions in this section.

decomposition is given by

$$\boldsymbol{F} = -\nabla D + \nabla \times \boldsymbol{R} = \text{gradient term (curl-free)} + \text{rotation term (divergence-free)}. \tag{3.96}$$

The scalar potential, D, is arbitrary up to a constant, and the vector potential, $\boldsymbol{R}$, is arbitrary up to the gradient of a scalar field. This ambiguity in specifying D and $\boldsymbol{R}$ is referred to as *gauge invariance* or *gauge freedom*, and we encounter it in other contexts within this book. For present purposes, gauge freedom allows us to choose the *Coulomb gauge* that is commonly used in electromagnetics (*Jackson*, 1975), whereby $\boldsymbol{R}$ is prescribed to be divergence-free

$$\nabla \cdot \boldsymbol{R} = 0. \tag{3.97}$$

As seen next, this constraint simplifies the boundary value problem satisfied by $\boldsymbol{R}$.

Taking the divergence of (3.96) reveals that the scalar potential satisfies the Poisson equation

$$-\nabla^2 D = \nabla \cdot \boldsymbol{F} \quad \text{for } \boldsymbol{x} \in \mathcal{R}. \tag{3.98}$$

Taking the curl of the decomposition (3.96), and using the curl identity (2.37c) along with the Coulomb gauge (3.97)

$$\nabla \times (\nabla \times \boldsymbol{R}) = \nabla(\nabla \cdot \boldsymbol{R}) - \nabla^2 \boldsymbol{R} = -\nabla^2 \boldsymbol{R}, \tag{3.99}$$

leads to the vector Poisson equation

$$-\nabla^2 \boldsymbol{R} = \nabla \times \boldsymbol{F} \quad \text{for } \boldsymbol{x} \in \mathcal{R}. \tag{3.100}$$

The two elliptic equations, (3.98) and (3.100), are supplemented by boundary conditions for points $\boldsymbol{x} \in \partial\mathcal{R}$. The choice of boundary conditions depend on information available about the vector $\boldsymbol{F}$ along the boundary. We here consider the following three sets of boundary conditions, with $\hat{\boldsymbol{n}}$ the outward unit normal along $\partial\mathcal{R}$:

$$\text{normal component} \qquad -\hat{\boldsymbol{n}} \cdot \nabla D = \hat{\boldsymbol{n}} \cdot \boldsymbol{F} \quad \text{and} \quad \hat{\boldsymbol{n}} \cdot (\nabla \times \boldsymbol{R}) = 0 \tag{3.101a}$$

$$\text{tangential component} \qquad \hat{\boldsymbol{n}} \times \nabla D = 0 \quad \text{and} \quad \hat{\boldsymbol{n}} \times (\nabla \times \boldsymbol{R}) = \hat{\boldsymbol{n}} \times \boldsymbol{F} \tag{3.101b}$$

$$\text{vanishing boundary} \qquad \hat{\boldsymbol{n}} \cdot \nabla D = 0 \quad \text{and} \quad \hat{\boldsymbol{n}} \times (\nabla \times \boldsymbol{R}) = 0 \Longrightarrow \boldsymbol{F} = 0. \tag{3.101c}$$

The homogeneous Neumann boundary condition $\hat{\boldsymbol{n}} \cdot (\nabla \times \boldsymbol{R}) = 0$ in equation (3.101a) means that $(\nabla \times \boldsymbol{R})$ is parallel to the boundary. Likewise, $\hat{\boldsymbol{n}} \times \nabla D = 0$ in equation (3.101b) means that ∇D is parallel to the boundary. If $\boldsymbol{F} = \boldsymbol{v}$ is the fluid velocity field, then $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ is the no-normal flow kinematic condition that holds for static solid boundaries (Section 20.4.1). Furthermore, the vanishing boundary condition (3.101c) holds for the velocity with the dynamic no-slip boundary condition discussed in Section 26.10.3.

3.7.2 Concerning a harmonic contribution

Consider a vector $\boldsymbol{H}$ that is both divergent-free and curl-free

$$\nabla \cdot \boldsymbol{H} = 0 \quad \text{and} \quad \nabla \times \boldsymbol{H} = 0. \tag{3.102}$$

$\boldsymbol{H}$ is a harmonic vector function (Section 3.4.1), which is seen by noting that with $\nabla \cdot \boldsymbol{H} = 0$ then (see equation (2.37c)) $\boldsymbol{H}$ satisfies the vector Laplace equation

$$\nabla \times (\nabla \times \boldsymbol{H}) = -\nabla^2 \boldsymbol{H} = 0, \tag{3.103}$$

so that each component of $\boldsymbol{H}$ is a harmonic function.

An arbitrary vector, $\boldsymbol{F}$, generally contains a portion that is harmonic, in which case we consider the three-component decomposition

$$\boldsymbol{F} = -\nabla E + \nabla \times \boldsymbol{S} + \boldsymbol{H} = \text{gradient term} + \text{rotation term} + \text{harmonic term}. \tag{3.104}$$

However, as we show in this section, there are many physically interesting cases in which the original two-component Helmholtz decomposition (3.96) is sufficient. That is, for many cases the two-component Helmholtz decomposition is able to include contributions from the harmonic portion of $\boldsymbol{F}$ as part of either ∇D or $\nabla \times \boldsymbol{R}$.

Normal component boundary condition

The constraint $\nabla \times \boldsymbol{H} = 0$ can be satisfied by writing $\boldsymbol{H} = -\nabla\phi$, which then brings the decomposition (3.104) into the form

$$\boldsymbol{F} = -(\nabla E + \nabla\phi) + \nabla \times \boldsymbol{S}. \tag{3.105}$$

We connect this decomposition to the orginal form of the Helmholtz decomposition in equation (3.96) by identifying

$$\nabla E + \nabla\phi \equiv \nabla D \quad \text{and} \quad \nabla \times \boldsymbol{S} \equiv \nabla \times \boldsymbol{R}. \tag{3.106}$$

In so doing, the harmonic term, here captured by $\nabla\phi$, is absorbed into the scalar potential, D. This method for absorbing the harmonic term is suited to the normal component boundary condition (3.101a), in which

$$-\hat{\boldsymbol{n}} \cdot \boldsymbol{F} = \hat{\boldsymbol{n}} \cdot (\nabla E + \nabla\phi) = \hat{\boldsymbol{n}} \cdot \nabla D \Longrightarrow \hat{\boldsymbol{n}} \cdot \nabla E = -\hat{\boldsymbol{n}} \cdot (\boldsymbol{F} + \nabla\phi). \tag{3.107}$$

In practice, we determine D and $\boldsymbol{R}$ as per the two-component decomposition (3.96), with the harmonic contribution to $\boldsymbol{F}$ contained as part of the scalar potential, D.

Tangential component boundary condition

The constraint $\nabla \cdot \boldsymbol{H} = 0$ is satisfied by writing $\boldsymbol{H} = \nabla \times \boldsymbol{A}$, so that the decomposition (3.104) takes on the form

$$\boldsymbol{F} = -\nabla E + \nabla \times (\boldsymbol{S} + \boldsymbol{A}). \tag{3.108}$$

We connect this decomposition to the orginal form of the Helmholtz decomposition of equation (3.96) by identifying

$$\nabla E \equiv \nabla D \quad \text{and} \quad \nabla \times (\boldsymbol{S} + \boldsymbol{A}) \equiv \nabla \times \boldsymbol{R}. \tag{3.109}$$

In so doing, the harmonic term, here captured by $\nabla \times \boldsymbol{A}$, is included in the vector potential, $\boldsymbol{R}$. This method for absorbing the harmonic term is suited for the tangential component boundary condition (3.101b), in which case

$$\hat{\boldsymbol{n}} \times \boldsymbol{F} = \hat{\boldsymbol{n}} \times (\boldsymbol{S} + \boldsymbol{A}) = \hat{\boldsymbol{n}} \times \boldsymbol{R} \Longrightarrow \hat{\boldsymbol{n}} \times \boldsymbol{S} = \hat{\boldsymbol{n}} \times (\boldsymbol{F} - \boldsymbol{A}). \tag{3.110}$$

Non-divergent velocity vector with no-normal flow boundary condition

As discussed in Chapters 22 and 30, many geophysical fluid flows maintain a non-divergent velocity field. Such velocity fields also maintain the no-normal flow boundary condition at static material boundaries (Section 20.4.1). For this vector field the scalar potential is harmonic and satisfies the

vanishing Neumann boundary condition

$$-\nabla^2 D = 0 \quad \text{for} \quad \boldsymbol{x} \in \mathcal{R} \tag{3.111a}$$
$$\hat{\boldsymbol{n}} \cdot \nabla D = 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\mathcal{R}. \tag{3.111b}$$

The solution to this boundary value problem is a spatially constant D, so that the velocity field is fully specified by a vector potential

$$\boldsymbol{F} = \nabla \times \boldsymbol{R}. \tag{3.112}$$

In the presence of a time dependent boundary condition, such as a fluctuating free surface, the scalar potential is not generally a spatial constant. We encounter an example when studying surface gravity waves in Section 50.3.

Vanishing boundary condition

The case with $\boldsymbol{F} = 0$ on the boundary means that

$$\boldsymbol{F} \cdot \hat{\boldsymbol{n}} = 0 \quad \text{and} \quad \hat{\boldsymbol{n}} \times \boldsymbol{F} = 0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{3.113}$$

We proceed with both of the previous boundary condition constraints whereby

$$\nabla E + \nabla\phi = \nabla D \quad \text{and} \quad \nabla \times \boldsymbol{S} = \nabla \times \boldsymbol{R} \tag{3.114a}$$
$$\nabla E = \nabla D \quad \text{and} \quad \nabla \times (\boldsymbol{A} + \boldsymbol{S}) = \nabla \times \boldsymbol{R}. \tag{3.114b}$$

These two sets of constraints are mutually satisfied only when

$$\nabla\phi = 0 \quad \text{and} \quad \nabla \times \boldsymbol{A} = 0, \tag{3.115}$$

so that the harmonic term vanishes identically for the case of $\boldsymbol{F} = 0$ along the boundary.

Summary comments

We have shown that for a simply connected domain, it is possible to absorb an arbitrary harmonic portion of $\boldsymbol{F}$ into either the scalar potential D (for the normal component boundary conditions (3.101a)) or vector potential, $\boldsymbol{R}$ (for tangential component boundary conditions (3.101b)). Furthermore, the harmonic term vanishes altogether for the vanishing boundary condition (e.g., no-slip velocity boundary condition).

We infer from this discussion that if both the normal and tangential components of $\boldsymbol{F}$ are specified nonzero values on the boundary, then the harmonic term cannot be fully absorbed into one of the potentials D or $\boldsymbol{R}$. Rather, the harmonic term must be explictly computed, in which case the three-component decomposition (3.104) is referred to as the *Helmholtz-Hodge decomposition*.

These considerations are analogous to the Cauchy-Stokes decomposition summarized by Figure 19.2. That is, Cauchy-Stokes decomposes the motion of a fluid element into three processes: a deformation plus a rigid rotation plus a uniform translation. The deformation corresponds to the curl-free vector in the Helmholtz decomposition ($-\nabla D$), the rotation corresponds to the divergent free vector ($\nabla \times \boldsymbol{R}$), and the uniform translation corresponds to the harmonic vector.

3.7.3 Self-consistency conditions

We here establish existence conditions for the scalar potential, D, and vector potential, $\boldsymbol{R}$, that satisfy the decomposition (3.96). We separately do so for the two sets of boundary conditions (3.101a) and (3.101b). The proof consists of showing that the source term on the right hand side of the Poisson equation is self-consistent with the boundary condition.

Normal component boundary condition

Consider the scalar Poisson equation with Neumann boundary conditions

$$-\nabla^2\chi = \Lambda \quad \text{for } \boldsymbol{x} \in \mathcal{R} \tag{3.116a}$$

$$-\hat{\boldsymbol{n}} \cdot \nabla\chi = \sigma \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{3.116b}$$

As discussed in Section 3.4.6, this elliptic boundary value problem has a solution so long as the source, Λ, and boundary condition, σ, satisfy a self-consistency condition given by equation (3.48)

$$\int_{\mathcal{R}} \Lambda \, \mathrm{d}V = \oint_{\partial\mathcal{R}} \sigma \, \mathrm{d}\mathcal{S}. \tag{3.117}$$

Now specialize to the Helmholtz decomposition (3.96) whereby $\chi = D$ is the scalar potential with source $\Lambda = \nabla \cdot \boldsymbol{F}$ and boundary condition $\sigma = \hat{\boldsymbol{n}} \cdot \boldsymbol{F}$. Gauss's divergence theorem (2.68) readily verifies self-consistency

$$\int_{\mathcal{R}} \Lambda \, \mathrm{d}V = \int_{\mathcal{R}} \nabla \cdot \boldsymbol{F} \, \mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{F} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{R}} \sigma \, \mathrm{d}\mathcal{S}. \tag{3.118}$$

As noted in Section 3.4.6, self-consistency ensures the existence of a solution to the Neumann problem that is unique up to an arbitrary constant. Hence, ∇D is unique so that

$$\nabla \times \boldsymbol{R} = \boldsymbol{F} + \nabla D \tag{3.119}$$

is also unique (we further discuss uniqueness in Section 3.7.5). Finally, the inhomogeneous Neumann boundary condition satisfied by the scalar potential, $-\hat{\boldsymbol{n}} \cdot \nabla D = \hat{\boldsymbol{n}} \cdot \boldsymbol{F}$, means that the curl satisfies the homogeneous Neumann boundary condition

$$\hat{\boldsymbol{n}} \cdot (\nabla \times \boldsymbol{R}) = \hat{\boldsymbol{n}} \cdot (\boldsymbol{F} + \nabla D) = 0, \tag{3.120}$$

so that $(\nabla \times \boldsymbol{R})$ is parallel to the boundary.

Tangential component boundary condition

Consider the vector Poisson equation

$$-\nabla^2\boldsymbol{\Psi} = \boldsymbol{\Lambda} \qquad \text{for } \boldsymbol{x} \in \mathcal{R} \tag{3.121a}$$

$$\hat{\boldsymbol{n}} \times (\nabla \times \boldsymbol{\Psi}) = \hat{\boldsymbol{n}} \times \boldsymbol{\Sigma} \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}, \tag{3.121b}$$

with an assumed non-divergence condition (Coulomb gauge) placed on $\boldsymbol{\Psi}$

$$\nabla \cdot \boldsymbol{\Psi} = 0. \tag{3.122}$$

The region $\mathcal{R}$ is assumed to be a bounded three-dimensional volume with a closed boundary surface, $\partial\mathcal{R}$. Now let $\mathcal{S}$ be an arbitrary simply connected portion of $\partial\mathcal{R}$, and write $\partial\mathcal{S}$ for the

closed contour that bounds $\mathcal{S}$. Integrate the normal projection of the vector Poisson equation over $\mathcal{S}$ and make use of Stokes' theorem (Section 2.6) to render

$$\int \boldsymbol{\Lambda} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = -\int \nabla^2 \boldsymbol{\Psi} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int \nabla \times (\nabla \times \boldsymbol{\Psi}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} (\nabla \times \boldsymbol{\Psi}) \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s, \tag{3.123}$$

with $\hat{\boldsymbol{t}}$ the unit tangent vector pointing counter-clockwise along the closed contour, and $\mathrm{d}s$ the increment of arc-length along the contour (see Section 2.4). The assumed boundary condition (3.121b) means that for $\boldsymbol{x} \in \partial\mathcal{R}$ we can write

$$\nabla \times \boldsymbol{\Psi} = \boldsymbol{\Sigma} + \boldsymbol{m}, \tag{3.124}$$

where $\boldsymbol{m}$ is parallel to $\hat{\boldsymbol{n}}$ so that $\hat{\boldsymbol{n}} \times \boldsymbol{m} = 0$. In turn, with $\boldsymbol{m}$ parallel to $\hat{\boldsymbol{n}}$ then it is also perpendicular to the unit tangent vector, $\hat{\boldsymbol{t}} \cdot \boldsymbol{m} = 0$, so that

$$\oint_{\partial\mathcal{S}} (\nabla \times \boldsymbol{\Psi}) \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = \oint_{\partial\mathcal{S}} \boldsymbol{\Sigma} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s. \tag{3.125}$$

We are thus led to the self-consistency condition between the source, $\boldsymbol{\Lambda}$, and boundary condition, $\boldsymbol{\Sigma}$

$$\int \boldsymbol{\Lambda} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \boldsymbol{\Sigma} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s, \tag{3.126}$$

with this condition holding for any arbitrary simply connected region, $\mathcal{S}$, that lives on the boundary, $\partial\mathcal{R}$.

Now apply the self-consistency condition (3.126) to the Helmholtz decomposition (3.96), in which case $\boldsymbol{\Psi} = \boldsymbol{R}$, $\boldsymbol{\Lambda} = \nabla \times \boldsymbol{F}$, and $\boldsymbol{\Sigma} = \boldsymbol{F}$. Making use of Stokes' theorem readily verifies self-consistency

$$\int \boldsymbol{\Lambda} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int (\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \boldsymbol{F} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = \oint_{\partial\mathcal{S}} \boldsymbol{\Sigma} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s. \tag{3.127}$$

We appeal to the scalar Poisson equation to conclude that self-consistency between the source and boundary conditions ensures the existence of a vector potential, $\boldsymbol{R}$, that is unique up to the gradient of a scalar. Hence, the gradient of the scalar potential is itself unique. Finally, we note that the assumed boundary condition (3.101b) for the vector potential, $\hat{\boldsymbol{n}} \times (\nabla \times \boldsymbol{R}) = \hat{\boldsymbol{n}} \times \boldsymbol{F}$, means that the scalar potential satisfies the homogeneous boundary condition

$$\hat{\boldsymbol{n}} \times \boldsymbol{F} = \hat{\boldsymbol{n}} \times (\nabla \times \boldsymbol{R}) = \hat{\boldsymbol{n}} \times (\boldsymbol{F} - \nabla D) \Longrightarrow \hat{\boldsymbol{n}} \times \nabla D = 0. \tag{3.128}$$

We thus see that ∇D is aligned parallel to $\hat{\boldsymbol{n}}$ along the boundary.

3.7.4 Orthogonality with the L^2 inner product

Consider an L^2 inner product for vector functions defined according to the volume integral of their scalar product

$$\langle \boldsymbol{A}, \boldsymbol{B} \rangle \equiv \int_{\mathcal{R}} \boldsymbol{A} \cdot \boldsymbol{B} \, \mathrm{d}V. \tag{3.129}$$

We here show that $\langle \nabla D, (\nabla \times \boldsymbol{R}) \rangle = 0$. That is, the Helmholtz decomposition (3.96) serves to decompose a vector into two orthogonal component vectors, where orthogonality is defined over the L^2 inner product (3.129). This orthogonality property is of great importance for the practical use of the Helmholtz decomposition.

Orthogonality with the normal component boundary condition

Assuming the normal component boundary conditions (3.101a), we readily find that the two vectors ∇D and $\nabla \times \boldsymbol{R}$ have a vanishing inner product

$$\langle \nabla D, \nabla \times \boldsymbol{R} \rangle = \int_{\mathcal{R}} \nabla D \cdot (\nabla \times \boldsymbol{R}) \, \mathrm{d}V = \int_{\mathcal{R}} \nabla \cdot (D \, \nabla \times \boldsymbol{R}) \, \mathrm{d}V = \int_{\partial \mathcal{R}} D \, (\nabla \times \boldsymbol{R}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = 0, \quad (3.130)$$

where the final equality made use of the homogeneous boundary condition $(\nabla \times \boldsymbol{R}) \cdot \hat{\boldsymbol{n}} = 0$.

Orthogonality with the tangential boundary condition

Now assume the tangential component boundary conditions (3.101b). For this case we make use of the following identities

$$\begin{aligned}
\nabla D \cdot (\nabla \times \boldsymbol{R}) &= \partial_i D \, (\nabla \times \boldsymbol{R})_i && \text{expose Cartesian tensor indices} && (3.131a)\\
&= \partial_i D \, \epsilon_{ijk} \, \partial_j R_k && \text{vector product as per equation (1.25d)} && (3.131b)\\
&= \partial_j (\epsilon_{ijk} \, \partial_i D \, R_k) && \text{since } \epsilon_{ijk} \partial_i \partial_j D = 0 \text{ and } \partial_j \epsilon_{ijk} = 0 && (3.131c)\\
&= -\partial_j (\epsilon_{jik} \, \partial_i D \, R_k) && \epsilon_{ijk} = -\epsilon_{jik} && (3.131d)\\
&= -\nabla \cdot (\nabla D \times \boldsymbol{R}) && \text{reintroduce Cartesian vector notation.} && (3.131e)
\end{aligned}$$

As a result we have orthogonality

$$\langle \nabla D, \nabla \times \boldsymbol{R} \rangle = \int_{\mathcal{R}} \nabla \cdot (\boldsymbol{R} \times \nabla D) \, \mathrm{d}V = \int_{\mathcal{R}} (\boldsymbol{R} \times \nabla D) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\partial \mathcal{R}} (\nabla D \times \hat{\boldsymbol{n}}) \cdot \boldsymbol{R} \, \mathrm{d}\mathcal{S} = 0, \quad (3.132)$$

where the final equality made use of the homogeneous boundary condition $(\nabla D \times \hat{\boldsymbol{n}}) = 0$.

Comments

We have shown that the set of boundary conditions (3.101a) and (3.101b) are sufficient to produce an L^2-orthogonal Helmholtz decomposition on a simply connected domain. However, we have *not* shown that these boundary conditions are necessary for orthogonality, with other boundary conditions generally available. Since orthogonality is central to the practical use of the Helmholtz decomposition, it is important to verify whether orthogonality property holds when using alternative boundary conditions.

3.7.5 Uniqueness of the decomposition

We already commented on the uniqueness of the scalar and vector potentials in Section 3.7.3. We here further that discussion by offering a uniqueness proof following a "proof by contradiction" method. For this approach we write the Helmholtz decomposition as

$$\boldsymbol{F} = -\nabla D_1 + \nabla \times \boldsymbol{R}_1 = -\nabla D_2 + \nabla \times \boldsymbol{R}_2, \quad (3.133)$$

and show that the only consistent solution has $D_1 = D_2$ and $\boldsymbol{R}_1 = \boldsymbol{R}_2$. Note that uniqueness is a function of the boundary conditions. That is, the normal component boundary conditions (3.101a) generally lead to a decomposition that is distinct from the tangential component boundary conditions (3.101b).

Uniqueness with the normal component boundary condition

From the assumed relation (3.133) we have

$$0 = -\nabla(D_1 - D_2) + \nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2). \tag{3.134}$$

Taking the scalar product of this equality with $\nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)$ and then integrating over the domain leads to

$$0 = -\int_{\mathcal{R}} [\nabla(D_1 - D_2) \cdot \nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)]\, \mathrm{d}V + \int_{\mathcal{R}} [\nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)]^2\, \mathrm{d}V. \tag{3.135}$$

The first integral vanishes, as seen by

$$-\int_{\mathcal{R}} [\nabla(D_1 - D_2) \cdot \nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)]\, \mathrm{d}V = \int_{\mathcal{R}} [\nabla D_1 \cdot (\nabla \times \boldsymbol{R}_2) + \nabla D_2 \cdot (\nabla \times \boldsymbol{R}_1)]\, \mathrm{d}V \tag{3.136a}$$

$$= \int_{\mathcal{R}} \nabla \cdot [D_1 (\nabla \times \boldsymbol{R}_2) + D_2 (\nabla \times \boldsymbol{R}_1)]\, \mathrm{d}V \tag{3.136b}$$

$$= \int_{\partial\mathcal{R}} [D_1 (\nabla \times \boldsymbol{R}_2) + D_2 (\nabla \times \boldsymbol{R}_1)] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{3.136c}$$

$$= 0, \tag{3.136d}$$

where the first equality follows from orthogonality as per equation (3.130); the second equality holds since the divergence of the curl vanishes (Section 2.3.4); the third equality follows from Gauss's divergence theorem (Section 2.7); and the fourth equality follows from the homogeneous boundary conditions, $\hat{\boldsymbol{n}} \cdot (\nabla \times \boldsymbol{R}_1) = \hat{\boldsymbol{n}} \cdot (\nabla \times \boldsymbol{R}_2) = 0$, satisfied with the normal component boundary conditions (3.101a). We are thus left with the equality

$$\int_{\mathcal{R}} [\nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)]^2\, \mathrm{d}V = 0, \tag{3.137}$$

which is generally satisfied only when $\nabla \times \boldsymbol{R}_1 = \nabla \times \boldsymbol{R}_2$ so that $\nabla D_1 = \nabla D_2$. We have thus shown that the Helmholtz decomposition $\boldsymbol{F} = -\nabla D + \nabla \times \boldsymbol{R}$ is unique with the normal component boundary conditions (3.101a).

Uniqueness with the tangential component boundary condition

Now consider the tangential component boundary conditions (3.101b). The proof proceeds much like above, only now we take the scalar product of equation (3.134) with $\nabla(D_1 - D_2)$ and integrate over the domain. In doing so we encounter the term

$$-\int_{\mathcal{R}} [\nabla(D_1 - D_2) \cdot \nabla \times (\boldsymbol{R}_1 - \boldsymbol{R}_2)]\, \mathrm{d}V = \int_{\mathcal{R}} [\nabla D_1 \cdot (\nabla \times \boldsymbol{R}_2) + \nabla D_2 \cdot (\nabla \times \boldsymbol{R}_1)]\, \mathrm{d}V \tag{3.138a}$$

$$= \int_{\mathcal{R}} \nabla \cdot [\nabla D_1 \times \boldsymbol{R}_2 + \nabla D_2 \times \boldsymbol{R}_1]\, \mathrm{d}V \tag{3.138b}$$

$$= \int_{\partial\mathcal{R}} [\boldsymbol{R}_2 \cdot (\hat{\boldsymbol{n}} \times \nabla D_1) + \boldsymbol{R}_1 \cdot (\hat{\boldsymbol{n}} \times \nabla D_2)] \tag{3.138c}$$

$$= 0, \tag{3.138d}$$

where the second equality made use of the identity (3.131e) derived when examining orthogonality, the third equality made of the divergence theorem, and the fourth equality holds according to the homogenous boundary conditions $\hat{\boldsymbol{n}} \times \nabla D = 0$ following from equation (3.101b). We are thus led

to

$$\int_{\mathcal{R}} [\nabla(D_1 - D_2)]^2 \, \mathrm{d}V = 0, \tag{3.139}$$

which generally holds only if $\nabla D_1 = \nabla D_2$ and hence $\nabla \times \boldsymbol{R}_1 = \nabla \times \boldsymbol{R}_2$. We have thus shown that the Helmholtz decomposition is unique with the tangential component boundary conditions (3.101b).

3.8 Euler's theorem for homogeneous functions

Consider a suite of Q independent variables, $X_1, X_2, ...X_Q$, and an arbitrary function of these variables, $F(X_1, X_2, ...X_Q)$. We say that this function is a *homogeneous function* of degree γ if the following property holds

$$F(\lambda\, X_1, \lambda\, X_2, ...\lambda\, X_Q) = \lambda^\gamma\, F(X_1, X_2, ...X_Q), \tag{3.140}$$

with λ an arbitrary scalar. The left hand side is the function evaluated with each of the independent variables scaled by the same number, λ. The right hand side is the function evaluated with the unscaled variables, but multiplied by the scale raised to the power γ.

A particularly remarkable and useful property of such functions can be found by taking $\partial/\partial\lambda$ on both sides of the identity (3.140). The left hand side has the following partial derivative, as found through the chain rule

$$\begin{aligned}\frac{\partial F(\lambda\, X_1, \lambda\, X_2, ...\lambda\, X_Q)}{\partial \lambda} &= \frac{\partial F(X_1, X_2, ...X_Q)}{\partial X_1}\,\frac{\partial(\lambda\, X_1)}{\partial \lambda} + ...\frac{\partial F(X_1, X_2, ...X_Q)}{\partial X_Q}\,\frac{\partial(\lambda\, X_Q)}{\partial \lambda} \\ &= \sum_{q=1}^{Q} \left[\frac{\partial F(X_1, X_2, ...X_Q)}{\partial X_q}\right]_{X_{r\neq q}} X_q \end{aligned} \tag{3.141}$$

The derivative of the right hand side of equation (3.140) is given by

$$\frac{\partial[\lambda^\gamma\, F(X_1, X_2, ...X_Q)]}{\partial \lambda} = \gamma\, \lambda^{\gamma-1}\, F(X_1, X_2, ...X_Q). \tag{3.142}$$

Bringing these results together leads to *Euler's theorem* for homogeneous functions, which is found by setting $\lambda = 1$

$$\sum_{q=1}^{Q} X_q \left[\frac{\partial F(X_1, X_2, ...X_Q)}{\partial X_q}\right]_{X_{r\neq q}} = \gamma\, F(X_1, X_2, ...X_Q). \tag{3.143}$$

Example homogeneous functions include the intensive thermodynamic properties from Part IV of this book, with such properties homogeneous functions of degree $\gamma = 0$, meaning they are scale invariant. For example, a bucket of homogeneous water has the same temperature whether or not we remove an arbitrary sample of the water. In contrast, as discussed below, extensive thermodynamic properties are homogeneous functions of degree $\gamma = 1$. Section 23.3 presents the thermodynamic implications of such mathematical properties. We also make use of these properties in proving the *Virial theorem* of classical mechanics in Section 12.7.

3.9 Evolution of time averages

In geophysical fluid mechanics, we generically refer to an equation with a time derivative, such as a parabolic or hyperbolic equation, as a *prognostic equation* or an *evolution equation*. In the

analysis of such equations, for example when analyzing simulation output or time series data, it is common to take the time average in order to focus on lower frequency behavior. This section provides a technical discussion concerning this time averaging operation, with the material here following *Bladwell et al.* (2022).

For this purpose, ignore all space coordinates and write a generic prognostic equation in the form

$$\frac{\mathrm{d}A}{\mathrm{d}t} = \mathcal{B}. \tag{3.144}$$

For example, the quantity A might be the velocity or temperature at a point in space, and $\mathcal{B}$ might be the acceleration due to pressure or the heating due to temperature diffusion. We term $\mathrm{d}A/\mathrm{d}t$ the *time tendency* of the quantity A whereas $\mathcal{B}$ is the "forcing" that gives rise to the time tendency. In the analysis of fluid flows, we commonly wish to diagnose terms appearing in the evolution equations for the purpose of ascribing physical understanding to the flow regime; e.g., what forces are more active in certain regions. Although sitting a bit outside the scope of a chapter on partial differential equations, the material in this section exposes some common questions that arise when time averaging terms appearing in the prognostic equations of geophysical fluid mechanics.

Time integration of equation (3.144) leads to

$$A(t) = A(t_0) + \int_{t_0}^{t} \mathcal{B}(s)\,\mathrm{d}s, \tag{3.145}$$

thus providing an expression for the instantaneous value of A at an arbitrary time t, assuming knowledge of the initial value, $A(t_0)$, as well as the time integral of $\mathcal{B}$. In practice, particularly when working with numerical models, we typically have access to time averages over some time interval (e.g., days, months, years, decades) rather than instantaneous (snapshot) values of A. Furthermore, instantaneous snapshots can be prone to relatively large fluctuations that expose the diagnostic calculations to numerical precision errors (e.g., small differences between relatively large fluctuating values). We are thus interested in relating time averages of A to time averages of $\mathcal{B}$.

3.9.1 Time averages

FIGURE 3.4: Example time axis for the discussion of time averaging. The labeled times, t_n, can represent, for example, days, months or years with the time interval, $\Delta T_{n,n+1} = t_{n+1} - t_n$, not necessarily the same (e.g., different number of days in a month or a leap year versus non-leap year). The smaller unlabeled time steps represent the time steps for the model's prognostic equations (e.g., days, hours, seconds, etc.), with fixed time step $\Delta\tau$.

Introduce a discrete partitioning of the time axis as in Figure 3.4 and define an unweighted time average over a chosen time interval $\Delta T_{n,n+1} = t_{n+1} - t_n > 0$

$$\overline{A}_{n,n+1} = \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} A(t)\,\mathrm{d}t \tag{3.146a}$$

$$\overline{\mathcal{B}}_{n,n+1} = \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} \mathcal{B}(t)\,\mathrm{d}t. \tag{3.146b}$$

These integrals are realized in practice as a discrete sum over the model time steps, with only the

lower limit inclusive so as to not double-count endpoints; i.e., $[t_n, t_{n+1})$. We allow for non-constant time intervals, $\Delta T_{n,n+1}$, as arises in monthly and yearly (with leap-years) time averages.

Substituting expression (3.145) into the time mean (3.146a) renders

$$\overline{A}_{n,n+1} - A(t_0) = \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} \left[\int_{t_0}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t, \tag{3.147}$$

and a similar expression over a later time interval $[t_p, t_{p+1})$ with $p \geq n+1$ leads to the difference between time averages

$$\overline{A}_{p,p+1} - \overline{A}_{n,n+1} = \frac{1}{\Delta T_{p,p+1}} \int_{t_p}^{t_{p+1}} \left[\int_{t_0}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t - \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} \left[\int_{t_0}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t. \tag{3.148}$$

The formalism allows us to take differences between time averages over intervals that are separated, such as might be of interest in taking decadal means between the beginning and end of a century, for example. Importantly, the initial value, $A(t_0)$, is absent from the difference in time means so that there are only time integrated quantities appearing in equation (3.148).

3.9.2 Massaging the double time integrals

The double time integrals in equation (3.148) can be massaged into a simpler form. We start by making the following decomposition and noting that $t_n \leq t \leq t_{n+1}$

$$\int_{t_n}^{t_{n+1}} \left[\int_{t_0}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t = \int_{t_n}^{t_{n+1}} \left[\int_{t_0}^{t_n} \mathcal{B}(s)\,\mathrm{d}s + \int_{t_n}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t \tag{3.149a}$$

$$= \Delta T_{n,n+1} \int_{t_0}^{t_n} \mathcal{B}(s)\,\mathrm{d}s + \int_{t_n}^{t_{n+1}} \left[\int_{t_n}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t. \tag{3.149b}$$

We are thus led to the difference

$$\begin{aligned} \overline{A}_{p,p+1} - \overline{A}_{n,n+1} &= \left[\int_{t_0}^{t_p} \mathcal{B}(s)\,\mathrm{d}s - \int_{t_0}^{t_n} \mathcal{B}(s)\,\mathrm{d}s \right] \\ &+ \frac{1}{\Delta T_{p,p+1}} \int_{t_p}^{t_{p+1}} \left[\int_{t_p}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t - \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} \left[\int_{t_n}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t \\ &= \int_{t_n}^{t_p} \mathcal{B}(t)\,\mathrm{d}t + \frac{1}{\Delta T_{p,p+1}} \int_{t_p}^{t_{p+1}} \left[\int_{t_p}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t - \frac{1}{\Delta T_{n,n+1}} \int_{t_n}^{t_{n+1}} \left[\int_{t_n}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t. \end{aligned} \tag{3.150}$$

The double integrals in equation (3.150) take place over triangular time domains, such as shown in Figure 3.5.

3.9.3 Making use of a double integral identity

We here derive an identity (originally due to *Cauchy* (1823)) that reduces the double integral in equation (3.150) to a single integral to expose the underlying geometry of the time windowing. For this purpose we make use of the following identity

$$\int_{t_n}^{t_{n+1}} \left[\int_{t_n}^{t} \mathcal{B}(s)\,\mathrm{d}s \right] \mathrm{d}t = \int_{t_n}^{t_{n+1}} (t_{n+1} - t)\,\mathcal{B}(t)\,\mathrm{d}t. \tag{3.151}$$

FIGURE 3.5: Gold region depicts the time integration domain used in one of the double integrals from equation (3.150) for the special case of $n = 2$. Note that the gray triangular region generally leads to a distinct integral.

To prove this identity we make the substitution $\mathscr{B}(s) = \mathrm{d}A/\mathrm{d}s$ from equation (3.144) and then show that both sides to equation (3.151) yield the same result. For the left hand side we have

$$\int_{t_n}^{t_{n+1}}\left[\int_{t_n}^{t}\mathscr{B}(s)\,\mathrm{d}s\right]\mathrm{d}t = \int_{t_n}^{t_{n+1}}\left[\int_{t_n}^{t}\frac{\mathrm{d}A(s)}{\mathrm{d}s}\,\mathrm{d}s\right]\mathrm{d}t \tag{3.152a}$$

$$= \int_{t_n}^{t_{n+1}}\left[\int_{t_n}^{t}\mathrm{d}A(s)\right]\mathrm{d}t \tag{3.152b}$$

$$= \int_{t_n}^{t_{n+1}}[A(t) - A(t_n)]\mathrm{d}t \tag{3.152c}$$

$$= \int_{t_n}^{t_{n+1}}A(t)\,\mathrm{d}t - (t_{n+1} - t_n)\,A(t_n), \tag{3.152d}$$

whereas the right hand side is

$$\int_{t_n}^{t_{n+1}}(t_{n+1} - t)\,\mathscr{B}(t)\,\mathrm{d}t = \int_{t_n}^{t_{n+1}}(t_{n+1} - t)\,\frac{\mathrm{d}A(t)}{\mathrm{d}t})\,\mathrm{d}t \tag{3.153a}$$

$$= \int_{t_n}^{t_{n+1}}(t_{n+1} - t)\,\mathrm{d}A(t) \tag{3.153b}$$

$$= \int_{t_n}^{t_{n+1}}\mathrm{d}[A(t)\,(t_{n+1} - t)] + A(t)\,\mathrm{d}t \tag{3.153c}$$

$$= -A(t_n)\,(t_{n+1} - t_n) + \int_{t_n}^{t_{n+1}}A(t)\,\mathrm{d}t, \tag{3.153d}$$

which is identical to the left hand side given by equation (3.152d). We have thus proven the double integral formula (3.151).

The right hand side of the double integral formula (3.151) can be written

$$\int_{t_n}^{t_{n+1}}(t_{n+1} - t)\,\mathscr{B}(t)\,\mathrm{d}t = t_{n+1}\,\Delta T_{n,n+1}\,\overline{\mathscr{B}}_{n,n+1} - \int_{t_n}^{t_{n+1}}t\,\mathscr{B}(t)\,\mathrm{d}t, \tag{3.154}$$

which might be useful in some contexts. However, it is awkward for our purposes since it exposes the absolute time, t_{n+1}, in the first term on the right hand side and the time, t, within the integral.

Since we generally do not hold any initial time as special (i.e., the initial time, t_0, is arbitrary), it is preferable to retain the time differences throughout the formulation. Hence, when making use of the double integral identity (3.151) we bring equation (3.150) into the form

$$\overline{A}_{p,p+1} - \overline{A}_{n,n+1} = \int_{t_n}^{t_p} \mathcal{B}(t)\,\mathrm{d}t + \int_{t_p}^{t_{p+1}} \frac{(t_{p+1}-t)\,\mathcal{B}(t)}{t_{p+1}-t_p}\,\mathrm{d}t - \int_{t_n}^{t_{n+1}} \frac{(t_{n+1}-t)\,\mathcal{B}(t)}{t_{n+1}-t_n}\,\mathrm{d}t \tag{3.155a}$$

$$= \int_{t_n}^{t_{n+1}} \frac{(t-t_n)\,\mathcal{B}(t)}{t_{n+1}-t_n}\,\mathrm{d}t + \int_{t_{n+1}}^{t_p} \mathcal{B}(t)\,\mathrm{d}t + \int_{t_p}^{t_{p+1}} \frac{(t_{p+1}-t)\,\mathcal{B}(t)}{t_{p+1}-t_p}\,\mathrm{d}t. \tag{3.155b}$$

The first right hand side term is a weighted integral with a linearly increasing weight from zero to unity, whereas the final right hand side term has a linearly descreasing weight from unity to zero. The middle term has a unity weight throughout and it vanishes if $p = n+1$, as when the averaging regions are adjacent. Figure 3.6. illustrates the time windowing used for equation (3.155b).

FIGURE 3.6: Illustrating the time window weighting used in computing the right hand side of equation (3.155b). Note that if $p = n+1$, then the middle term in equation (3.155b) and there is no plateau region of unit weight, in which case the window region becomes two adjacent triangles.

As a final means to write equation (3.155b), extend the middle term to the end of the time period and then subtract the extra piece and recombine to render

$$\overline{A}_{p,p+1} - \overline{A}_{n,n+1} = \int_{t_{n+1}}^{t_{p+1}} \mathcal{B}(t)\,\mathrm{d}t + \int_{t_n}^{t_{n+1}} \frac{(t-t_n)\,\mathcal{B}(t)}{t_{n+1}-t_n}\,\mathrm{d}t - \int_{t_p}^{t_{p+1}} \frac{(t-t_p)\,\mathcal{B}(t)}{t_{p+1}-t_p}\,\mathrm{d}t. \tag{3.156}$$

The first term on the right hand side is an unweighted integral from the end of the first interval to the end of the final interval, whereas the other two terms both have increasing weights over their respective integration intervals. This form allows for some advantages diagnostically since we only need to save unweighted integrals plus linearly increasing weighted integrals; there is no need to save decreasing weighted integrals.

Chapter 4

Fourier analysis

In this chapter we survey salient features of Fourier analysis, with particular application to the study of wave mechanics in Part IX of this book. We are only concerned in this book with classical physical systems, in which all physical quantities are real numbers. Hence, our use of complex numbers, common in Fourier analysis, is soley for convenience.

The following are some conventions for Fourier analysis followed in this book, with further context for these conventions provided later in the chapter.

- P is the period for functions represented using a Fourier series. Some treatments instead write the period as $P = 2\,L$.
- A factor of $1/2\pi$ is placed on the inverse Fourier transform as per equation (4.68c), whereas there is unity for the Fourier transform. An alternative convention, commonly used in quantum mechanics, is to place $1/\sqrt{2\pi}$ for both Fourier transform and its inverse. We have more to say about this convention in Section 4.4.7. Note that the $1/2\pi$ factor for the inverse Fourier transform in one-dimension becomes $(1/2\pi)^n$ for n-dimensions. In this chapter we focus on $n = 1$ since generalizations are straightforward.
- Fourier space is referred to as $\boldsymbol{k}$-space or *wavevector space*, which is a dual vector space (through the Fourier integral transform) to $\boldsymbol{x}$-space or *position space*. Some treatments refer to $\boldsymbol{x}$-space as "physical space". We avoid that language since for describing a physical system, $\boldsymbol{x}$-space is no more or less physical than $\boldsymbol{k}$-space. Rather, they emphasize complementary features and both offer physical insights.

CHAPTER GUIDE

Fourier analysis is particularly relevant to the study of wave mechanics considered in Part IX of this book, thus motivating the use of wave mechanics terminology in this chapter. We follow standard treatments found in physics and applied maths texts. The following offer compatible treatments to that here, with many also providing far more details: Chapters 2 and 5 of *Spiegel* (1974b), Appendix A of *Gasiorowicz* (1974), Appendix I of *Cohen-Tannoudji et al.* (1977), Sections 5.10-5.15 of *Hildebrand* (1976), Section 5.6 of *Stakgold* (2000b), and Section 6.4.2 of *Thorne and Blandford* (2017). However, as noted above, there are slight inconsistencies in conventions that warrant care if taking results from the literature, such as integral tables for Fourier transforms. This video from 3Blue1Brown provides an insightful introduction to Fourier series, and this video, also from 3Blue1Brown provides a corresponding introduction to Fourier transforms.

4.2 Complex numbers

All physical fields are real in the classical physics considered in this book. Even so, we sometimes make use of complex numbers for convenience, particularly when studying linear waves since manipulating exponentials is simpler than the alternative sines and cosines. We here summarize a few salient points for working with complex numbers in classical physics.

4.2.1 Modulus and phase

A complex number, $\mathcal{A}$, is the sum of its real and imaginary parts, which we write as[1]

$$\mathcal{A} = \mathrm{Re}[\mathcal{A}] + \mathrm{i}\ \mathrm{Im}[\mathcal{A}], \tag{4.1}$$

and its complex conjugate is given by[2]

$$\mathcal{A}^* = \mathrm{Re}[\mathcal{A}] - \mathrm{i}\ \mathrm{Im}[\mathcal{A}]. \tag{4.2}$$

[1] In this book, we generally use the LaTeX *mathcal* notation for complex numbers.

[2] The star is the symbol commonly used in mathematics to represent the complex conjugate of a complex number.

Making use of the *Euler identity*,[3]

$$e^{\mathrm{i}\alpha} = \cos\alpha + \mathrm{i}\sin\alpha, \tag{4.3}$$

allows us to write a complex number as

$$\mathcal{A} = \sqrt{\mathcal{A}\,\mathcal{A}^*}\,e^{\mathrm{i}\,\alpha} = |\mathcal{A}|\,(\cos\alpha + \mathrm{i}\sin\alpha) \quad \text{with } \tan\alpha = \mathrm{Im}[\mathcal{A}]/\,\mathrm{Re}[\mathcal{A}]. \tag{4.4}$$

The term

$$|\mathcal{A}| = \sqrt{\mathcal{A}\,\mathcal{A}^*} = \sqrt{\mathrm{Re}[\mathcal{A}]^2 + \mathrm{Im}[\mathcal{A}]^2} \tag{4.5}$$

is the *modulus* of the complex number $\mathcal{A}$. The notation $|\mathcal{A}|$ is motivated since the modulus is a generalization of the absolute value used for real numbers. The angle, α, is called the *argument* in the maths literature, whereas we refer to it as the *phase* to correspond to its use in wave mechanics.

The complex conjugate of the product of two complex numbers is the product of the conjugate, which can be shown by

$$\mathcal{A}\,\mathcal{B} = |\mathcal{A}|\,|\mathcal{B}|\,\mathrm{e}^{\mathrm{i}\,(\alpha+\beta)} \tag{4.6a}$$

$$\mathcal{A}^*\,\mathcal{B}^* = |\mathcal{A}|\,|\mathcal{B}|\,\mathrm{e}^{-\mathrm{i}\,(\alpha+\beta)} = (\mathcal{A}\,\mathcal{B})^*. \tag{4.6b}$$

When we write a complex number in this book, it is the real part that is of physical interest

$$\mathrm{Re}[\mathcal{A}] = \sqrt{\mathcal{A}\,\mathcal{A}^*}\cos\alpha. \tag{4.7}$$

Hence, for most purposes we evaluate the product, $\mathcal{A}\,\mathcal{A}$, as the product of the real parts

$$\mathrm{Re}[\mathcal{A}]\,\mathrm{Re}[\mathcal{A}] = |\mathcal{A}|^2\cos^2\alpha. \tag{4.8}$$

Likewise, with $\mathcal{B} = |\mathcal{B}|\,e^{\mathrm{i}\,\beta}$, we interpret the product $\mathcal{A}\,\mathcal{B}$ as

$$\mathrm{Re}[\mathcal{A}]\,\mathrm{Re}[\mathcal{B}] = |\mathcal{A}|\,|\mathcal{B}|\cos\alpha\cos\beta. \tag{4.9}$$

These considerations are particularly important when computing energetics of wave fields. Namely, energetics involves the product of real fields rather than the product of complex fields. So if we work with the complex representation of a wave, then we must compute its real part prior to computing the product; i.e., the real part of the product of two complex fields is not equal to the product of the real parts

$$\mathrm{Re}[\mathcal{A}\,\mathcal{B}] \neq \mathrm{Re}[\mathcal{A}]\,\mathrm{Re}[\mathcal{B}]. \tag{4.10}$$

The following identities are particularly useful when computing energetics of wave fields (e.g., Section 57.3.6)

$$\mathrm{Re}[\mathrm{i}\,\mathcal{A}] = \mathrm{Re}[\mathrm{i}\,\mathrm{Re}[\mathcal{A}] - \mathrm{Im}[\mathcal{A}]] = -\,\mathrm{Im}[\mathcal{A}] \tag{4.11a}$$

$$\mathrm{Re}[\mathcal{A}^*\,\mathcal{B}] = |\mathcal{A}|\,|\mathcal{B}|\cos(\alpha+\beta) = \mathrm{Re}[\mathcal{A}\,\mathcal{B}^*] \tag{4.11b}$$

$$\mathrm{Im}[\mathcal{A}^*\,\mathcal{B}] = |\mathcal{A}|\,|\mathcal{B}|\sin(-\alpha+\beta) = -|\mathcal{A}|\,|\mathcal{B}|\sin(\alpha-\beta) = -\,\mathrm{Im}[\mathcal{A}\,\mathcal{B}^*]. \tag{4.11c}$$

4.2.2 Phase averaging

There are many occasions in the study of waves where it is useful to average over the extent of a wave, either in space or time. Doing so provides a measure for the "wave averaged" properties.

[3] There are few equations in mathematics that are more elegant and powerful than Euler's identity.

We here add precision to this notion. For this purpose, consider two real wave fields written in the form of a traveling plane wave

$$A = \mathrm{Re}[\mathcal{A}\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)}] = |\mathcal{A}|\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\alpha) \tag{4.12a}$$

$$B = \mathrm{Re}[\mathcal{B}\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)}] = |\mathcal{B}|\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\beta), \tag{4.12b}$$

where $\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t$ is the space-time dependence found for a traveling plane wave, with $\boldsymbol{k}$ the wavevector and ω the angular frequency (e.g., Section 47.5). We wrote the complex wave amplitudes as

$$\mathcal{A} = |\mathcal{A}|\, e^{\mathrm{i}\,\alpha} \quad \text{and} \quad \mathcal{B} = |\mathcal{B}|\, e^{\mathrm{i}\,\beta}, \tag{4.13}$$

where α and β are phase shifts relative to $\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t$. To introduce the notion of a *phase average*, introduce a constant phase shift, φ, according to

$$\alpha = \alpha' + \varphi \quad \text{and} \quad \beta = \beta' + \varphi, \tag{4.14}$$

in which case we define a *phase average* as

$$\langle\cdots\rangle \equiv \frac{1}{2\pi}\int_0^{2\pi} (\cdots)\,\mathrm{d}\varphi, \tag{4.15}$$

so that a phase average is computed by sampling over the extent of a single wavelength or single wave period. The phase average of a traveling plane wave is zero

$$\langle A\rangle = \frac{1}{2\pi}\int_0^{2\pi} |\mathcal{A}|\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\alpha'+\varphi)\,\mathrm{d}\varphi = 0, \tag{4.16}$$

whereas the phase average for the product of two real wave fields does not generally vanish

$$\langle A\, B\rangle = \frac{1}{2\pi}\int_0^{2\pi} |\mathcal{A}|\,|\mathcal{B}|\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\alpha'+\varphi)\cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t+\beta'+\varphi)\,\mathrm{d}\varphi \tag{4.17a}$$

$$= \frac{1}{4\pi}\int_0^{2\pi} |\mathcal{A}|\,|\mathcal{B}|\,[\cos(\alpha'-\beta') + \cos(2\,\boldsymbol{k}\cdot\boldsymbol{x}-2\,\omega\, t+2\,\varphi+\alpha'-\beta')]\,\mathrm{d}\varphi \tag{4.17b}$$

$$= \frac{1}{2}\,|\mathcal{A}|\,|\mathcal{B}|\cos(\alpha'-\beta') \tag{4.17c}$$

$$= \frac{1}{2}\,\mathrm{Re}[\mathcal{A}^*\,\mathcal{B}] \tag{4.17d}$$

$$= \frac{1}{2}\,\mathrm{Re}[\mathcal{A}\,\mathcal{B}^*]. \tag{4.17e}$$

We see that the phase average of a product acts to remove information about the common phase, leaving only information about the modulus of the wave amplitudes and their phase difference. For example,

$$\langle A^2\rangle = |\mathcal{A}|^2/2, \tag{4.18}$$

so that the phase average for the square of a real wave field is one-half the squared modulus of the wave amplitude. Similarly, if $\mathcal{B} = \mathrm{i}\,\mathcal{A}$ then

$$\langle A\, B\rangle = \frac{1}{2\pi}\int_0^{2\pi} |\mathcal{A}|\,|\mathcal{B}|\,\cos(\pi/2)\,\mathrm{d}\varphi = 0, \tag{4.19}$$

in which we say that the real wave fields A and B are *out of phase*.

4.2.3 Euler's identity motivates the use of complex numbers

As noted earlier, there is no physical reason to introduce complex numbers in classical physics. However, there are many mathematical reasons. In particular, it is generally more convenient to use complex Fourier analysis than real Fourier analysis when establishing various theoretical results in wave mechanics.

The central reason to employ complex numbers is the shear elegance and power of Euler's identity (4.3). We encountered examples in Section 4.2.2 when discussing phase averaging. One more example concerns the sum of two waves, such as the sum of the two real wave fields (4.12a) and (4.12b)

$$C = A + B = |\mathcal{A}|\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \alpha) + |\mathcal{B}|\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \beta). \tag{4.20}$$

It is certainly possible to determine an expression for the combined wave, C, through the use of trigonometric identities. However, it is far less tedious to compute the sum via Euler's identity, in which case

$$\begin{aligned}
C &= |\mathcal{A}|\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \alpha) + |\mathcal{B}|\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \beta) && (4.21a)\\
&= \mathrm{Re}[|\mathcal{A}|\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \alpha)} + |\mathcal{B}|\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \beta)}] && (4.21b)\\
&= \mathrm{Re}[(|\mathcal{A}|\, e^{\mathrm{i}\,\alpha} + |\mathcal{B}|\, e^{\mathrm{i}\,\beta})\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t)}] && (4.21c)\\
&\equiv \mathrm{Re}[|\mathcal{C}|\, e^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \gamma)}] && (4.21d)\\
&= |\mathcal{C}|\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\, t + \gamma), && (4.21e)
\end{aligned}$$

where we introduced the complex amplitude

$$|\mathcal{C}|\, e^{\mathrm{i}\,\gamma} \equiv |\mathcal{A}|\, e^{\mathrm{i}\,\alpha} + |\mathcal{B}|\, e^{\mathrm{i}\,\beta}. \tag{4.22}$$

We can further use Euler's identity and some trigonometric identities to determine the real amplitude and phase shift for the combined wave

$$\begin{aligned}
|\mathcal{C}|^2 &= |\mathcal{A}|^2 + |\mathcal{B}|^2 + 2\,|\mathcal{A}|\,|\mathcal{B}|\cos(\alpha - \beta) && (4.23a)\\
\tan\gamma &= \frac{|\mathcal{A}|\sin\alpha + |\mathcal{B}|\sin\beta}{|\mathcal{A}|\cos\alpha + |\mathcal{B}|\cos\beta}. && (4.23b)
\end{aligned}$$

The curious reader is encouraged to compute the expression (4.21e), along with the real amplitude (4.23a) and phase shift (4.23b), using only real analysis.

4.3 Fourier series

Consider an arbitrary real function, $F(x)$, defined over the real line and that is piecewise continuous on every finite interval, as is its first derivative.[4] We also assume the function satisfies the periodicity condition[5]

$$F(x + P) = F(x), \tag{4.24}$$

[4] These properties for $F(x)$ are commonly satisfied for functions considered in this book.

[5] We use the notation x as for a spatial coordinate. Yet everything that follows holds if x is interpreted as time.

where $P > 0$ is the period.[6] The periodicity condition (4.24) holds for every point on the real line so that

$$F(x + n\,P) = F(x) \quad \text{for arbitrary positive or negative integer } n. \tag{4.25}$$

How general are periodic functions defined over the full real line? To answer this question, consider a function defined only over a finite domain, $x \in [\alpha, \beta]$, and that is periodic over that domain

$$G(\alpha) = G(\beta). \tag{4.26}$$

Quite trivially, we can construct the extended function, $F(x)$, that equals to $G(x)$ for $x \in [\alpha, \beta]$ and that is periodic over the real line, $F(x) = F(x + P)$, with period $P = \beta - \alpha$. For this reason, it is sufficient to focus on periodic functions defined over the full real line, $x \in (-\infty, \infty)$.

4.3.1 Fourier series of sines and cosines

A *Fourier series* decomposes an arbitrary periodic function in terms of the function's mean value over a period, plus an infinite series of sines and cosines[7]

$$F(x) = a_0 + \sum_{n=1}^{\infty} [a_n \cos(k_n\,x) + b_n \sin(k_n\,x)], \tag{4.27}$$

where we introduced the discrete *wavenumber*

$$k_n = 2\,\pi\,n/P. \tag{4.28}$$

Clearly the Fourier series (4.27) satisfies the periodicity condition, $F(x) = F(x + n\,P)$. Mathematically, the Fourier series is enabled by completeness of the trigonometric functions as a basis for periodic functions over a finite interval. Furthermore, the real coefficients, a_n and b_n, are determined through use of orthonormality conditions satisfied by the sine and cosine functions

$$\frac{2}{P}\int_{x_0}^{x_0+P} \cos(k_n\,x)\sin(k_m\,x)\,\mathrm{d}x = 0 \tag{4.29a}$$

$$\frac{2}{P}\int_{x_0}^{x_0+P} \cos(k_n\,x)\cos(k_m\,x)\,\mathrm{d}x = \delta_{mn} \tag{4.29b}$$

$$\frac{2}{P}\int_{x_0}^{x_0+P} \sin(k_n\,x)\sin(k_m\,x)\,\mathrm{d}x = \delta_{mn}, \tag{4.29c}$$

where δ_{mn} is the Kronecker delta tensor, which is unity if $m = n$ and vanishes otherwise.[8] Furthermore, note that the constant, x_0, is arbitrary and with the equalities holding for any value. We can understand this arbitrariness by noting that the integral over a single period of a periodic function is unchanged when shifting the start point of the integration. All that matters

[6] Some treatments, such as Chapter 2 of *Spiegel* (1974b), assume the function has period $F(x) = F(x + 2L)$, in which case $P = 2L$. In general, care is needed when making use of expressions from the literature to account for slight differences in conventions.

[7] There are certain mathematical conditions required of $F(x)$ that allow for the Fourier series to be an identity. These conditions are typically satisfied by functions encountered in physics. See Section 5.10 of *Hildebrand* (1976) for more details.

[8] As seen in Section 1.3, the Kronecker tensor is the metric for Euclidean space using Cartesian coordinates. For equations (4.29b) and (4.29c), we use the Kronecker merely as a signal of orthonormality of the trigonometric functions.

is that we extend over a single period.[9]

The orthonormality conditions (4.29a)-(4.29c) directly lead to the following expressions for the Fourier series expansion coefficients

$$a_0 = \frac{1}{P}\int_{x_0}^{x_0+P} F(x)\,\mathrm{d}x \tag{4.30a}$$

$$a_{n>0} = \frac{2}{P}\int_{x_0}^{x_0+P} \cos(k_n\,x)\,F(x)\,\mathrm{d}x \tag{4.30b}$$

$$b_{n>0} = \frac{2}{P}\int_{x_0}^{x_0+P} \sin(k_n\,x)\,F(x)\,\mathrm{d}x. \tag{4.30c}$$

Evidently, a_0 is the mean value of $F(x)$ over a single period. As an exercise, we verify equation (4.30b) by multiplying the Fourier series (4.27) by $\cos(k_m\,x)$ for $m > 0$ and integrating over a period

$$\int_{x_0}^{x_0+P} \cos(k_m\,x)\,F(x)\,\mathrm{d}x = \int_{x_0}^{x_0+P} \cos(k_m\,x)\left[a_0 + \sum_{n=1}^{\infty}[a_n\cos(k_n\,x) + b_n\sin(k_n\,x)]\right]\mathrm{d}x \tag{4.31a}$$

$$= (P/2)\,a_n\,\delta_{mn}, \tag{4.31b}$$

where the second equality used the orthogonality conditions (4.29a)-(4.29c). Analogous steps are used to verify equation (4.30c)

$$\int_{x_0}^{x_0+P} \sin(k_m\,x)\,F(x)\,\mathrm{d}x = \int_{x_0}^{x_0+P} \sin(k_m\,x)\left[a_0 + \sum_{n=1}^{\infty}[a_n\cos(k_n\,x) + b_n\sin(k_n\,x)]\right]\mathrm{d}x \tag{4.32a}$$

$$= (P/2)\,b_n\,\delta_{mn}. \tag{4.32b}$$

4.3.2 Functions with a particular parity

Any function, $F(x)$, can be written as the sum

$$F(x) = \frac{F(x)+F(-x)}{2} + \frac{F(x)-F(-x)}{2} = F^{\text{even}}(x) + F^{\text{odd}}(x). \tag{4.33}$$

The function $F^{\text{odd}}(x)$ is said to have *odd parity* since it swaps sign upon the transformation $x \to -x$

$$F^{\text{odd}}(-x) = -F^{\text{odd}}(x), \tag{4.34}$$

whereas F^{even} has *even parity* since it maintains the same value upon the transformation $x \to -x$

$$F^{\text{even}}(-x) = F^{\text{even}}(x). \tag{4.35}$$

The cosine and sine functions used in the Fourier series have even and odd parities, respectively

$$\cos(k_n\,x) = \cos(-k_n\,x) \Longrightarrow \text{cosine has even parity} \tag{4.36a}$$

$$\sin(k_n\,x) = -\sin(-k_n\,x) \Longrightarrow \text{sine has odd parity.} \tag{4.36b}$$

As we show next, the Fourier series expansion of F^{even} and F^{odd} are particularly simple relative to the full series (4.27).

[9] We make use of this arbitrariness in Section 4.4.1 where we choose a particularly useful value for developing the notion of a Fourier integral.

4.3.3 Fourier series of periodic functions with parity

Consider an even parity periodic function

$$F^{\text{even}}(x) = F^{\text{even}}(x + P), \tag{4.37}$$

so that this function has a Fourier series representation (equation (4.27))

$$F^{\text{even}}(x) = a_0 + \sum_{n=1}^{\infty}[a_n \cos(k_n\, x) + b_n \sin(k_n\, x)]. \tag{4.38}$$

Making use of the even parity property, $F^{\text{even}}(-x) = F^{\text{even}}(x)$, on the left hand side, as well as the parity properties (4.36a) and (4.36b) of the cosine and sine functions on the right hand side, leads to

$$F^{\text{even}}(x) = a_0 + \sum_{n=1}^{\infty}[a_n \cos(k_n\, x) - b_n \sin(k_n\, x)]. \tag{4.39}$$

For the series expansions (4.38) and (4.39) to be consistent for arbitrary even functions requires $b_n = 0$ for all n. Evidently, an even periodic function only has a Fourier cosine series expansion

$$F^{\text{even}}(x) = a_0 + \sum_{n=1}^{\infty} a_n \cos(k_n\, x), \tag{4.40}$$

An analogous result holds for an odd parity periodic function, in which $a_n = 0$ so that F^{odd} only has sine functions for its Fourier expansion

$$F^{\text{odd}}(x) = \sum_{n=1}^{\infty} b_n \sin(k_n\, x). \tag{4.41}$$

As a self-consistency check on the cosine expansion (4.40), compute the b_n coefficients according to equation (4.30c) whereby (setting $x_0 = -P/2$ for convenience)

$$\begin{aligned}
b_{n>0} &= \frac{2}{P}\int_{-P/2}^{P/2} \sin(k_n\, x)\, F^{\text{even}}(x)\, \mathrm{d}x && \text{equation (4.30c)} && (4.42a)\\
&= \frac{2}{P}\int_{P/2}^{-P/2} \sin(-k_n\, y)\, F^{\text{even}}(-y)\, (-\mathrm{d}y) && \text{let } x = -y && (4.42b)\\
&= \frac{2}{P}\int_{P/2}^{-P/2} \sin(k_n\, y)\, F^{\text{even}}(-y)\, \mathrm{d}y && \sin(-k_n y) = -\sin(k_n y) && (4.42c)\\
&= -\frac{2}{P}\int_{-P/2}^{P/2} \sin(k_n\, y)\, F^{\text{even}}(-y)\, \mathrm{d}y. && \text{swap integration limits} && (4.42d)\\
&= -\frac{2}{P}\int_{-P/2}^{P/2} \sin(k_n\, y)\, F^{\text{even}}(y)\, \mathrm{d}y. && \text{even parity of } F^{\text{even}}. && (4.42e)
\end{aligned}$$

The only way to satisfy this equation is for $b_n = 0$ for each n, thus verifying the expansion (4.40). The same sort of argument is used to prove that $a_n = 0$ when computing the Fourier series expansion of an odd function, thus verifying the Fourier sine expansion (4.41).

4.3.4 Complex Fourier series of exponentials

Rather than a sum of sines and cosines, we can use the Euler identity (4.3) to decompose a periodic function into a series of exponentials by introducing the complex expansion coefficients

$$c_0 = a_0 \tag{4.43a}$$
$$c_{-n} = (a_n + \mathrm{i}\, b_n)/2 \quad \text{for } n > 0 \tag{4.43b}$$
$$c_n = (a_n - \mathrm{i}\, b_n)/2 \quad \text{for } n > 0. \tag{4.43c}$$

Making use of the expressions (4.30b) and (4.30c) yields

$$c_n = \frac{1}{P} \int_{x_0}^{x_0+P} e^{-\mathrm{i}\, k_n\, x}\, F(x)\, \mathrm{d}x. \tag{4.44}$$

The reality condition, sometimes referred to as *conjugate symmetry*,

$$c_{-n} = c_n^*, \tag{4.45}$$

holds since we are only considering real functions, $F(x)$. Inverting the relations (4.43a)-(4.43c)

$$a_0 = c_0 \tag{4.46a}$$
$$a_n = c_n + c_{-n} \qquad \text{for } n > 0 \tag{4.46b}$$
$$b_n = \mathrm{i}\,(c_n - c_{-n}) \quad \text{for } n > 0 \tag{4.46c}$$

then allows us to write the Fourier series (4.27) as

$$F(x) = a_0 + \sum_{n=1}^{\infty} [a_n \cos(k_n\, x) + b_n \sin(k_n\, x)] \tag{4.47a}$$
$$= c_0 + \sum_{n=1}^{\infty} [(c_n + c_{-n}) \cos(k_n\, x) + \mathrm{i}\,(c_n - c_{-n}) \sin(k_n\, x)] \tag{4.47b}$$
$$= c_0 + \sum_{n=1}^{\infty} c_n\, [\cos(k_n\, x) + \mathrm{i} \sin(k_n\, x)] + \sum_{n=1}^{\infty} c_{-n}\, [\cos(k_n\, x) - \mathrm{i} \sin(k_n\, x)] \tag{4.47c}$$
$$= c_0 + \sum_{n=1}^{\infty} c_n\, e^{\mathrm{i}\, k_n\, x} + \sum_{n=1}^{\infty} c_{-n}\, e^{-\mathrm{i}\, k_n\, x} \tag{4.47d}$$
$$= c_0 + \sum_{n=1}^{\infty} c_n\, e^{\mathrm{i}\, k_n\, x} + \sum_{n=1}^{\infty} c_{-n}\, e^{\mathrm{i}\, k_{-n}\, x} \tag{4.47e}$$
$$= \sum_{n=-\infty}^{\infty} c_n\, e^{\mathrm{i}\, k_n\, x}, \tag{4.47f}$$

where the penultimate step made use of equation (4.28) for the wavenumber, whereby

$$k_n = 2\, \pi\, n/P = -k_{-n}. \tag{4.48}$$

The exponential expression in equation (4.47f) is commonly more convenient for manipulations, with the reality condition (4.45) of fundamental importance when working with real fields. Importantly, note that the real coefficients, a_n and b_n, are defined for $n \geq 0$ (with $b_0 = 0$) , whereas the complex coefficients, c_n, are defined for all integers.

4.3.5 Bessel-Parseval relations

Making use of the reality condition (4.45) allows us to write the square of a real periodic function as

$$F(x)\,F(x) = \left[\sum_{n=-\infty}^{\infty} c_n\, e^{\mathrm{i}\,k_n\,x}\right]\left[\sum_{m=-\infty}^{\infty} c_m\, e^{\mathrm{i}\,k_m\,x}\right] \qquad \text{equation (4.47f)} \tag{4.49a}$$

$$= \left[\sum_{n=-\infty}^{\infty} c_n\, e^{\mathrm{i}\,k_n\,x}\right]\left[\sum_{m=-\infty}^{\infty} c_{-m}\, e^{-\mathrm{i}\,k_m\,x}\right] \qquad \text{swap } m \text{ summation order} \tag{4.49b}$$

$$= \left[\sum_{n=-\infty}^{\infty} c_n\, e^{\mathrm{i}\,k_n\,x}\right]\left[\sum_{m=-\infty}^{\infty} c_m^*\, e^{-\mathrm{i}\,k_m\,x}\right] \qquad \text{reality condition (4.45)} \tag{4.49c}$$

$$= \sum_{n,m=-\infty}^{\infty} c_n\, c_m^*\, e^{\mathrm{i}\,(k_n-k_m)\,x} \qquad \text{combine sums.} \tag{4.49d}$$

The *Bessel-Parseval relation* (sometimes just referred to as *Parseval's identity*) results from performing an average of equation (4.49d) over a single period

$$\frac{1}{P}\int_{x_0}^{x_0+P} F(x)\,F(x)\,\mathrm{d}x = \sum_{n=-\infty}^{\infty} c_n\, c_n^* = \sum_{n=-\infty}^{\infty} |c_n|^2 = \sum_{n=-\infty}^{\infty} c_n\, c_{-n}. \tag{4.50}$$

To reach this identity we used the orthonormality condition holding for the exponentials

$$\frac{1}{P}\int_{x_0}^{x_0+P} e^{\mathrm{i}\,(k_n-k_m)x}\,\mathrm{d}x = \delta_{mn}, \tag{4.51}$$

and the final equality in equation (4.50) follows from the reality condition (4.45) that holds since F is real. The analogous form of Parseval's identity holds when using the sine/cosine version of the Fourier series (4.27), whereby

$$F(x)\,F(x) = \left[a_0 + \sum_{n=1}^{\infty}[a_n\cos(k_n\,x) + b_n\sin(k_n\,x)]\right]\left[a_0 + \sum_{m=1}^{\infty}[a_m\cos(k_m\,x) + b_m\sin(k_m\,x)]\right], \tag{4.52}$$

with integration and the orthonormality relations (4.29a)-(4.29c) resulting in

$$\frac{1}{P}\int_{x_0}^{x_0+P} F(x)\,F(x)\,\mathrm{d}x = a_0^2 + \frac{1}{2}\sum_{n=1}^{\infty}\big[a_n^2 + b_n^2\big]. \tag{4.53}$$

We find it useful to double-check this form of Parseval's identity while confirming we are consistently using both the real and complex forms of the Fourier series. For this purpose, substitute the expressions (4.43a)-(4.43c) for c_n into the final form of Parsevel's identity (4.50) to yield

$$\sum_{n=-\infty}^{\infty} c_n\, c_{-n} = c_0^2 + \sum_{n=-\infty}^{-1} c_n\, c_{-n} + \sum_{n=1}^{\infty} c_n\, c_{-n} = c_0^2 + 2\sum_{n=1}^{\infty} c_n\, c_{-n} = a_0^2 + \frac{1}{2}\sum_{n=1}^{\infty}\big[a_n^2 + b_n^2\big], \tag{4.54a}$$

which agrees with equation (4.53).

We can go one further step by introducing a second real and periodic function, $H(x) =$

$H(x + m\,P)$, in which case

$$H(x) = \sum_{n=-\infty}^{\infty} d_n\, e^{\mathrm{i}\,k_n\,x}. \tag{4.55}$$

The Bessel-Parseval relation (4.50) can thus be generalized to

$$\frac{1}{P}\int_{x_0}^{x_0+P} F(x)\,H(x)\,\mathrm{d}x = \sum_{n=-\infty}^{\infty} c_n\,d_n^* = \sum_{n=-\infty}^{\infty} c_n\,d_{-n}. \tag{4.56}$$

4.4 Fourier integrals

We develop *Fourier integrals* as the limit of a Fourier series and then derive some properties of these integrals. Our treatment is heuristic.[10]

4.4.1 Fourier's integral theorem

Consider a real periodic function, $F(x) = F(x + n\,P)$ with n an integer, and decompose it according to the Fourier series (4.27). Also, insert the expressions (4.30a)-(4.30c) for the expansion coefficients and specify the arbitrary constant $x_0 = -P/2$ in order to symmetrize the integral limits. The resulting Fourier series is given by

$$F(x) = \frac{2}{P}\int_{-P/2}^{P/2} F(u)\left[\frac{1}{2} + \sum_{n=1}^{\infty}[\cos(k_n\,u)\cos(k_n\,x) + \sin(k_n\,u)\sin(k_n\,x)]\right]\mathrm{d}u. \tag{4.57}$$

We now consider the limit as $P \to \infty$, in which case the period becomes infinite so that the function, $F(x)$, is no longer periodic over a finite interval. Precisely, we make the following assumptions and conversions.

- FINITE INTEGRAL: We assume the absolute value of the function has a finite integral for arbitrary P, which in turn means that its average tends to zero as P becomes infinite:

$$\int_{-P/2}^{P/2} |F(u)|\,\mathrm{d}u < \infty \Longrightarrow \lim_{P\to\infty}\frac{1}{P}\int_{-P/2}^{P/2} F(u)\,\mathrm{d}u = 0. \tag{4.58}$$

- INFINITESIMAL WAVENUMBER INCREMENT: We introduce the wavenumber increment

$$k_{n+1} - k_n = \Delta k = 2\pi/P, \tag{4.59}$$

  which becomes infinitesimal as P becomes large. As a result, the infinite sum over discrete wavenumbers transitions to an integral over continuous wavenumbers

$$\lim_{P\to\infty}\sum_{n=1}^{\infty}\frac{2}{P} = \frac{1}{\pi}\int_0^{\infty}\mathrm{d}k. \tag{4.60}$$

Making use of these results in equation (4.57) leads to

$$F(x) = \frac{1}{\pi}\int_0^{\infty}\left[\cos(k\,x)\int_{-\infty}^{\infty} F(u)\cos(k\,u)\,\mathrm{d}u + \sin(k\,x)\int_{-\infty}^{\infty} F(u)\sin(k\,u)\,\mathrm{d}u\right]\mathrm{d}k, \tag{4.61}$$

[10] The derivation of the Fourier transform equations in this section follows that given by Chapter 5 of *Spiegel* (1974b), particularly worked exercise 5.11, yet note that L in *Spiegel* (1974b) is given by $L = P/2$.

which is known as *Fourier's integral theorem*. We can bring Fourier's integral theorem a bit closer to the discrete Fourier sum (4.27) by introducing the real amplitude functions

$$A(k) \equiv \frac{1}{\pi} \int_{-\infty}^{\infty} F(u) \cos(k\,u)\,\mathrm{d}u \quad \text{and} \quad B(k) \equiv \frac{1}{\pi} \int_{-\infty}^{\infty} F(u) \sin(k\,u)\,\mathrm{d}u, \tag{4.62}$$

thus resulting in the tidy expression of the Fourier integral theorem (4.61)

$$F(x) = \int_{0}^{\infty} [A(k)\cos(k\,x) + B(k)\sin(k\,x)]\,\mathrm{d}k. \tag{4.63}$$

This version of Fourier's integral theorem forms the foundation for the remainder of this section, which largely consists of rewriting this identity in a variety of forms. Before doing so, we emphasize the following points.

All classical physical fields produce real numbers

As noted at the start of this chapter, all physical fields in this book are real. Hence, every term in equation (4.63) is real, including the amplitude functions, $A(k)$ and $B(k)$. So although many versions of Fourier analysis involve complex numbers, as we do in Section 4.4.2, the introduction of complex numbers is not fundamental.

Concerning the functional degrees of freedom

For each function, $F(x)$, there are two amplitude functions, $A(k)$ and $B(k)$. However, there is no explosion of functional degrees of freedom since $F(x)$ is defined over the full real line, $-\infty < x < \infty$ whereas $A(k)$ and $B(k)$ are defined with $k \geq 0$. The equal functional degrees of freedom manifest when using the complex version of the Fourier integral theorem in Section 4.4.2.

Parity properties of the amplitude functions

The parity properties of the amplitude functions, $A(k)$ and $B(k)$, are directly inherited from the cosine and sine functions appearing in their definition (4.62), so that we find

$$A(k) = A(-k) \quad \text{and} \quad B(k) = -B(-k). \tag{4.64}$$

As shown in Section 4.4.5, these properties are reflected in the nature of the integral theorem when representing functions, $F(x)$, with a particular parity.

Allowing the wavenumber to range over the full real line

The integral over wavenumber, k, in equation (4.62) extends from $k = 0$ to $k = \infty$. When moving to a complex representation that involves the Fourier transform in Section 4.4.2, the integral is extended to $-\infty < k < \infty$. As discussed in Section 47.6.10, the extension to $k < 0$ can be interpreted as a plane wave moving in the direction opposite to the wave with $k > 0$.

4.4.2 Fourier transform

Introducing the *Fourier transform*, $\mathcal{F}(k)$, allows us to connect to the complex Fourier series from Section (4.3.4)

$$\mathcal{F}(k) \equiv \pi\,[A(k) - \mathrm{i}\,B(k)] = \int_{-\infty}^{\infty} F(u)\,e^{-\mathrm{i}\,k\,u}\,\mathrm{d}u \quad \Longleftarrow \text{Fourier transform.} \tag{4.65}$$

We can write the Fourier integral theorem (4.63) in terms of $\mathcal{F}(k)$ according to

$$F(x) = \int_0^\infty [A(k)\cos(k\,x) + B(k)\sin(k\,x)]\,\mathrm{d}k \tag{4.66a}$$

$$= \frac{1}{2\pi}\int_0^\infty \big[\cos(k\,x)\,[\mathcal{F}(k) + \mathcal{F}^*(k)] + \mathrm{i}\,\sin(k\,x)\,[\mathcal{F}(k) - \mathcal{F}^*(k)]\,\big]\,\mathrm{d}k \tag{4.66b}$$

$$= \frac{1}{2\pi}\int_0^\infty \left[\mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x} + \big[\mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\big]^*\right]\mathrm{d}k. \tag{4.66c}$$

From its definition (4.65), we know that the complex conjugate of the Fourier transform satisfies the *conjugate symmetry* identity

$$\mathcal{F}^*(k) = \int_{-\infty}^\infty F(u)\,e^{\mathrm{i}\,k\,u}\,\mathrm{d}u = \mathcal{F}(-k). \tag{4.67}$$

This identity is directly analogous to the discrete Fourier transform identity (4.45), both of which hold due to the reality of the function, $F(x)$. We are thus led to the complex version of the Fourier integral theorem

$$F(x) = \frac{1}{2\pi}\int_0^\infty \mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k + \frac{1}{2\pi}\int_0^\infty \mathcal{F}(-k)\,\mathrm{e}^{-\mathrm{i}\,k\,x}\,\mathrm{d}k \tag{4.68a}$$

$$= \frac{1}{2\pi}\int_0^\infty \mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k - \frac{1}{2\pi}\int_0^{-\infty} \mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k \tag{4.68b}$$

$$= \frac{1}{2\pi}\int_{-\infty}^\infty \mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k. \tag{4.68c}$$

With $\mathcal{F}(k)$ referred to as the Fourier transform we sometimes refer to $F(x)$ as the *inverse Fourier transform*. Correspondingly, $\mathcal{F}(k)$ and $F(x)$ are *Fourier transform pairs*.

4.4.3 A comment on conjugate symmetry

As noted above, reality of the function, $F(x)$, is ensured by a Fourier transform that satisfies the conjugate symmetry property (4.67). We make use of this property in much of our analysis in this book, such as when studying wave packets in Chapter 47. However, there are reasons to sometimes dispense with conjugate symmetry. One example is provided in Sections 47.6.4 and 50.9.1 when providing information about a wave packet's initial tendency rather than its initial position. Evidently, the identity (4.66c) ensures that $F(x)$ is real, even if the Fourier amplitudes, $\mathcal{F}(k)$, do not satisfy conjugate symmetry. That is, conjugate symmetry is a sufficient condition to ensure $F(x)$ is real, but it is not a necessary condition.

4.4.4 Integrals over a symmetric interval

Consider the integral of a function, $F(x)$, defined over an arbitrary, but symmetric, interval $x \in [-L, L]$. Decomposing this function into its even an odd components leads to

$$\int_{-L}^L F(x)\,\mathrm{d}x = \frac{1}{2}\int_{-L}^L [F(x) + F(-x)]\,\mathrm{d}x + \frac{1}{2}\int_{-L}^L [F(x) - F(-x)]\,\mathrm{d}x \tag{4.69a}$$

$$\equiv \int_{-L}^L F^{\mathrm{even}}(x)\mathrm{d}x + \int_{-L}^L F^{\mathrm{odd}}(x)\,\mathrm{d}x. \tag{4.69b}$$

The integral of the even parity component can be written

$$\int_{-L}^{L} F^{\text{even}}(x)\,\mathrm{d}x = \int_{-L}^{0} F^{\text{even}}(x)\,\mathrm{d}x + \int_{0}^{L} F^{\text{even}}(x)\,\mathrm{d}x \tag{4.70a}$$

$$= -\int_{L}^{0} F^{\text{even}}(-x)\,\mathrm{d}x + \int_{0}^{L} F^{\text{even}}(x)\,\mathrm{d}x \tag{4.70b}$$

$$= 2\int_{0}^{L} F^{\text{even}}(x)\,\mathrm{d}x. \tag{4.70c}$$

Evidently, the integral of an even parity function over a symmetric interval equals to twice the integral over half the interval

$$\int_{-L}^{L} F^{\text{even}}(x)\,\mathrm{d}x = 2\int_{0}^{L} F^{\text{even}}(x)\,\mathrm{d}x. \tag{4.71}$$

In a similar manner we find that the integral of an odd parity function over a symmetric interval vanishes

$$\int_{-L}^{L} F^{\text{odd}}(x)\,\mathrm{d}x = \int_{-L}^{0} F^{\text{odd}}(x)\,\mathrm{d}x + \int_{0}^{L} F^{\text{odd}}(x)\,\mathrm{d}x \tag{4.72a}$$

$$= -\int_{L}^{0} F^{\text{odd}}(-x)\,\mathrm{d}x + \int_{0}^{L} F^{\text{odd}}(x)\,\mathrm{d}x \tag{4.72b}$$

$$= \int_{0}^{L} [F^{\text{odd}}(-x) + F^{\text{odd}}(x)]\,\mathrm{d}x \tag{4.72c}$$

$$= 0. \tag{4.72d}$$

We thus find that the integral of an arbitrary function over a symmetric interval is given by twice the integral of the even component over half the interval

$$\int_{-L}^{L} F(x)\,\mathrm{d}x = 2\int_{0}^{L} F_{\text{even}}(x)\,\mathrm{d}x = \int_{0}^{L} [F(x) + F(-x)]\,\mathrm{d}x. \tag{4.73}$$

We make use of these relations in developing parity conditions for Fourier transforms, in which case the integral limits are infinity, $L = \infty$.

4.4.5 Fourier cosine and sine transforms

The Fourier integral theorem simplifies when acting on functions of a particular parity. As any function can be decomposed into its even and odd parity components (see Section 4.4.4), it is common to make use of the simplification by introducing the cosine and sine transforms. These transforms allow one to work with all real valued functions when convenient, rather than the complex valued functions used with the standard Fourier transform of Section 4.4.2.

Fourier cosine transform for even functions: $F(x) = F(-x)$

Consider an even function, $F(x) = F(-x)$, and expand it in terms of the Fourier integral theorem (4.63)

$$F(x) = \int_{0}^{\infty} [A(k)\cos(k\,x) + B(k)\sin(k\,x)]\,\mathrm{d}k = \int_{0}^{\infty} [A(k)\cos(k\,x) - B(k)\sin(k\,x)]\,\mathrm{d}k, \tag{4.74}$$

which follows from the odd parity of the sine function and even parity of $F(x)$. For this relation to hold requires $B(k) = 0$, which indeed follows from its definition

$$\pi\, B(k) = \int_{-\infty}^{\infty} F(u) \sin(k\, u)\, \mathrm{d}u \tag{4.75a}$$

$$= \int_{-\infty}^{0} F(u) \sin(k\, u)\, \mathrm{d}u + \int_{0}^{\infty} F(u) \sin(k\, u)\, \mathrm{d}u \tag{4.75b}$$

$$= \int_{0}^{\infty} [-F(u) + F(u)] \sin(k\, u)\, \mathrm{d}u \tag{4.75c}$$

$$= 0. \tag{4.75d}$$

These simplification of Fourier's integral theorem motivate us to define the *Fourier cosine transform* for functions with even parity

$$F_{\mathrm{C}}(k) \equiv (\pi/2)\, A(k) = \frac{1}{2} \int_{-\infty}^{\infty} F(u) \cos(k\, u)\, \mathrm{d}u = \int_{0}^{\infty} F(u) \cos(k\, u)\, \mathrm{d}u, \tag{4.76}$$

so that Fourier's integral theorem (4.74) for an even parity function is

$$F(x) = \int_{0}^{\infty} A(k) \cos(k\, x)\, \mathrm{d}k = \frac{2}{\pi} \int_{0}^{\infty} F_{\mathrm{C}}(k) \cos(k\, x)\, \mathrm{d}k \tag{4.77}$$

Correspondingly, the Fourier cosine transform of an odd parity function vanishes.

Fourier sine transform for odd functions: $F(x) = -F(-x)$

We now consider the case of an odd function, $F(x) = -F(-x)$, and expand it in terms of the Fourier integral theorem (4.63)

$$F(x) = \int_{0}^{\infty} [A(k) \cos(k\, x) + B(k) \sin(k\, x)]\, \mathrm{d}k = \int_{0}^{\infty} [-A(k) \cos(k\, x) + B(k) \sin(k\, x)]\, \mathrm{d}k. \tag{4.78}$$

This relation is consistent only if $A(k) = 0$ for odd functions, which indeed follows from its definition

$$\pi\, A(k) = \int_{-\infty}^{\infty} F(u) \cos(k\, u)\, \mathrm{d}u \tag{4.79a}$$

$$= \int_{-\infty}^{0} F(u) \cos(k\, u)\, \mathrm{d}u + \int_{0}^{\infty} F(u) \cos(k\, u)\, \mathrm{d}u \tag{4.79b}$$

$$= \int_{0}^{\infty} [F(-u) + F(u)] \cos(k\, u)\, \mathrm{d}u \tag{4.79c}$$

$$= 0. \tag{4.79d}$$

We are thus motivated to define the *Fourier sine transform* for functions with odd parity

$$F_{\mathrm{S}}(k) \equiv (\pi/2)\, B(k) = \frac{1}{2} \int_{-\infty}^{\infty} F(u) \sin(k\, u)\, \mathrm{d}u = \int_{0}^{\infty} F(u) \sin(k\, u)\, \mathrm{d}u, \tag{4.80}$$

so that Fourier's integral theorem (4.78) for an odd parity function takes the form

$$F(x) = \int_{0}^{\infty} B(k) \sin(k\, x)\, \mathrm{d}k = \frac{2}{\pi} \int_{0}^{\infty} F_{\mathrm{S}}(k) \sin(k\, x)\, \mathrm{d}k \tag{4.81}$$

Correspondingly, the Fourier sine transform of an even parity function vanishes.

4.4.6 Parseval-Plancherel formulas

In Section 4.3.5 we showed that a Fourier series expansion of a periodic function satisfies the Parseval identities (4.50) and (4.56). Here we derive the analog for Fourier integral transforms. For this purpose, consider the integral of the product of two real functions

$$\int_{-\infty}^{\infty} G(x)\, F(x)\, \mathrm{d}x = \frac{1}{2\pi} \int_{-\infty}^{\infty} G(x) \left[\int_{-\infty}^{\infty} \mathcal{F}(k)\, e^{\mathrm{i}\, k\, x}\, \mathrm{d}k \right] \mathrm{d}x, \tag{4.82}$$

where we expressed $F(x)$ in terms of its inverse Fourier transform (4.68c). Now swap the integration order and rearrange to render

$$\int_{-\infty}^{\infty} G(x)\, F(x)\, \mathrm{d}x = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} G(x)\, e^{-\mathrm{i}\, k\, x}\, \mathrm{d}x \right]^{*} \mathcal{F}(k)\, \mathrm{d}k, \tag{4.83}$$

where we noted that

$$\left[e^{\mathrm{i}\, k\, x} \right]^{*} = e^{-\mathrm{i}\, k\, x} \quad \text{and} \quad G^{*} = G. \tag{4.84}$$

We recognize the bracketed term in equation (4.83) as the complex conjugate Fourier transform of G, thus bringing us to the identity

$$\int_{-\infty}^{\infty} G(x)\, F(x)\, \mathrm{d}x = \frac{1}{2\pi} \int_{-\infty}^{\infty} [\mathcal{G}(k)]^{*}\, \mathcal{F}(k)\, \mathrm{d}k. \tag{4.85}$$

For the special case with $G = F$ we recover the *Parseval-Plancherel formula*, commonly referred to as *Parseval's identity*

$$\int_{-\infty}^{\infty} [F(x)]^2\, \mathrm{d}x = \frac{1}{2\pi} \int_{-\infty}^{\infty} |\mathcal{F}(k)|^2\, \mathrm{d}k. \tag{4.86}$$

If $[F(x)]^2$ is proportional to the energy, then Parseval's identity expresses the identity of energy when expressed in either $\boldsymbol{x}$-space or $\boldsymbol{k}$-space.[11]

4.4.7 Concerning the placement of $1/2\pi$

There is no universal convention for the pre-factors appearing in the Fourier transform pairs (4.65) and (4.68c). That is, the unity for the Fourier transform pre-factor in equation (4.65), versus the $1/2\pi$ pre-factor for the inverse Fourier transform (4.68c), could just as well be swapped, or alternatively they could both be equal to $1/\sqrt{2\pi}$. However these factors are chosen, their product must equal to $1/2\pi$.

Furthermore, the $1/2\pi$ factor in the inverse Fourier transform (4.68c) can be eliminated through use of the *reduced wavenumber*, $\bar{k}$, defined as

$$\bar{k} = k/2\pi, \tag{4.87}$$

in which case the inverse Fourier transform (4.68c) is given by

$$F(x) = \int_{-\infty}^{\infty} \mathcal{F}(\bar{k})\, e^{\mathrm{i}\, 2\, \pi\, \bar{k} x}\, \mathrm{d}\bar{k}. \tag{4.88}$$

[11] The $1/2\pi$ factor in the Parsevel identity (4.86) can be eliminated by distributing a $1/\sqrt{2\pi}$ equally between the Fourier transform and the inverse Fourier transform. That convention is generally followed in the quantum mechanics literature but not in the fluid mechanics literature. See Section 4.4.7 for more on the 2π factor.

An analogous approach is used when working in the time-frequency domain and using the frequency, f, rather than the angular frequency, ω, where $f = \omega/2\pi$ (see Section 4.5). Even though $\bar{k}$ is somewhat more elegant, we generally work with the wavenumber, k, thus necessitating care to properly place the $1/2\pi$ factor.

4.4.8 Fourier transforms and derivatives

Here we examine some properties of the Fourier transform of derivatives. Note that for all of the results, we must assume that the function and its Fourier transform decay to zero at infinity at a rate sufficient to ensure that all integrals are all bounded.

Each derivative operation multiplies by $(\mathrm{i}\,k)^p$

Consider a function expressed as the inverse Fourier transform (4.68c)

$$F(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{F}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k, \tag{4.89}$$

where $\mathcal{F}(k)$ is the Fourier transform of $F(x)$ as per equation (4.65). Now take the p'th derivative of $F(x)$ and note that the derivative operator commutes with the $\boldsymbol{k}$-space integral

$$\frac{\mathrm{d}^p F(x)}{\mathrm{d}x^p} = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{F}(k)\,(\mathrm{i}\,k)^p\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k, \tag{4.90}$$

where we set

$$\frac{\mathrm{d}^p\,(\mathrm{e}^{\mathrm{i}\,k\,x})}{\mathrm{d}x^p} = (\mathrm{i}\,k)^p\,\mathrm{e}^{\mathrm{i}\,k\,x}. \tag{4.91}$$

Equation (4.90) indicates that each derivative increases the power of $(\mathrm{i}\,k)$ inside the $\boldsymbol{k}$-space integral, in which case the relative contribution from higher wavenumber is enhanced relative to lower wavenumbers.[12]

Furthering the above result

To further the above remarks, consider a function, $G(x)$, that is expressed as an inverse Fourier transform

$$G(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{G}(k)\,\mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k, \tag{4.92}$$

and define $G(x)$ as the p'th derivative of $F(x)$

$$G^{(p)}(x) = \frac{\mathrm{d}^p F(x)}{\mathrm{d}x^p}. \tag{4.93}$$

From equation (4.90) we make the identification

$$\mathcal{G}^{(p)}(k) = (\mathrm{i}\,k)^p\,\mathcal{F}(k). \tag{4.94}$$

[12] As noted at the start of this subsection, we must assume a finite wavenumber cutoff to ensure the integral (4.90) is bounded. That is, we must assume a length scale below which there is no structure in $F(x)$, which then means that $\mathcal{F}(k)$ vanishes (or is exponentially small) for wavenumbers above some finite wavenumber. This assumption is typically satisfied by physical fields.

Hence, the Fourier transform of the derivative of a function results in a power of $(\mathrm{i}\,k)$ for each derivative, so that, for example,

$$\mathcal{G}^{(1)}(k) = \mathrm{i}\,k\,\mathcal{F}(k) \tag{4.95a}$$

$$\mathcal{G}^{(2)}(k) = -k^2\,\mathcal{F}(k). \tag{4.95b}$$

For $p = 1$ we see that the Fourier transform of the derivative of a function has a $\pi/2$ phase shift relative to the function, whereas for $p = 2$ there is a π phase shift.

Directly computing the Fourier transform of the derivative of a function

There is yet another way to compute the Fourier transform of the derivative of a function, through use of integration by parts

$$\mathcal{G}^{(1)}(k) = \int_{-\infty}^{\infty} \frac{\mathrm{d}F}{\mathrm{d}x}\,\mathrm{e}^{-\mathrm{i}\,k\,x}\,\mathrm{d}x \tag{4.96a}$$

$$= \int_{-\infty}^{\infty} \left[\frac{\mathrm{d}(F\,\mathrm{e}^{-\mathrm{i}\,k\,x})}{\mathrm{d}x} - F\,\frac{\mathrm{d}(\mathrm{e}^{-\mathrm{i}\,k\,x})}{\mathrm{d}x}\right]\mathrm{d}x \tag{4.96b}$$

$$= \int_{-\infty}^{\infty} \left[\frac{\mathrm{d}(F\,\mathrm{e}^{-\mathrm{i}\,k\,x})}{\mathrm{d}x} + (\mathrm{i}\,k)\,F(x)\,\mathrm{e}^{-\mathrm{i}\,k\,x}\right]\mathrm{d}x. \tag{4.96c}$$

If we assume $F(x)$ decays to zero as $x \to \pm\infty$, then the total derivative vanishes, in which case we are left with

$$\mathcal{G}^{(1)}(k) = (\mathrm{i}\,k)\int_{-\infty}^{\infty} F(x)\,\mathrm{e}^{-\mathrm{i}\,k\,x}\,\mathrm{d}x = (\mathrm{i}\,k)\,\mathcal{F}(k). \tag{4.97}$$

This result agrees with equation (4.95a) derived earlier. Higher derivatives can be computed likewise.

A Fourier series example with two Fourier components

To further illustrate the role of derivatives and how they enhance the relative contribution of small scales versus large scales, consider a finite sized one-dimensional periodic domain. For a function, $F(x)$, that is periodic on this domain we can represent it according to its Fourier series (4.27), and assume there are just two non-zero wavenumbers contributing to the function

$$F(x) = a_1\cos(k_1\,x) + a_{10}\cos(k_{10}\,x). \tag{4.98}$$

As illustrated in Figure 4.1, the function $F(x)$ is the sum of a low wavenumber Fourier component, $a_1\cos(k_1\,x)$, plus a high wavenumber component, $a_{10}\cos(k_{10}\,x)$. The second derivative of this function is given by

$$\mathrm{d}^2F(x)/\mathrm{d}x^2 = -a_1\,k_1^2\cos(k_1\,x) - a_{10}\,k_{10}^2\cos(k_{10}\,x), \tag{4.99}$$

so that each wavenumber contribution is multiplied by its respective wavenumber squared. Evidently, the contribution from $n = 10$ is enhanced relative to the $n = 1$ contribution by the ratio $(k_{10}/k_1)^2 = (10/1)^2 = 100$. In general, any nonzero a_n coefficient in the expansion of a function is amplified by its respective wavenumber when taking a derivative, so that higher wavenumber features are enhanced relative to lower wavenumber features.

FIGURE 4.1: Left panel: a function comprised of two Fourier components, $F(x) = F_1(x) + F_2(x) = a_1 \cos(k_1\, x) + a_{10} \cos(k_{10}\, x)$, with a low wavenumber $k_1 = 2\,\pi/L$, and a high wavenumber, $k_{10} = 2\,\pi/(L/10)$, along with the amplitudes $a_1 = 0.95$ and $a_{10} = 0.05$. We choose $L = 1$ in arbitrary units. Given that $a_1/a_{10} = 19$, the low wavenumber component dominates $F(x)$. Right panel: the second derivative of the function, $\mathrm{d}^2F(x)/\mathrm{d}x^2 = -a_1\, k_1^2 \cos(k_1\, x) - a_{10}\, k_{10}^2 \cos(k_{10}\, x)$, which is dominated by the high wavenumber component, with the high wavenumber component having an amplitude that is roughly five times larger than the low wavenumber component, $a_{10}\, k_{10}^2/(a_1\, k_1^2) \approx 5$.

Streamfunction and vorticity example

An example from fluid mechanics occurs with a horizontally non-divergent barotropic fluid from Chapter 39. In this case the vorticity, ζ is the Laplacian of the streamfunction, ψ, so that

$$\zeta = \nabla^2 \psi. \tag{4.100}$$

Taking the Fourier transform of this equation reveals that the Fourier transform of the vorticity equals to $-k^2$ times the Fourier transform of the streamfunction. Hence, if there is any structure in the streamfunction at scale k, then the vorticity at that same scale is amplified by k^2. Consequently, the vorticity field has higher wavenumber features (i.e., smaller spatial scales) than the streamfunction field.

4.5 Time-frequency Fourier transforms

Our notation has thus far been based on space, x, and wavenumber, k. However, all formula hold whatever interpretation one gives to these coordinates, with time and frequency commonly used as well as space and wavenumber. Even so, for the time/frequency Fourier analysis we follow the typical physics convention of swapping sign in the exponents. Doing so accords with conventions in wave mechanics as pursued in in Chapter 47. With that motivation we define the time/frequency Fourier transform and its inverse according to

$$\mathcal{F}(\omega) = \int_{-\infty}^{\infty} F(t)\, e^{\mathrm{i}\,\omega\, t}\, \mathrm{d}t \tag{4.101a}$$

$$F(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathcal{F}(\omega)\, e^{-\mathrm{i}\,\omega\, t}\, \mathrm{d}\omega, \tag{4.101b}$$

where ω is the angular frequency. The time integral extends from $-\infty$ to ∞, meaning that it extends arbitrarily far in the past and arbitrarily far into the future. The negative angular frequency arises from the same symmetrization of the integral limits made when moving to the complex Fourier transform in Section 4.4.2. As in Section 47.6.10, we here find it important to

interpret the negative angular frequency, $\omega < 0$, which we do next.

4.5.1 How to interpret negative frequency for waves

As noted at the start of this chapter, we generally make use of Fourier analysis for the study of waves in Part IX of this book. When working in $\boldsymbol{x}$-space and $\boldsymbol{k}$-space, we can consider the components of a wavevector to be positive or negative given that the wavevector determines the direction of a wave. We consider this particular point in Section 47.6.10. Since information about the direction of the wave is fully carried by the wavevector, we consider the angular frequency of a wave to be a non-negative number, $\omega \geq 0$ (Section 47.4), which corresponds to a non-negative wave period, $2\pi/\omega$. Hence, when working with waves, we interpret the expression (4.101b) for the inverse Fourier transform, with its negative frequency integral limits, as a convenient means to bring the Fourier sine and cosine functions together into a single integral. We do not give any physical meaning to $\omega < 0$.

To provide details to support the above words, return to the Fourier integral theorem (4.63), only now interpreted for time and angular frequency

$$F(t) = \int_0^\infty [A(\omega)\cos(\omega\, t) + B(\omega)\sin(\omega\, t)]\mathrm{d}\omega. \tag{4.102}$$

Note that the frequency integral extends only over non-negative frequencies, consistent with ω as a frequency. In contrast, the amplitude functions are built from integrals over all time according to equation (4.62)

$$A(\omega) = \frac{1}{\pi}\int_{-\infty}^{\infty} F(t)\cos(\omega\, t)\,\mathrm{d}t \quad \text{and} \quad B(\omega) = \frac{1}{\pi}\int_{-\infty}^{\infty} F(t)\sin(\omega\, t)\,\mathrm{d}t, \tag{4.103}$$

so that[13]

$$\mathcal{F}(\omega) = \pi\,[A(\omega) + \mathrm{i}\,B(\omega)] \tag{4.104}$$

We have no problem with negative time simply because the origin of time is arbitrary. In contrast, we ascribe no physical meaning to a negative frequency, but instead interpret a negative frequency as a mathematical expedient enabling us to write equation (4.101b) in a compact form. We emphasize this point by writing

$$F(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\,\omega\, t}\,\mathcal{F}(\omega)\,\mathrm{d}\omega \qquad \text{Fourier equation (4.101b)} \tag{4.105a}$$

$$= \frac{1}{2}\int_{-\infty}^{\infty} [\cos(\omega\, t) - \mathrm{i}\sin(\omega\, t)]\,[A(\omega) + \mathrm{i}\,B(\omega)]\mathrm{d}\omega \qquad \text{Euler + equation (4.103)} \tag{4.105b}$$

$$= \frac{1}{2}\int_{-\infty}^{\infty} [A(\omega)\cos(\omega\, t) + B(\omega)\sin(\omega\, t)]\mathrm{d}\omega \qquad \text{parity properties} \tag{4.105c}$$

$$= \int_0^{\infty} [A(\omega)\cos(\omega\, t) + B(\omega)\sin(\omega\, t)]\mathrm{d}\omega \qquad \text{parity properties.} \tag{4.105d}$$

So again, we compute the inverse Fourier transform as in equation (4.101b) with a frequency interval including negative frequencies. Yet there is no physical meaning given to the negative frequencies. Instead, they simply offer the means to unify the Fourier cosine and sine amplitude functions according to the above identities.

[13] Compare equation (4.104) to equation (4.65). The sign difference arises from the sign convention: we use $\mathrm{e}^{-\mathrm{i}\,\omega\, t}$ for the time-domain inverse Fourier transform (4.101b), whereas $\mathrm{e}^{\mathrm{i}\,k\,x}$ for the space-domain inverse Fourier transform (4.68c).

4.5.2 Frequency versus angular frequency

As noted in Section 4.4.7, we can eliminate the $1/2\pi$ factor appearing in the inverse Fourier transform (4.101b) through using the frequency, f (cycles per time), rather than the angular frequency, ω (radians per time),

$$f = \omega/2\pi, \tag{4.106}$$

in which case the Fourier transform partners (4.101a) and (4.101b) take the form

$$\mathcal{F}(f) = \int_{-\infty}^{\infty} F(t)\, e^{\mathrm{i}\, 2\pi\, f\, t}\, \mathrm{d}t \tag{4.107a}$$

$$F(t) = \int_{-\infty}^{\infty} \mathcal{F}(f)\, e^{-\mathrm{i}\, 2\pi\, f\, t}\, \mathrm{d}f. \tag{4.107b}$$

Even though f is rather elegant from this perspective, we generally use the angular frequency, ω (along with the angular wavenumber, k), thus necessitating care with the placement of the $1/2\pi$ factor for the Fourier transform pair given by equations (4.101a) and (4.101b).

4.6 Example Fourier transform pairs

In this section we offer a few examples of Fourier transform pairs.

4.6.1 Dirac delta

We introduce the Dirac delta in Section 5.3

$$F(x) = \delta(x). \tag{4.108}$$

Following from its sifting property (5.7), we find that the Fourier transform (equation (4.65)) of the Dirac delta is given by

$$\mathcal{F}(k) = \int_{-\infty}^{\infty} \delta(x)\, e^{-\mathrm{i}\, k\, x}\, \mathrm{d}x = 1. \tag{4.109}$$

This result provides an extreme example of the *complementarity* relation maintained between the Fourier transform and its inverse. Namely, if a function is concentrated in $\boldsymbol{x}$-space then its Fourier transform is widely distributed in $\boldsymbol{k}$-space. The Dirac delta is infinitely concentrated in $\boldsymbol{x}$-space at the origin, whereas it has a uniform and constant distribution in $\boldsymbol{k}$-space. That is, the $\boldsymbol{x}$-space distribution is infinitesimally narrow whereas the $\boldsymbol{k}$-space distribution is infinitely broad. As a consistency check, we note the physical dimensionality of the terms in equation (4.109). The Dirac delta, $\delta(x)$, has dimensions of inverse length (Section 5.3.3), so that $\delta(x)\,\mathrm{d}x$ is non-dimensional. We thus expect its Fourier transform, $\mathcal{F}(k)$, to be non-dimensional.

It follows that the inverse Fourier transform (equation (4.68c)) of the Dirac delta is given by

$$\delta(x-x_0) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{\mathrm{i}\, k\, (x-x_0)}\, \mathrm{d}k = \frac{1}{2\pi}\int_{-\infty}^{\infty} \cos[k\,(x-x_0)]\, \mathrm{d}k = \frac{2}{2\pi}\int_{0}^{\infty} \cos[k\,(x-x_0)]\, \mathrm{d}k, \tag{4.110}$$

where we introduced an arbitrary shift from the origin, x_0. We also noted that

$$\int_{-\infty}^{\infty} \sin[k\,(x-x_0)]\, \mathrm{d}k = 0, \tag{4.111}$$

which follows since the $\boldsymbol{k}$-space integral is over a symmetric domain yet the integrand has odd $\boldsymbol{k}$-space parity. Equation (4.110) is a rather remarkable expression that can be heuristically

explained by noting that for all values of $x - x_0 \neq 0$, the cosine function oscillates so that any positive values are exactly matched by negative values, thus yielding a zero integral. However, when $x - x_0 = 0$, the integral diverges to infinity.

4.6.2 Gaussian

Consider a Gaussian function,

$$F(x) = (2\,\pi\,\sigma)^{-1/2}\, e^{-x^2/4\sigma}, \tag{4.112}$$

where $\sigma > 0$ determines the standard deviation. Its Fourier transform is given by

$$\mathcal{F}(k) = (2\,\pi\,\sigma)^{-1/2} \int_{-\infty}^{\infty} e^{-x^2/4\sigma}\, e^{-\mathrm{i}\,k\,x}\, \mathrm{d}x = e^{-\sigma\,k^2}, \tag{4.113}$$

with evaluation of this integral following from the calculus of residues.[14] We expect the Fourier transform to be real since the Gaussian has even parity so that the Fourier sine transform vanishes (see Section 4.4.5). It is remarkable that the Fourier transform of a Gaussian function is itself a Gaussian, with this property unique to the Gaussian. We also note the inverse placement of σ between the two Gaussians. Hence, if the Gaussian is narrow in $\boldsymbol{x}$-space, as per a small value of σ, then it is broad in $\boldsymbol{k}$-space, and vice versa. This behavior again reflects the complementarity property of Fourier transform pairs.

4.7 Exercises

EXERCISE 4.1: SOLVING AN ODE (PROBLEM 9.8 OF *Fetter and Walecka* (2003))
In this exercise we find a general expression for a forced ordinary differential equation using Fourier transform methods to determine the Green's function. We provide a detailed study of Green's functions in Chapter 5, though understanding of that material is not needed for this exercise.

(a) Use a Fourier transform to solve the one-dimensional ordinary differential equation

$$\frac{\mathrm{d}^2 H(x)}{\mathrm{d}x^2} - \lambda^2\, H(x) = -F(x), \tag{4.114}$$

for $\lambda > 0$ and assuming that $H(x)$ vanishes as $|x| \to \infty$. Express your answer in the form of a Green's function, $G(x, x')$, so that the solutino can be written

$$H(x) = \int_{-\infty}^{\infty} G(x, x')\, F(x')\, \mathrm{d}x'. \tag{4.115}$$

(b) Find an explicit expression for the Green's function. Hint: you might wish to make use of an integral table.

(c) What are the physical dimensions of the Green's function, G? Relative to F, what are the dimensions of H?

(d) Discuss the limit $\lambda \to 0$.

[14] We discuss a few of the steps in Section 47.7.5 when studying Gaussian wave packets.

Chapter 5

Green's function methods

In this chapter we develop the Green's function method for a variety of linear partial differential equations. Even without an analytical expression for the Green's function in a particular problem, an appreciation of Green's function methods deepens both physical and mathematical understanding of the various linear partial differential equations encountered in this book

Our treatment of the *Dirac delta* (a central component of the Green's function theory) and Green's functions is *physically formal*. By that, we offer a deductive formulation that is motivated predominantly from a physical perspective rather than serving the needs for a *mathematically rigorous* presentation.[1] The physically formal treatment presented here is supported by *heuristic* arguments taken from Newtonian gravity (see Section 13.10); electrostatics (e.g., *Jackson* (1975)); and the diffusion of temperature or matter within a continuous media.[2] The tracer and temperature examples are directly relevant to geophysical fluid mechanics and will be developed in this book, whereas the electrostatic and gravity examples provided motivation for development of Green's function methods in the 19th and 20th centuries.

READER'S GUIDE TO THIS CHAPTER

We encounter a variety of Green's functions that differ according to the differential operator and boundary conditions. Use of the common symbol, G, for Green's function and $\mathcal{G}$ for free-space Green's function minimizes the adornments otherwise needed to distinguish Green's functions. Confusion is avoided by noting that properties of any particular Green's function are specific to the section where the function is discussed. Much in this chapter is based on the treatments found in Chapter 7 of *Morse and Feshbach* (1953) as well as *Stakgold* (2000a,b). Both of these books are classics whose presentations have stood the test of time.[a]

[a] *Stakgold* (2000a,b) are reprints of books originally published in 1967.

[1] The term *physically formal* is often used in the mathematical physics and applied mathematics literature as a complement to *mathematically rigorous*. A mathematically rigorous treatment for the topics of this chapter require an array of mathematical apparatus, particularly in topics of functional analysis, that are outside our scope.

[2] A heuristic technique or argument employs a practical method not guaranteed to be fully rational or deductive from all perspectives, but is sufficient for establishing a self-consistent formalism. The study of the Dirac delta and Green's functions are examples where physical heuristics established a formalism whose mathematical rigor followed later.

5.1 Loose threads

- Biot-Savart expression for the free space vorticity as per the magnetic field. Discuss on in the context of 2d turbulence and connect to the inverse cascade arguments given in Section 11.3.1 of *Vallis* (2017). Need to understand the two-dimensional Green's function (5.40b).

5.2 Conceptual foundations

The basic mathematical problem of classical continuum field theory concerns an arbitrary field, $\psi(\boldsymbol{x}, t)$, that represents a physical property such as material tracer concentration, velocity stream-function, temperature in a continuous media, Newtonian gravitational potential, or classical electrostatic potential. The space-time structure of the field is the result of a space-time distributed source (e.g., tracer source, potential vorticity distribution, mass distribution, or electric charge distribution) along with differential operators (e.g., time derivative, Laplacian, diffusion operator, wave operator) that connect the field across points in space-time as well as initial and boundary conditions that fix the behavior of ψ in selected space-time regions.[3]

For our studies, the differential equations describing ψ are generally nonlinear. However, in some important cases it is possible to linearize the governing equations and learn much about the underlying mathematical and physical properties of the system. Furthermore, the advection-diffusion equation describing a passive tracer (Chapter 64) is linear even when the dynamical flow field is nonlinear. The conceptual foundation of the Green's function method is based on observing that if the field equations are linear, then ψ can be constructed by accumulating contributions from point-sized portions of the distributed source, including sources on the region boundaries. Let us write $G(\boldsymbol{x}, t|\boldsymbol{x}_0, t)$ for the field at an observation space-time point $(\boldsymbol{x}, t)$ (the *field point*) caused by a point source at $(\boldsymbol{x}_0, t_0)$ (the *source point*) . We then observe that $\psi(\boldsymbol{x}, t)$ caused by a source that is distributed through space and time is the product of G multiplied by the source and integrated over the space-time domain. Similar superpositions are made for the initial and boundary conditions. The function, G, is referred to as the *Green's function* in honor of the 19th century mathematician who first developed the method for studies of electrostatics.

The above arguments rely on the *superposition principle* of linear systems. It does so by finding a particular solution (the Green's function) to a linear initial-boundary value problem with a singular point source (Dirac delta) and homogeneous boundary conditions. The solution to the original problem is found by integrating (convolving) the Green's function with the boundary conditions, initial conditions, and distributed sources. The Green's function is generally simpler to determine than the solution to the original initial-boundary value problem, thus providing a key practical reason to pursue the method. Furthermore, the Green's function provides a formal inverse to the linear partial differential operator in a manner reminiscent of matrix inversion used to solve a matrix-vector problem. Just as for the matrix-vector problem, once we have the Green's function we can write the solution to any of the associated initial-boundary value problems regardless the details of the distributed source, initial data, or boundary data. Herein lies the power of the Green's function method and why it has found much use across mathematical physics.

[3] In some cases, sources are present only along spatial boundaries.

5.3 Dirac delta

The *Dirac delta* provides an idealization of a point source and it serves a core role in the study of Green's functions. In mathematics, the Dirac delta is known as a *generalized function* (e.g., chapter 5 of *Stakgold* (2000b)). We use the terse nomenclature *Dirac delta*, rather than the commonly used "delta function", to emphasize its special nature as a generalized function.

5.3.1 A point mass source

In Newtonian gravity we encounter the Poisson equation for the gravitational potential, Φ, arising from an arbitrary mass density, ρ

$$\nabla^2 \Phi = 4\,\pi\, G^{\rm grv}\,\rho, \tag{5.1}$$

with $G^{\rm grv}$ Newton's gravitational constant (see Section 13.10.1).[4] The gravitational potential for an arbitrary spherically symmetric mass, when sampled at a point outside the mass, equals to the potential of a point mass located at the origin. Making precise the notion of a "point mass" provides a venue to introduce the Dirac delta.

For that purpose, consider a mass, M, distributed uniformly within a sphere of radius ϵ and volume

$$V_\epsilon = \frac{4}{3}\,\pi\,\epsilon^3, \tag{5.2}$$

and let the sphere be centered at the origin of a coordinate system. The mass distribution thus has a density

$$\rho(\boldsymbol{x}) = M\,\delta^{(\epsilon)}(\boldsymbol{x}), \tag{5.3}$$

where we introduced the $\epsilon-$distribution

$$\delta^{(\epsilon)}(\boldsymbol{x}) \equiv \begin{cases} V_\epsilon^{-1} & \text{if } |\boldsymbol{x}| \le \epsilon \\ 0 & \text{if } |\boldsymbol{x}| > \epsilon. \end{cases} \tag{5.4}$$

By construction, an integral over a domain fully encompassing the sphere yields the mass

$$\int_{\mathcal{R}} \rho\,{\rm d}V = M \int_{\mathcal{R}} \delta^{(\epsilon)}(\boldsymbol{x})\,{\rm d}V = M, \tag{5.5}$$

with this result holding even as the radius of the sphere becomes arbitrarily small, $\epsilon \to 0$. We define the Dirac delta as the limiting ϵ-distribution

$$\delta(\boldsymbol{x}) \equiv \lim_{\epsilon\to 0} \delta^{(\epsilon)}(\boldsymbol{x}). \tag{5.6}$$

By construction, the Dirac delta arises from taking the limit of a mass source that is zero everywhere in space except at a single point, at which point the Dirac delta is formally infinite. Concerns with how to interpret the infinite value of $\delta(\boldsymbol{x})$ at the origin are ameliorated by recognizing that $\delta(\boldsymbol{x})$ is evaluated only within an integral, with these integral properties described in the remainder of this section. Connecting to the other physical analogs, the Dirac delta corresponds to a point charge in electrostatics or to a point source of trace matter within a fluid.

[4] Elsewhere in this book we write $G^{\rm grv} = G$. We add the "grv" label in this chapter and reserve G for the Green's function.

5.3.2 Sifting property

Now consider multiplying an ϵ-distribution by an arbitrary smooth function, $\psi(\boldsymbol{x})$. Since the ϵ-distribution has support only within the ϵ-sphere surrounding the origin, an integral of $\delta^{(\epsilon)}(\boldsymbol{x})\,\psi(\boldsymbol{x})$ over the sphere, in the limit that $\epsilon \to 0$, leads to the *sifting property*

$$\lim_{\epsilon\to 0}\int_{\mathcal{R}} \delta^{(\epsilon)}(\boldsymbol{x})\,\psi(\boldsymbol{x})\,\mathrm{d}V = \int_{\mathcal{R}} \delta(\boldsymbol{x})\,\psi(\boldsymbol{x})\,\mathrm{d}V = \psi(\boldsymbol{x}=0). \tag{5.7}$$

Hence, the Dirac delta acts to "sift" out the value of the function at the location of the Dirac delta source. For our purposes, the sifting property is the key defining feature of the Dirac delta.

5.3.3 Cartesian, spherical, and cylindrical-polar coordinates

We here display the form of the Dirac delta for various space dimensions and using Cartesian, spherical, and cylindrical coordinates.

Different numbers of spatial dimensions

The definition (5.6) was constructed in three space dimensions, with the Dirac delta having dimensions of inverse volume. We can use the same procedure for a single space dimension, with the one-dimensional Dirac delta having dimension of inverse length and thus satisfying the normalization condition

$$\int_{\mathcal{R}} \delta(x)\,\mathrm{d}x = 1, \tag{5.8}$$

where the integration domain, $\mathcal{R}$, includes the origin. Correspondingly, we can decompose the three-dimensional Dirac delta according to

$$\delta(\boldsymbol{x}) = \delta(x)\,\delta(y)\,\delta(z), \tag{5.9}$$

so that, with the domain $\mathcal{R}$ containing the origin, we have

$$\int_{\mathcal{R}} \delta(\boldsymbol{x})\mathrm{d}V = \int_{\mathcal{R}} \delta(x)\,\delta(y)\,\delta(z)\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z = 1. \tag{5.10}$$

Spherical coordinates

Rather than Cartesian coordinates, we sometimes find it useful to make use of the spherical coordinates[5] to render

$$\delta(\boldsymbol{x}) = \frac{\delta(r)\,\delta(\phi)\,\delta(\lambda)}{r^2\cos\phi}, \tag{5.11}$$

so that

$$\int_{\mathcal{R}} \delta(\boldsymbol{x})\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z = \int_{\mathcal{R}} \delta(\boldsymbol{x})\,r^2\cos\phi\,\mathrm{d}r\,\mathrm{d}\phi\,\mathrm{d}\lambda = \int_{\mathcal{R}} \delta(r)\,\delta(\phi)\,\delta(\lambda)\,\mathrm{d}r\,\mathrm{d}\phi\,\mathrm{d}\lambda = 1. \tag{5.12}$$

Notice how the dimensions of a particular Dirac delta equals to the inverse dimensions of its argument, so that both $\delta(\phi)$ and $\delta(\lambda)$ are dimensionless whereas $\delta(r)$ has dimensions of inverse length. Similar treatments hold for other coordinates.

[5] We discuss spherical coordinates in Section 10.2.

Cylindrical-polar coordinates

Now we consider cylindrical-polar coordinates coordinates[6] to render

$$\delta(\boldsymbol{x}) = \frac{\delta(r)\,\delta(\vartheta)\,\delta(z)}{r}, \tag{5.13}$$

so that

$$\int_{\mathcal{R}} \delta(\boldsymbol{x})\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z = \int_{\mathcal{R}} \delta(\boldsymbol{x})\,r\,\mathrm{d}r\,\mathrm{d}\vartheta\,\mathrm{d}z = \int_{\mathcal{R}} \delta(r)\,\delta(\vartheta)\,\delta(z)\,\mathrm{d}r\,\mathrm{d}\vartheta\,\mathrm{d}z = 1. \tag{5.14}$$

Again, the dimensions of a particular Dirac delta equals to the inverse dimensions of its argument, so that $\delta(\vartheta)$ is dimensionless whereas $\delta(r)$ and $\delta(z)$ have dimensions of inverse length.

5.3.4 Example $\delta^{(\epsilon)}(x)$ functions

The particular construction of the Dirac delta given by equation (5.6) is not unique. That is, there are many other suitable ϵ-distributions whose limiting behavior also result in a Dirac delta as defined by the unit normalization and sifting properties. We here list a few that appear in applications

$$\delta^{(\epsilon)}(x) = \epsilon^{-1} \quad \text{for } |x| < \epsilon/2 \text{ and } 0 \text{ for } |x| > \epsilon/2 \tag{5.15a}$$

$$\delta^{(\epsilon)}(x) = \frac{e^{-|x|/\epsilon}}{2\,\epsilon} \tag{5.15b}$$

$$\delta^{(\epsilon)}(x) = \frac{\epsilon}{\pi\,(x^2+\epsilon^2)} \tag{5.15c}$$

$$\delta^{(\epsilon)}(x) = \frac{e^{-x^2/\epsilon^2}}{\epsilon\,\pi} \tag{5.15d}$$

$$\delta^{(\epsilon)}(x) = \frac{\sin(x/\epsilon)}{x\,\epsilon} \tag{5.15e}$$

$$\delta^{(\epsilon)}(x) = \frac{\epsilon\,\sin^2(x/\epsilon)}{\pi\,x^2}. \tag{5.15f}$$

With x corresponding to a spatial position, note how each of these one-dimensional functions has dimensions of inverse length. Figure 5.1 depicts the rectangular function (5.15a) as a canonical example.

Consider the multiplication of each of the above functions $\delta^{(\epsilon)}(x)$, by a non-dimensional, continuous and bounded function, $F(x)$, that is unity at the origin, $F(0) = 1$. In this case, $F(x)\,\delta^{(\epsilon)}(x)$ still satisfies the normalization and sifting properties required of a Dirac delta

$$\lim_{\epsilon\to 0} \int_{\mathcal{R}} F(x)\,\delta^{(\epsilon)}(x)\,\mathrm{d}x = F(0) = 1 \tag{5.16a}$$

$$\lim_{\epsilon\to 0} \int_{\mathcal{R}} \psi(x)\,F(x)\,\delta^{(\epsilon)}(x)\,\mathrm{d}x = \psi(0)\,F(0) = \psi(0), \tag{5.16b}$$

so that

$$\lim_{\epsilon\to 0} F(x)\,\delta^{(\epsilon)}(x) = \delta(x). \tag{5.17}$$

Correspondingly, whenever working with a Dirac delta, if it is multiplied by a non-dimensional function $F(x)$ with $F(0) = 1$, then we can disregard this function since it does not modify the Dirac source.

[6] We discuss cylindrical-polar coordinates in Section 10.3.

FIGURE 5.1: Left panel: Heaviside step function, $\mathcal{H}(x)$, as given by equation (5.18). Right panel: the square pulse function $\delta^{(\epsilon)}(x)$ given by equation (5.15a), with $\lim_{\epsilon\to 0}\delta^{(\epsilon)}(x) = \delta(x) = \mathrm{d}\mathcal{H}(x)/\mathrm{d}x$.

5.3.5 Connection to the Heaviside step function

The Heaviside step function (Figure 5.1) is given by[7]

$$\mathcal{H}(x) = \begin{cases} 0 & \text{if } x < 0 \\ 1/2 & \text{if } x = 0 \\ 1 & \text{if } x > 0, \end{cases} \tag{5.18}$$

and it is related to the sgn function

$$\mathrm{sgn}(x) = \begin{cases} -1 & \text{if } x < 0 \\ 0 & \text{if } x = 0 \\ 1 & \text{if } x > 0, \end{cases} \tag{5.19}$$

according to

$$\mathrm{sgn}(x) = 2\,\mathcal{H}(x) - 1. \tag{5.20}$$

Both the Heaviside and sgn functions are piecewise continuous and have infinite derivatives at $x = 0$. In particular, the derivative of the Heaviside step function equals to the Dirac delta

$$\frac{\mathrm{d}\mathcal{H}(x)}{\mathrm{d}x} = \delta(x). \tag{5.21}$$

This identity is most apparent by considering the square pulse approximation to the Dirac delta given by equation (5.15a), which can be written

$$\delta(x) = \lim_{\epsilon\to 0}\delta^{(\epsilon)}(x) = \lim_{\epsilon\to 0}\frac{\mathcal{H}(x+\epsilon/2) - \mathcal{H}(x-\epsilon/2)}{\epsilon} = \frac{\mathrm{d}\mathcal{H}(x)}{\mathrm{d}x}. \tag{5.22}$$

Equivalently, we see that the Heaviside step function is the cumulative distribution of the Dirac delta

$$\int_{-\infty}^{x}\delta(x')\,\mathrm{d}x' = \int_{-\infty}^{x}\frac{\mathrm{d}\mathcal{H}(x')}{\mathrm{d}x'}\,\mathrm{d}x' = \mathcal{H}(x) - \mathcal{H}(-\infty) = \mathcal{H}(x). \tag{5.23}$$

[7] In some treatments, $\mathcal{H}(x)$ is undefined at $x = 0$. For our purposes, the properties of the Heaviside step function remain unchanged whether it is defined at $x = 0$ or not. See footnote on page 20 of *Stakgold* (2000a) for more details.

Connecting to the language of probability theory, the Dirac delta corresponds to a probability density function peaked over an infinitesimal region, whereas the Heaviside step function is the corresponding probability distribution function.

5.3.6 Sifting property for the Dirac dipole

The derivative of a Dirac delta represents an idealization of a dipole (e.g., see exercise 1.14 of *Stakgold* (2000a)). There are occasions when it is useful to know how a dipole acts on a function inside of an integral. For this purpose we make use of the identity

$$\int_{-\epsilon}^{\epsilon} \frac{\mathrm{d}[\psi(x)\,\delta(x)]}{\mathrm{d}x}\,\mathrm{d}x = \psi(\epsilon)\,\delta(\epsilon) - \psi(-\epsilon)\,\delta(-\epsilon). \tag{5.24}$$

Each term on the right hand side vanishes when $\epsilon > 0$ since the Dirac delta never fires. Applying the product rule inside of the integral renders the identity

$$\int_{-\epsilon}^{\epsilon} \frac{\mathrm{d}[\psi(x)\,\delta(x)]}{\mathrm{d}x}\,\mathrm{d}x = \int_{-\epsilon}^{\epsilon} \left[\psi(x)\,\frac{\mathrm{d}\delta(x)}{\mathrm{d}x} + \delta(x)\,\frac{\mathrm{d}\psi(x)}{\mathrm{d}x}\right]\mathrm{d}x = 0, \tag{5.25}$$

so that

$$\int_{-\epsilon}^{\epsilon} \psi(x)\,\frac{\mathrm{d}\delta(x)}{\mathrm{d}x}\,\mathrm{d}x = -\left[\frac{\mathrm{d}\psi(x)}{\mathrm{d}x}\right]_{x=0}. \tag{5.26}$$

For example, let $\psi(x) = x$, in which case

$$\int_{-\epsilon}^{\epsilon} x\,\frac{\mathrm{d}\delta(x)}{\mathrm{d}x}\,\mathrm{d}x = -1 \Longrightarrow \int_{-\epsilon}^{\epsilon} \left[x\,\frac{\mathrm{d}\delta(x)}{\mathrm{d}x} + \delta(x)\right]\mathrm{d}x = 0, \tag{5.27}$$

which can be formally written

$$x\,(\mathrm{d}\delta(x)/\mathrm{d}x) = -\delta(x). \tag{5.28}$$

5.3.7 Temporal Dirac delta and impulses

Poisson's equation for the gravitational potential is an elliptic partial differential equation (see Section 3.4), in which there is no time derivative. We now introduce the temporal Dirac delta to build towards our study of evolution equations, such as the diffusion equation of Section 5.8 and the advection-diffusion equation of Section 64.10. The temporal Dirac delta is a point source that is turned on just at one time instance and it is normalized according to

$$\int_{\mathcal{T}} \delta(t)\,\mathrm{d}t = 1, \tag{5.29}$$

where $\mathcal{T}$ is a time interval containing the source time, $t = 0$. This normalization means that $\delta(t)$ has dimensions of inverse time. The temporal Dirac delta also possesses the sifting property from Section 5.3.2, in which

$$\int_{\mathcal{T}} \delta(t)\,\psi(t)\,\mathrm{d}t = \psi(t=0). \tag{5.30}$$

In the study of transient behavior of dynamical systems, it is often of interest to examine the response of the system to an idealized force, $\mathcal{F}(t)$, where the force occurs over a small time increment. The time integral of this force is referred to as the *impulse*

$$I(\tau) = \int_{-\tau}^{\tau} \mathcal{F}(t)\,\mathrm{d}t. \tag{5.31}$$

If the force is further idealized to occur just at a single moment in time, and it is normalized to unity, then we have the *unit impulse*, which is just the integral of the Dirac delta

$$I(\tau) = 1 = \int_{-\tau}^{\tau} \delta(t)\,\mathrm{d}t. \tag{5.32}$$

The corresponding response of the dynamical system is referred to as the *impulse response function*. If the dynamical system is linear, then the impulse response function equals to the Green's function for the initial value problem. We further discuss the response function in Section 5.10.

5.3.8 Shifting the space-time position of the source

Thus far we have assumed the point source is located at the origin in space and time. But there is nothing special about that point. Correspondingly, we can arbitrarily place the source at $(\boldsymbol{x}_0, t_0)$, in which case the Dirac delta is written

$$\delta(\boldsymbol{x} - \boldsymbol{x}_0)\,\delta(t - t_0) = \delta(x - x_0)\,\delta(y - y_0)\,\delta(z - z_0)\,\delta(t - t_0). \tag{5.33}$$

Defining the region, $\mathcal{R}$, to now encompass the source point in space, $\boldsymbol{x} = \boldsymbol{x}_0$, and the time increment $\mathcal{T}$ to encompasses the source time, $t = t_0$, we have the normalization condition

$$\int_{\mathcal{R}} \int_{\mathcal{T}} \delta(\boldsymbol{x} - \boldsymbol{x}_0)\,\delta(t - t_0)\,\mathrm{d}V\,\mathrm{d}t = 1, \tag{5.34}$$

as well as the sifting property

$$\int_{\mathcal{R}} \int_{\mathcal{T}} \psi(\boldsymbol{x}, t)\,\delta(\boldsymbol{x} - \boldsymbol{x}_0)\,\delta(t - t_0)\,\mathrm{d}V\,\mathrm{d}t = \psi(\boldsymbol{x}_0, t_0). \tag{5.35}$$

5.3.9 Dirac delta carries physical dimensions

In this book, the Dirac delta carries physical dimensions given by the inverse dimension of its arguments. For example, $\delta(z)$ has dimensions inverse length (here, z is a Cartesian space coordinate), $\delta(t)$ has dimensions inverse time (t is time), and $\delta(\phi)$ is non-dimensional (ϕ is latitude in radians). The dimensional properties of a Dirac delta are manifest from its corresponding sifting property.

It is notable that many treatments, particularly in the maths literature, ignore physical dimensions. Hence, it is important to exercise care when transferring Dirac delta identities from a maths text to a physics problem.

5.4 Elliptic free space Green's functions

We introduced the Dirac delta in Section 5.3 by considering the Newtonian gravitational potential in the presence of a point mass source. This physical example also serves to introduce the notion of a Green's function, in this case a particularly simple Green's function known as a *free space Green's function* for Laplace's equation. The free space Green's function serves an important role in the analytical theory of Green's functions, and it offers us a pedagogical introduction to Green's functions. We here derive Laplace's free space Green's function as well as that for the screened Poisson equation.

5.4.1 Gravitational potential from a point mass source

Consider the gravitational potential, Φ, in the presence of a point mass source at $\boldsymbol{x} = \boldsymbol{x}_0$ in the absence of boundaries (i.e., in *free space*), and with an assumed decay of the potential when moving away from the source. In the study of Green's functions this potential is referred to as the *fundamental solution* to Laplace's equation.[8] In other contexts it is referred to as the *free space Green's function*, which is the terminology we choose since it emphasizes the absence of any spatial boundaries. From our discussion of Newtonian gravity in Section 5.3.1, the free space Green's function for Newtonian gravity satisfies the Poisson equation with a point mass source

$$\nabla^2_{\boldsymbol{x}} \Phi(\boldsymbol{x}|\boldsymbol{x}_0) = 4\,\pi\, G^{\text{grv}}\, M\, \delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad \text{and} \qquad \Phi(\boldsymbol{x}|\boldsymbol{x}_0) \to 0 \text{ as } |\boldsymbol{x}| \to \infty, \tag{5.36}$$

where we wrote the point mass density in terms of the Dirac delta

$$\rho(\boldsymbol{x}|\boldsymbol{x}_0) = M\, \delta(\boldsymbol{x} - \boldsymbol{x}_0). \tag{5.37}$$

We write the gravitational potential with two arguments, $\Phi(\boldsymbol{x}|\boldsymbol{x}_0)$. The first argument, $\boldsymbol{x}$, is the point where the field is sampled and is referred to as the *field point* or sometimes the *observation point*. The second argument, $\boldsymbol{x}_0$, is where the source is located and is thus referred to as the *source point*. Figure 5.2 summarizes the notation. The Laplacian operator acts on the field point and is written as $\nabla^2_{\boldsymbol{x}}$ for clarity. The dimensonal multiplier, $4\,\pi\, G^{\text{grv}}\, M$, acting on the Dirac delta in equation (5.36) is specific to the physical problem, here being for Newtonian gravity. In this case the Green's function has dimensions of $\text{L}^2\ \text{T}^{-2}$ since it is a gravitational potential. In other cases, the Green's function will have distinct dimensions, whereas the Dirac delta remains with the same dimensions.[9]

The gravitational potential for a point mass source, in the absence of any boundaries, is the free space Green's function for Newtonian gravity. Anticipating our study in Section 13.10.2, we write this free space Green's function in the form

$$\Phi(\boldsymbol{x}|\boldsymbol{x}_0) = -\frac{M\, G^{\text{grv}}}{|\boldsymbol{x} - \boldsymbol{x}_0|}. \tag{5.38}$$

This function is singular when sampling the field at the source location, $\boldsymbol{x} = \boldsymbol{x}_0$, and it decreases according to the inverse distance when moving away from the source.

5.4.2 Free space Green's function for Laplace's equation

Abstracting the previous discussion motivates us to define the free space Green's function, $\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0)$, for the Laplace operator as the solution to the singular Poisson equation

$$-\nabla^2_{\boldsymbol{x}} \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad \text{and} \qquad \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) \to 0 \text{ as } |\boldsymbol{x}| \to \infty. \tag{5.39}$$

It is conventional in many treatments to place a minus sign on the Laplacian operator to correspond to how it appears in the diffusion equation of Section 5.8. In one, two and three space

[8] For example, see Section 5.8 of *Stakgold* (2000b) where he provides a discussion of a variety of such free space or fundamental solutions.

[9] As emphasized throughout this book, checking for physical dimensional consistency offers a powerful means to ensure that a mathematical expression makes physical sense. If the equation is not dimensionally consistent, then something is wrong either with the maths or the physics.

FIGURE 5.2: Depicting the geometry of a typical Green's function problem in space, shown here for a finite domain whereas the free-space Green's function has no boundaries. The field or observation point, $\boldsymbol{x}$, is where the Green's function is sampled, whereas the source point, $\boldsymbol{x}_0$, is where the Dirac delta source is located. The origin is at an arbitrary position within the domain, $\mathcal{R}$, whose boundary is written $\partial\mathcal{R}$.

dimensions the free space Green's function is given by

$$\mathcal{G}(x|x_0) = -|x - x_0|/2 \qquad \text{for } x, x_0 \in \mathbb{R}^1 \tag{5.40a}$$

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = -(2\,\pi)^{-1} \ln|\boldsymbol{x} - \boldsymbol{x}_0|, \quad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \mathbb{R}^2 \tag{5.40b}$$

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = (4\,\pi\,|\boldsymbol{x} - \boldsymbol{x}_0|)^{-1} \qquad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \mathbb{R}^3. \tag{5.40c}$$

We examine the three-dimensional Green's function in Section 5.4.3 and provide a derivation in Section 5.4.4. We then derive the two-dimensional Green's function (39.2.7) in Section 5.4.5, and make use of it for studying flow around a point vortex in Section 39.2.7. Finally, we encounter the one-dimensional Green's function in Section 5.5.

5.4.3 Properties of the 3d Laplace Green's function

We here verify that the expression (5.40c) is indeed the free space Green's function for $\mathbb{R}^3$. This exercise provides some exposure to some of the formal manipulations encountered with Dirac deltas and Green's functions.

To simplify notation, place the Dirac delta at $\boldsymbol{x}_0 = 0$ so that

$$\mathcal{G}(\boldsymbol{x}|0) = \frac{1}{4\,\pi\,r}, \tag{5.41}$$

where $|\boldsymbol{x}| = r$ is the radial distance from the origin. Introduce the continuous and non-singular function

$$G^{(\epsilon)}(\boldsymbol{x}) = \frac{1}{4\pi} \begin{cases} r^{-1} & \text{for } r > \epsilon \\ \epsilon^{-1} & \text{for } r \leq \epsilon, \end{cases} \tag{5.42}$$

with $\epsilon > 0$, in which case $G^{(\epsilon)}(\boldsymbol{x})$ has removed the singularity at $r = 0$. Now consider the integral

$$\mathcal{I}(\epsilon) = \int_{r \leq \epsilon} \psi(\boldsymbol{x})\, \nabla^2 G^{(\epsilon)}(\boldsymbol{x})\, \mathrm{d}V, \tag{5.43}$$

for an arbitrary smooth function ψ and for a spherical region of radius $r = \epsilon$ centered on the origin. Since ψ is a smooth function, taking the limit as $\epsilon \to 0$ allows us to remove ψ from the integral

$$\lim_{\epsilon \to 0} \mathcal{I}(\epsilon) = \psi(r = 0) \lim_{\epsilon \to 0} \left[\int_{r \leq \epsilon} \nabla^2 G^{(\epsilon)}(\boldsymbol{x})\, \mathrm{d}V \right]. \tag{5.44}$$

Making use of the divergence theorem brings the volume integral to a surface integral over the ϵ-sphere

$$\lim_{\epsilon\to 0} \mathcal{I}(\epsilon) = \psi(r=0) \lim_{\epsilon\to 0} \left[4\,\pi \int_{r=\epsilon} \hat{\boldsymbol{r}} \cdot \nabla(1/r)\, r^2 \,\mathrm{d}r \right] = -4\,\pi\,\psi(r=0), \tag{5.45}$$

where we introduced spherical coordinates from Section 10.2. This result establishes the sifting property for $\nabla^2|\boldsymbol{x}|^{-1}$. The sifting property is the key property of a Dirac delta required for our purposes, in which case we write

$$-\nabla^2 \frac{1}{4\,\pi\,|\boldsymbol{x}|} = \delta(\boldsymbol{x}). \tag{5.46}$$

5.4.4 Deriving the 3d Laplace Green's function

As a means to further understand the free space Green's function (5.40c), we here offer a derivation using Fourier transform methods. For that purpose, introduce the Fourier representation (4.110) of the Dirac delta so that[10]

$$-\nabla^2_{\boldsymbol{x}} \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) = \frac{1}{(2\pi)^3} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}_0)}\,\mathrm{d}\boldsymbol{k}, \tag{5.47}$$

where $\mathrm{d}\boldsymbol{k}$ is the $\boldsymbol{k}$-space volume element. It is straightforward to verify that

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{(2\pi)^3} \int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}_0)}}{|\boldsymbol{k}|^2}\,\mathrm{d}\boldsymbol{k} \tag{5.48}$$

solves the Green's function equation (5.47), thus providing an integral expression for the Green's function. Now let us perform the integral to derive a closed form expression by introducing spherical coordinates in $\boldsymbol{k}$-space, whereby[11]

$$k_x = |\boldsymbol{k}|\cos\phi\cos\lambda \quad \text{and} \quad k_y = |\boldsymbol{k}|\cos\phi\sin\lambda \quad \text{and} \quad k_z = |\boldsymbol{k}|\sin\phi. \tag{5.49}$$

We are free to orient the axes as suits the integration, with the following choice rather convenient

$$\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}_0) = |\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\sin\phi, \tag{5.50}$$

thus bringing the integral (5.48) to

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{(2\pi)^3} \int_0^\infty \mathrm{d}|\boldsymbol{k}| \int_{-\pi/2}^{\pi/2} \cos\phi\,\mathrm{d}\phi \int_0^{2\pi} \mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\sin\phi}\,\mathrm{d}\lambda. \tag{5.51}$$

The λ integral trivially picks up a factor of 2π since the integrand is independent of λ. Performing the ϕ integral takes just a bit more work

$$\int_{-\pi/2}^{\pi/2} \mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\sin\phi}\,\cos\phi\,\mathrm{d}\phi = \int_{-\pi/2}^{\pi/2} \mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\sin\phi}\,\mathrm{d}(-\sin\phi) \tag{5.52a}$$

$$= -\int_{-1}^{1} \mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\alpha}\,\mathrm{d}\alpha \tag{5.52b}$$

$$= \frac{2\sin[|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|]}{|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|}, \tag{5.52c}$$

[10] This approach follows Section 28 of *Dennery and Krzywicki* (1967).
[11] See Section 10.2 for a discussion of spherical coordinates.

so that the Green's function is

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{4\pi}{(2\pi)^3}\int_0^\infty \frac{\sin[|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|]}{|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|}\,\mathrm{d}|\boldsymbol{k}| = \frac{4\pi}{(2\pi)^3\,|\boldsymbol{x}-\boldsymbol{x}_0|}\int_0^\infty \frac{\sin\alpha}{\alpha}\,\mathrm{d}\alpha. \tag{5.53}$$

The integral in equation (5.53) can be readily found in an integral table. Nonetheless, we use this integral as an opportunity to introduce a version of *Feynman's trick*, which for this integral proceeds by considering the LaPlace transform

$$F(s) = \int_0^\infty \mathrm{e}^{-s\,\alpha}\,\frac{\sin\alpha}{\alpha}\,\mathrm{d}\alpha, \tag{5.54}$$

where $s \geq 0$ is a parameter. The desired integral is $F(0)$, but we first determine $F(s)$ by taking its derivative

$$\frac{\mathrm{d}F(s)}{\mathrm{d}s} = -s\int_0^\infty \mathrm{e}^{-s\,\alpha}\,\sin\alpha\,\mathrm{d}\alpha. \tag{5.55}$$

Integrating by parts two times leads to

$$-\frac{\mathrm{d}F(s)}{\mathrm{d}s} = \frac{1}{1+s^2}, \tag{5.56}$$

which can be directly integrated to find

$$-F(s) = \tan^{-1}(s) + C. \tag{5.57}$$

To determine the constant of integration, C, take the limit $s \to \infty$, in which case $F(s)$ vanishes so that

$$C = -\lim_{s\to\infty}\tan^{-1}(s) = -\pi/2, \tag{5.58}$$

in which case

$$F(s) = -\tan^{-1}(s) + \pi/2 = \int_0^\infty \mathrm{e}^{-s\,\alpha}\,\frac{\sin\alpha}{\alpha}\,\mathrm{d}\alpha. \tag{5.59}$$

Setting $s = 0$ and noting that $\tan^{-1}(s=0) = 0$ leads to the desired integral

$$\int_0^\infty \mathrm{e}^{-s\,\alpha}\,\frac{\sin\alpha}{\alpha}\,\mathrm{d}\alpha = \pi/2, \tag{5.60}$$

and then to the free space Green's function (5.40c)

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = (4\,\pi\,|\boldsymbol{x}-\boldsymbol{x}_0|)^{-1}. \tag{5.61}$$

5.4.5 Deriving the 2d Laplace Green's function

To simplify the derivation of the two-dimensional free space Green's function (5.40b), place the Dirac delta at the origin so that $\boldsymbol{x}_0 = 0$. Furthermore, the Dirac delta induces no angular asymmetry, so that it is convenient to use polar coordinates since the Green's function is independent of the polar angle. As detailed in Section 10.3, the two-dimensional Laplacian acting on a circularly symmetric function leads to the Green's function equation

$$-\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\,\frac{\mathrm{d}\mathcal{G}}{\mathrm{d}r}\right] = \frac{\delta(r)\,\delta(\vartheta)}{r}, \tag{5.62}$$

where we made use of equation (5.13) for the polar coordinate form of the Dirac delta. Integrating over the angle to remove $\delta(\vartheta)$ renders

$$-\frac{1}{r}\frac{\mathrm{d}}{\mathrm{d}r}\left[r\,\frac{\mathrm{d}\mathcal{G}}{\mathrm{d}r}\right] = -\frac{\delta(r)}{2\,\pi\,r}. \tag{5.63}$$

One radial integral that includes the origin yields

$$\frac{\mathrm{d}\mathcal{G}}{\mathrm{d}r} = -\frac{1}{2\,\pi\,r}, \tag{5.64}$$

with a second radial integral leading to

$$\mathcal{G}(r|0) - \mathcal{G}(r_0|0) = -(2\pi)^{-1}\ln(r/r_0), \tag{5.65}$$

where $r_0 \neq 0$ is an arbitrary reference radius. Without loss of generality we set $\mathcal{G}(r_0|0) = -(2\pi)^{-1}\ln r_0$ so that

$$\mathcal{G}(r|0) = -(2\pi)^{-1}\ln r, \tag{5.66}$$

whose more general expression is given by equation (5.40b).

5.4.6 The screened Poisson equation

We briefly introduce an extension of the Coulomb potential of electrostatics by considering the following elliptic equation

$$(-\nabla^2 + \mu^2)\,\psi = \Lambda, \tag{5.67}$$

where $\mu^2 > 0$ is a constant with dimesion L^{-2}. As noted in Section 50 of *Fetter and Walecka* (2003), this equation looks occurs in the Yukawa theory of mesons and the Debye-Hückel screening of ionic solutions, hence the name *screened Poisson equation*. Although not of direct use for our studies of geophysical fluid mechanics, we see in Section 5.9.8 that there is a direct connection to the Helmholtz equation, which is of some importance for geophysical wave theory.

We consider the screened Poisson equation (5.67) in the absence of boundaries, with its corresponding free space Green's function satisfying

$$(\nabla^2 - \mu^2)\,\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = -\delta(\boldsymbol{x} - \boldsymbol{x}_0). \tag{5.68}$$

Assuming ψ and $\mathcal{G}$ suitably decay at infinity leads to the Green's function solution to equation (5.67)

$$\psi(\boldsymbol{x}_0) = \int_{\mathcal{R}} \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x})\,\mathrm{V}_{\boldsymbol{x}}. \tag{5.69}$$

Since there are no boundaries, we follow the Fourier transform method from Section 5.4.4 to derive the free space Green's function, which satisfies

$$(-\nabla^2 + \mu^2)\,\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}_0)}\,\mathrm{d}\boldsymbol{k}, \tag{5.70}$$

and has the Fourier integral expression

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{1}{(2\pi)^3}\int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{x}_0)}\,\mathrm{d}\boldsymbol{k}}{|\boldsymbol{k}|^2 + \mu^2}. \tag{5.71}$$

Setting $\mu = 0$ recovers expression (5.48) for Laplace's free space Green's function. As for that

case, we introduce spherical wavevector coordinates (5.49) and orient the axes according to $\boldsymbol{x}-\boldsymbol{x}_0$ so that equation (5.50) holds. We thus have integral

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \frac{2\pi}{(2\pi)^3}\int_0^\infty \left[\int_{-\pi/2}^{\pi/2} \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{k}|\,|\boldsymbol{x}-\boldsymbol{x}_0|\sin\phi}}{|\boldsymbol{k}|^2+\mu^2}\mathrm{d}(-\sin\phi)\right]\mathrm{d}|\boldsymbol{k}| \tag{5.72a}$$

$$= \frac{1}{2\pi^2\,|\boldsymbol{x}-\boldsymbol{x}_0|}\int_0^\infty \frac{|\boldsymbol{k}|\sin[|\boldsymbol{k}||\boldsymbol{x}-\boldsymbol{x}_0|]\,\mathrm{d}|\boldsymbol{k}|}{|\boldsymbol{k}|^2+\mu^2} \tag{5.72b}$$

$$= \frac{\mathrm{e}^{-\mu\,|\boldsymbol{x}-\boldsymbol{x}_0|}}{4\pi\,|\boldsymbol{x}-\boldsymbol{x}_0|}, \tag{5.72c}$$

where the final equality made use of an integral table.[12] The screened Poisson equation Green's function (5.72c) earns its name since it exponentially decays when moving away from the origin at $\boldsymbol{x}=\boldsymbol{x}_0$, with this behaviour contrasting to the much slower $1/|\boldsymbol{x}-\boldsymbol{x}_0|$ decay of the electrostatics Coulomb potential with $\mu=0$.

5.5 One-dimensional Poisson's equation

To illustrate the Green's function method for solving differential equations, consider the one-dimensional Poisson equation on a finite domain

$$-\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = \Lambda \quad \text{for } -L \le x \le L. \tag{5.73}$$

The corresponding Green's function satisfies

$$-\frac{\mathrm{d}^2 G(x|x_0)}{\mathrm{d}x^2} = \delta(x-x_0) \quad \text{for } -L \le x, x_0 \le L, \tag{5.74}$$

with boundary conditions taken as the homogeneous form of whatever boundary conditions are satisfied by ψ. For the Green's function problem, the source, $\Lambda(x)$, appearing in the ψ equation has been replaced by the Dirac delta, $\delta(x-x_0)$. Since the Dirac delta has dimensions of inverse length, equation (5.74) implies that the Green's function has dimensions of length. Keeping track of physical dimensions offers an essential means to check the integrity of the mathematical manipulations.

5.5.1 Integral expression for ψ in terms of G

Multiplying the differential equation (5.73) with G and the Green's function equation (5.74) with ψ, and then subtracting, yields

$$-G(x|x_0)\,\frac{\mathrm{d}^2\psi(x)}{\mathrm{d}x^2} + \psi(x)\,\frac{\mathrm{d}^2 G(x|x_0)}{\mathrm{d}x^2} = G(x|x_0)\,\Lambda(x) - \psi(x)\,\delta(x-x_0). \tag{5.75}$$

[12] See Section 50 of *Fetter and Walecka* (2003) for details of the calculation.

Integrating this equation over the domain, and use of the sifting property (5.7), yields

$$\psi(x_0) = \int_{-L}^{L} G(x|x_0)\,\Lambda(x)\,\mathrm{d}x + \int_{-L}^{L}\left[G(x|x_0)\,\frac{\mathrm{d}^2\psi(x)}{\mathrm{d}x^2} - \psi(x)\,\frac{\mathrm{d}^2 G(x|x_0)}{\mathrm{d}x^2}\right]\mathrm{d}x \tag{5.76a}$$

$$= \int_{-L}^{L} G(x|x_0)\,\Lambda(x)\,\mathrm{d}x + \int_{-L}^{L}\frac{\mathrm{d}}{\mathrm{d}x}\left[G(x|x_0)\,\frac{\mathrm{d}\psi}{\mathrm{d}x} - \psi(x)\,\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]\mathrm{d}x \tag{5.76b}$$

$$= \int_{-L}^{L} G(x|x_0)\,\Lambda(x)\,\mathrm{d}x + \left[G(x|x_0)\,\frac{\mathrm{d}\psi}{\mathrm{d}x}\right]_{x=-L}^{x=L} - \left[\psi(x)\,\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=-L}^{x=L}, \tag{5.76c}$$

where the final expression exposed the boundary contributions. Specializing to *Dirichlet boundary conditions*, with $G(x=\pm L|x_0)=0$, renders

$$\psi^{\text{Dirichlet}}(x_0) = \int_{-L}^{L} G(x|x_0)\,\Lambda(x)\,\mathrm{d}x - \left[\psi(x)\,\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=L} + \left[\psi(x)\,\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=-L}, \tag{5.77}$$

whereas the solution with *Neumann boundary conditions*, where $\mathrm{d}G(x=\pm L|x_0)/\mathrm{d}x=0$, is

$$\psi^{\text{Neumann}}(x_0) = \int_{-L}^{L} G(x|x_0)\,\Lambda(x)\,\mathrm{d}x + \left[G(x|x_0)\,\frac{\mathrm{d}\psi(x)}{\mathrm{d}x}\right]_{x=L} - \left[G(x|x_0)\,\frac{\mathrm{d}\psi(x)}{\mathrm{d}x}\right]_{x=-L}. \tag{5.78}$$

5.5.2 Preliminary steps for obtaining the Green's function

The solution to the Green's function equation (5.74) is given by the linear functions

$$G(x|x_0) = \begin{cases} A\,x + B & \text{for } -L \le x \le x_0 \\ C\,x + D & \text{for } x_0 \le x \le L. \end{cases} \tag{5.79}$$

The constants A, B, C, D are determined by the following conditions: (i) jump condition for $\mathrm{d}G(x|x_0)/\mathrm{d}x$ at $x=x_0$, (ii) continuity of $G(x|x_0)$ at $x=x_0$, and (iii) homogeneous boundary conditions at $x=\pm L$.

Jump condition for the Green's function derivative at $x=x_0$

The Green's function differential equation (5.74) shows that the second derivative to the Green's function equals to a Dirac delta. Integrating this equation over an arbitrary region straddling $x=x_0$ yields the finite jump condition for the first derivative of the Green's function

$$\lim_{\epsilon\to 0}\left[\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=x_0+\epsilon} - \lim_{\epsilon\to 0}\left[\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=x_0-\epsilon} = -1. \tag{5.80}$$

That is, the derivative of the Green's function is not continuous across the point $x=x_0$. Instead, it has a finite jump.[13] Making use of this condition in equation (5.79) leads to $C=A-1$ so that

$$G(x|x_0) = \begin{cases} A\,x + B & \text{for } -L \le x \le x_0 \\ (A-1)\,x + D & \text{for } x_0 \le x \le L. \end{cases} \tag{5.81}$$

[13] The jump condition on the derivative of the Green's function is related to the jump found in the Heaviside step function discussed in Section 5.3.5. Namely, both the derivative of the Heaviside and the second derivative of the Green's function render a Dirac delta.

Continuity of the Green's function at $x = x_0$

A finite jump in the derivative at $x = x_0$ means that the Green's function is continuous at this point

$$\lim_{\epsilon \to 0} G(x = x_0 + \epsilon | x_0) = \lim_{\epsilon \to 0} G(x = x_0 - \epsilon | x_0). \tag{5.82}$$

Making use of this condition in equation (5.81) yields

$$G(x|x_0) = \begin{cases} A\,x - x_0 + D & \text{for } -L \le x \le x_0 \\ (A-1)\,x + D & \text{for } x_0 \le x \le L. \end{cases} \tag{5.83}$$

5.5.3 Green's function satisfying Dirichlet boundary conditions

The two constants A and D in equation (5.83) are determined by specifying the boundary conditions. With Dirichlet conditions we set $G(x = \pm L|x_0) = 0$, which then leads to

$$G(x|x_0) = \frac{1}{2\,L} \begin{cases} (L - x_0)\,(L + x) & \text{for } -L \le x \le x_0 \\ (L - x)\,(L + x_0) & \text{for } x_0 \le x \le L, \end{cases} \tag{5.84}$$

which is depicted in Figure 5.3. The structure of this function motivates the name *impulse response function* or *influence function*. We identify the following properties of this Green's function, with these properties also appearing in the higher dimension elliptical problems discussed in Sections 5.6 and 5.7.

Reciprocity condition

The Green's function (5.84) satisfies the symmetry condition

$$G(x|x_0) = G(x_0|x), \tag{5.85}$$

so that the Green's function is invariant under interchange of the source point, x_0, and field point, x. In Section 5.6.4, we show how this *reciprocity condition* generally holds for all Green's functions of the Poisson equation.

Sum of free-space Green's function plus harmonic function

We can write the Green's function (5.84) as the sum of the free space Green's function (5.40a) plus a harmonic function

$$G(x|x_0) = -|x - x_0|/2 + \frac{L^2 - x\,x_0}{2\,L} = \mathcal{G}(x|x_0) + H(x|x_0), \tag{5.86}$$

where

$$-\frac{\mathrm{d}^2 H(x|x_0)}{\mathrm{d}x^2} = 0 \quad \text{and} \quad H(x = \pm L|x_0) = -\mathcal{G}(x = \pm L|x_0). \tag{5.87}$$

As shown in Section 5.6.3, the Green's function for an elliptic partial differential equation generally takes on this form.

Boundary condition satisfied by Green's function derivative

The Green's function is itself independent of the Dirichlet boundary conditions placed on the function ψ, as well as the source function Λ. Hence, we can establish general properties of the Green's function by considering special cases for the boundary conditions and source function.

For this purpose, set $\Lambda = 0$ and $\psi(x = -L) = \psi(x = L)$, in which case ψ is itself a constant throughout the domain. The Dirichlet solution (5.77) then leads to the condition placed on the Green's function derivatives at the boundaries

$$\left[\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=L} - \left[\frac{\mathrm{d}G(x|x_0)}{\mathrm{d}x}\right]_{x=-L} = -1. \tag{5.88}$$

Interpreting G as a tracer concentration, this result means that the positive tracer input by the Dirac delta source is exactly balanced by a negative tracer departing the region through its boundaries. It is by this balance that the Green's function is able to maintain its homogeneous Dirichlet boundary condition, $G(x = \pm L|x_0) = 0$. A similar interpretation holds when G is the gravitational potential induced by the Dirac source in the region interior. In this case, for the gravitational potential to vanish on the boundaries, the positive gravitational acceleration induced by the Dirac delta source at $x = x_0$ must be compensated by an opposing gravitational acceleration along the boundaries.

FIGURE 5.3: The Green's function (5.84) for the one-dimensional Poisson equation satisfying Dirichlet boundary conditions at $x = \pm L$. The Dirac delta source is located at $x = x_0$, which is the point where the Green's function has its maximum displacement of $(L^2 - x_0^2)/(2\,L)$.

5.5.4 Green's function satisfying Neumann boundary conditions

A constant is the only solution to $-\mathrm{d}^2G/\mathrm{d}x^2 = 0$ with homogeneous Neumann boundary conditions, $\mathrm{d}G/\mathrm{d}x = 0$ at $x = \pm L$. However, a constant cannot satisfy the derivative jump condition at $x = x_0$, and thus cannot satisfy the differential equation $-\mathrm{d}^2G/\mathrm{d}x^2 = \delta(x - x_0)$. Hence, there is no Green's function satisfying Neumann boundary conditions for a one-dimensional bounded domain. As we will see, in higher space dimensions there are nontrivial Green's functions for the Neumann boundary case. Even so, this result identifies a key condition required for a Green's function to exist. Namely, if the completely homogeneous problem ($\Lambda = 0$ with homogeneous boundary conditions) only has the trivial solution, then the Green's function exists and is unique. For the case of Dirichlet boundary conditions

$$-\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = 0 \quad \text{and} \quad \psi(x = \pm L) = 0 \Longrightarrow \psi = 0, \tag{5.89}$$

whereas for Neumann boundary conditions

$$-\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = 0 \quad \text{and} \quad \left[\frac{\mathrm{d}\psi}{\mathrm{d}x}\right]_{x=\pm L} = 0 \Longrightarrow \psi = \text{constant}. \tag{5.90}$$

The existence of a nontrival (an arbitrary constant) solution to the one-dimensional homogeneous Neumann boundary value problem signals the absence of a corresponding Green's function.

5.5.5 Uniqueness of the Dirichlet solution

Consider again the Dirichlet problem

$$-\frac{\mathrm{d}^2\psi}{\mathrm{d}x^2} = \Lambda \quad \text{for } -L \leq x \leq L \quad \text{with} \quad \psi(x = \pm L) = \text{prescribed constants.} \tag{5.91}$$

To prove that the solution to this problem is unique, assume there are two distinct solution, ψ_A and ψ_B, and define $\Psi = \psi_A - \psi_B$. By construction, Ψ satisfies Laplace's equation with homogeneous Dirichlet boundaries

$$-\frac{\mathrm{d}^2\Psi}{\mathrm{d}x^2} = 0 \quad \text{for } -L \leq x \leq L, \quad \Psi(x = \pm L) = 0. \tag{5.92}$$

As discussed above, the only solution to this problem is $\Psi = 0$, which means that $\psi_A = \psi_B$, hence proving that the solution to equation (5.91) is unique. Uniqueness holds regardless the source function, so that the Green's function from Section 5.5.3 is also unique.

5.6 Poisson's equation with Dirichlet boundaries

In this section we develop the Green's function method for Poisson's equation in three-dimensions with a *Dirichlet boundary condition*

$$-\nabla^2\psi = \Lambda, \quad \text{for } \boldsymbol{x} \in \mathcal{R} \qquad \text{and} \qquad \psi = \sigma, \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.93}$$

We separately consider the Neumann boundary condition in Section 5.7, whereby $\hat{\boldsymbol{n}}\cdot\nabla\psi$ is specified on the boundary rather than ψ itself. Although the Dirichlet and Neumann problems share many features, there are sufficient distinctions to warrant a separate treatment.

In the following, our mathematical goal is to determine an integral expression for ψ in terms of the distributed source, $\Lambda(\boldsymbol{x})$, and boundary data, $\sigma(\boldsymbol{x})$. Before doing so, we highlight the two elements determining the solution to any boundary value problem. The first element concerns the region interior, $\boldsymbol{x} \in \mathcal{R}$, whereby we have the partial differential operator (here the Laplacian) and the distributed source, Λ. The second element concerns the boundary data that prescribes the solution (either its value or its boundary normal derivative) for points on the boundary, $\boldsymbol{x} \in \partial\mathcal{R}$. The distributed source can be defined everywhere, including the boundary. However, it only affects the solution for points within the region interior since the boundary conditions determine the solution structure on the boundary. Conversely, the boundary conditions are only prescribed along the boundary, and yet they affect the solution throughout the interior. A key feature of the Green's function method is that it clearly delineates these aspects of the solution, and in so doing it provides both a useful conceptual and computational framework.

5.6.1 Constraints on the source and boundary normal derivative

Assuming there exists a solution to the boundary value problem (5.93), we can derive a constraint on the normal derivative of ψ along the domain boundary.[14] This constraint is revealed by

[14] To be self-contained, we here repeat the discussion of the constraint (5.95) that is also provided in Section 3.4.6.

integrating the Poisson equation (5.93) over the spatial domain, with the left hand side yielding

$$-\int_{\mathcal{R}} \nabla^2 \psi \, \mathrm{d}V = -\oint_{\partial\mathcal{R}} \nabla\psi \cdot \hat{\boldsymbol{n}} \, \mathrm{d}S, \tag{5.94}$$

where we made use of the divergence theorem and with $\partial\mathcal{R}$ the closed boundary of the domain $\mathcal{R}$. Equating this result to the integral of the source, Λ, leads to the constraint

$$\oint_{\partial\mathcal{R}} \nabla\psi \cdot \hat{\boldsymbol{n}} \, \mathrm{d}S = -\int_{\mathcal{R}} \Lambda \, \mathrm{d}V. \tag{5.95}$$

We can physically understand this constraint by invoking the steady state tracer diffusion interpretation of the Poisson equation. For a steady state solution to exist in the presence of specified boundary tracer concentration along with interior sources, there must be a balance between the normal gradient of the tracer concentration, as integrated over the boundary, plus the volume integrated source in the interior. This balance is required to maintain the specified Dirichlet boundary values in the presence of the interior source. Absent this balance, there will be depletion or accumulation of ψ that leads to a transient adjustment, thus breaking the steady state assumption. Notably, the constraint (5.95) can be realized for arbitrary Dirichlet boundary data, σ. An analogous interpretation holds when ψ is the gravitational potential resulting from the mass source, Λ. For ψ to be a specified value along the domain boundary requires the volume integrated mass source to balance a gravitational acceleration integrated along the boundary.

5.6.2 Uniqueness of the solution

Just like the one-dimensional case in Section 5.5.5, we can readily establish uniquess of the solution to the Dirichlet problem by considering two functions, ψ_A and ψ_B, each satisfying the boundary value problem (5.93). In turn, their difference, $\Psi = \psi_A - \psi_B$, satisfies the homogeneous problem

$$-\nabla^2 \Psi = 0, \quad \text{for } \boldsymbol{x} \in \mathcal{R} \qquad \text{and} \qquad \Psi = 0, \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.96}$$

The solution to this Laplace equation is $\Psi = 0$, which then means that $\psi_A = \psi_B$ so that the solution to equation (5.93) is unique. This result also means that the Green's function considered in Section 5.6.3 is unique.

We provide a formal proof that the solution to equation (5.96) is indeed zero. To do so, assume it is not zero and see what happens. First consider the case where Ψ is a constant, so that $\psi_A - \psi_B =$ constant. But zero is the only constant that can satisfy the Dirichlet boundary condition, $\Psi = 0$. Next, assume Ψ has spatial dependence so that $\nabla\Psi \neq 0$ and consider the non-negative integral over the domain

$$\mathcal{I} = \int_{\mathcal{R}} \nabla\Psi \cdot \nabla\Psi \, \mathrm{d}V. \tag{5.97}$$

Since $\nabla^2\Psi = 0$ we have $\nabla \cdot (\Psi \, \nabla\Psi) = \nabla\Psi \cdot \nabla\Psi$ so that

$$\mathcal{I} = \int_{\mathcal{R}} \nabla \cdot (\Psi \, \nabla\Psi) \, \mathrm{d}V = \oint_{\partial\mathcal{R}} \Psi \, \nabla\Psi \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{5.98}$$

where we used the divergence theorem. But since $\Psi = 0$ on $\partial\mathcal{R}$ we find that $\mathcal{I} = 0$, in which case $\nabla\Psi = 0$ everywhere. We are thus led to $\Psi = 0$ throughout the domain, thus allowing us to conclude that the solution to the boundary value problem (5.93) is indeed unique.

5.6.3 The Green's function problem

The Green's function corresponding to the boundary value problem (5.93) is the solution to the Poisson equation with a Dirac delta source (rather than Λ) and a homogeneous Dirichlet boundary condition (rather than σ)

$$-\nabla_{\boldsymbol{x}}^2 G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) \quad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \mathcal{R} \quad \text{and} \quad G(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.99}$$

For this three-dimensional problem, we see that the Green's function has dimensions of inverse length since the Dirac delta has dimensions of inverse volume. By construction, the Green's function, $G(\boldsymbol{x}|\boldsymbol{x}_0)$, is harmonic everywhere except at the location of the singular Dirac delta source, $\boldsymbol{x} = \boldsymbol{x}_0$, at which point the Green's function equals to minus the inverse Laplacian of the Dirac delta. Furthermore, the Green's function satisfies a homogenous Dirichlet boundary condition whenever the field point, $\boldsymbol{x}$, is on the boundary and for an arbitrary source position, $\boldsymbol{x}_0$.

Connection to the free space Green's function

Since $G(\boldsymbol{x}|\boldsymbol{x}_0)$ satisfies a boundary condition, it is distinct from the free space Green's function, $\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0)$, which has no concern for boundaries. Even so, linearity enables us to write the Green's function as the sum of the free space Green's function plus a harmonic function

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) + H(\boldsymbol{x}|\boldsymbol{x}_0), \tag{5.100}$$

where the free space Green's function and harmonic function satisfy

$$-\nabla_{\boldsymbol{x}}^2 \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) \quad \text{for} \quad \boldsymbol{x}, \boldsymbol{x}_0 \in \mathbb{R}^3 \tag{5.101a}$$

$$-\nabla_{\boldsymbol{x}}^2 H(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \quad \text{for} \quad \boldsymbol{x}, \boldsymbol{x}_0 \in \mathcal{R} \tag{5.101b}$$

$$-H(\boldsymbol{x}|\boldsymbol{x}_0) = \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) \quad \text{for} \quad \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.101c}$$

Assuming we know the free space Green's function from equation (5.40c), the mathematical problem of finding $G(\boldsymbol{x}|\boldsymbol{x}_0)$ reduces to finding the harmonic function, $H(\boldsymbol{x}|\boldsymbol{x}_0)$, satisfying the inhomogeneous Dirichlet boundary condition (5.101c).

Although the Green's function, G, cares about the existence of spatial boundaries, it is independent of the boundary data, σ, and the distributed source, Λ, that appear in the boundary value problem (5.93) for ψ. In that manner, the Green's function is connected to the original boundary value problem only through the differential operator (here the Laplacian) and the type of boundary condition (here the Dirichlet condition).

Jump condition induced by the Dirac source

Integrating the Green's function partial differential equation (5.99) over a volume, $\mathcal{R}_0$, that encloses the Dirac delta source point at $\boldsymbol{x}_0 \in \mathcal{R}_0$ leads to

$$\int_{\mathcal{R}_0} \nabla_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)\,\mathrm{d}V = \oint_{\partial\mathcal{R}_0} \hat{\boldsymbol{n}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)\,\mathrm{d}S = -1, \tag{5.102}$$

where we used the divergence theorem for the first equality. This result means that for any domain enclosing the Dirac source point, the normal derivative of the Green's function has a jump condition across the boundary of this region. We encountered this property in Section 5.5.2 for the one-dimensional Green's function, and will see it again when discussing the boundary

Green's function in Section 5.6.6.

5.6.4 Reciprocity of the Green's function

The Green's function satisfies reciprocity

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = G(\boldsymbol{x}_0|\boldsymbol{x}), \tag{5.103}$$

with this property holding for both Dirichlet and Neumann boundary conditions. As introduced in Section 5.5.3 for the one-dimensional Poisson equation, reciprocity says that the Green's function at the field point, $\boldsymbol{x}$, arising from a Dirac delta source at the source point, $\boldsymbol{x}_0$ is identical to the Green's function at the field point, $\boldsymbol{x}_0$, arising from a Dirac delta source at point, $\boldsymbol{x}$. By inspection, the free space Green's functions (5.40a)-(5.40c) satisfy reciprocity. Hence, by implication the harmonic function, $H(\boldsymbol{x}|\boldsymbol{x}_0)$, also satisfies reciprocity. Even so, we find it pedagogically useful to offer a direct derivation of reciprocity by using steps similar to those used for establishing the second form of Green's integral identity (2.81). These steps are utilized for many purposes when working with Green's functions.

Derivation of reciprocity

Consider the two Green's functions, $G(\boldsymbol{x}|\boldsymbol{a})$ and $G(\boldsymbol{x}|\boldsymbol{b})$, arising from Dirac delta sources at source points $\boldsymbol{a} \in \mathcal{R}$ and $\boldsymbol{b} \in \mathcal{R}$

$$-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{a}) = \delta(\boldsymbol{x} - \boldsymbol{a}) \tag{5.104a}$$

$$-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{b}) = \delta(\boldsymbol{x} - \boldsymbol{b}). \tag{5.104b}$$

Multiplying the first equation by $G(\boldsymbol{x}, \boldsymbol{b})$ and the second by $G(\boldsymbol{x}, \boldsymbol{a})$, and subtracting leads to

$$-G(\boldsymbol{x}|\boldsymbol{b})\, \nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{a}) + G(\boldsymbol{x}|\boldsymbol{a})\, \nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{b}) = G(\boldsymbol{x}|\boldsymbol{b})\, \delta(\boldsymbol{x} - \boldsymbol{a}) - G(\boldsymbol{x}|\boldsymbol{a})\, \delta(\boldsymbol{x} - \boldsymbol{b}). \tag{5.105}$$

Now integrate this equation over the region $\mathcal{R}$, with the right hand side rendering

$$\int_{\mathcal{R}} [G(\boldsymbol{x}|\boldsymbol{b})\, \delta(\boldsymbol{x} - \boldsymbol{a}) - G(\boldsymbol{x}|\boldsymbol{a})\, \delta(\boldsymbol{x} - \boldsymbol{b})]\, \mathrm{d}V = G(\boldsymbol{a}, \boldsymbol{b}) - G(\boldsymbol{b}, \boldsymbol{a}), \tag{5.106}$$

where we made use of the sifting property (5.7). Integrating the left hand side of equation (5.105) leads to

$$\int_{\mathcal{R}} [-G(\boldsymbol{x}|\boldsymbol{b})\, \nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{a}) + G(\boldsymbol{x}|\boldsymbol{a})\, \nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{b})]\, \mathrm{d}V \tag{5.107a}$$

$$= \int_{\mathcal{R}} [-\nabla_{\boldsymbol{x}} \cdot [G(\boldsymbol{x}|\boldsymbol{b})\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{a})] + \nabla_{\boldsymbol{x}} \cdot [G(\boldsymbol{x}|\boldsymbol{a})\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{b})]]\, \mathrm{d}V \tag{5.107b}$$

$$= \oint_{\partial\mathcal{R}} [-G(\boldsymbol{x}|\boldsymbol{b})\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{a}) + G(\boldsymbol{x}|\boldsymbol{a})\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{b})] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{5.107c}$$

where we made use of the divergence theorem for the second equality. The final result vanishes when making use of either the homogeneous Dirichlet boundary condition (5.99) or the homogeneous Neumann boundary condition (5.130) considered in Section 5.7. We are thus led to the reciprocity relation (5.103).

Comments on self-adjoint operators

Reciprocity in the relatively simple form of equation (5.103) is a signature of *self-adjoint* differential operators. Self-adjointness reflects properties of both the differential operator and the boundary conditions, with the discussion in this section revealing that the Laplacian operator is self-adjoint with either Dirichlet or Neumann boundary conditions. Operators that are not self-adjoint, such as the diffusion operator in Section 5.8, satisfy a slightly more general reciprocity relation (see Section 5.8.4).

The absence of self-adjointness reflects some form of symmetry breaking either through the operator itself or through the boundary and/or initial conditions. The diffusion operator has a single time derivative, ∂_t, which breaks symmetry between past and future thus leading to the absence of self-adjointness. Furthermore, self-adjointness is a property that depends on the nature of the chosen inner product, with the inner product in the present discussion defined by integration over the domain $\mathcal{R}$. See *Stakgold* (2000a,b) for a thorough discussion accessible to physicists.

5.6.5 The integral solution

We have the elements in place to determine ψ as an integral expression involving $G(\boldsymbol{x}|\boldsymbol{x}_0)$ along with the prescribed source, Λ, and boundary data, σ. To do so we follow steps similar to those used to establish reciprocity. Recall the Poisson boundary value problem for ψ and the associated Green's function problem, here exposing arguments for clarity

$$-\nabla^2_{\boldsymbol{x}}\psi(\boldsymbol{x}) = \Lambda(\boldsymbol{x}) \tag{5.108a}$$

$$-\nabla^2_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0). \tag{5.108b}$$

Multiply the $\psi(\boldsymbol{x})$ equation by $G(\boldsymbol{x}|\boldsymbol{x}_0)$ and the $G(\boldsymbol{x}|\boldsymbol{x}_0)$ equation by $\psi(\boldsymbol{x})$ to find

$$-G(\boldsymbol{x}|\boldsymbol{x}_0)\,\nabla^2_{\boldsymbol{x}}\psi(\boldsymbol{x}) = G(\boldsymbol{x}|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x}) \tag{5.109a}$$

$$-\psi(\boldsymbol{x})\,\nabla^2_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0) = \psi(\boldsymbol{x})\,\delta(\boldsymbol{x}-\boldsymbol{x}_0), \tag{5.109b}$$

and then subtract these two equations

$$-G(\boldsymbol{x}|\boldsymbol{x}_0)\,\nabla^2_{\boldsymbol{x}}\psi(\boldsymbol{x}) + \psi(\boldsymbol{x})\,\nabla^2_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0) = G(\boldsymbol{x}|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x}) - \psi(\boldsymbol{x})\,\delta(\boldsymbol{x}-\boldsymbol{x}_0). \tag{5.110}$$

Now integrate over observational points, $\boldsymbol{x}$, sampled over the region $\mathcal{R}$, in which case the right hand side becomes

$$\int_{\mathcal{R}} [G(\boldsymbol{x}|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x}) - \psi(\boldsymbol{x})\,\delta(\boldsymbol{x}-\boldsymbol{x}_0)]\,\mathrm{d}V = -\psi(\boldsymbol{x}_0) + \int_{\mathcal{R}} G(\boldsymbol{x}|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x})\,\mathrm{d}V, \tag{5.111}$$

where we made use of the sifting property (5.7) to expose the function, ψ, at the location of the Dirac source, $\boldsymbol{x}_0$. Integrating the left hand side of equation (5.110) yields

$$\int_{\mathcal{R}} [-G(\boldsymbol{x}|\boldsymbol{x}_0)\,\nabla^2_{\boldsymbol{x}}\psi(\boldsymbol{x}) + \psi(\boldsymbol{x})\,\nabla^2_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}V \tag{5.112a}$$

$$= \int_{\mathcal{R}} \nabla_{\boldsymbol{x}}\cdot[-G(\boldsymbol{x}|\boldsymbol{x}_0)\,\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) + \psi(\boldsymbol{x})\,\nabla_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}V \tag{5.112b}$$

$$= \oint_{\partial\mathcal{R}} [-G(\boldsymbol{x}|\boldsymbol{x}_0)\,\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) + \psi(\boldsymbol{x})\,\nabla_{\boldsymbol{x}}G(\boldsymbol{x}|\boldsymbol{x}_0)]\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}}\,\mathrm{d}\mathcal{S}. \tag{5.112c}$$

Bringing the two sides to equation (5.110) together leads to

$$\psi(\boldsymbol{x}_0) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x})\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V + \oint_{\partial\mathcal{R}} [G(\boldsymbol{x}|\boldsymbol{x}_0)\, \nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) - \psi(\boldsymbol{x})\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)] \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}}\, \mathrm{d}\mathcal{S}. \tag{5.113}$$

As a final step, it is convenient to relabel $\boldsymbol{x}_0 \leftrightarrow \boldsymbol{x}$ and make use of reciprocity, $G(\boldsymbol{x}|\boldsymbol{x}_0) = G(\boldsymbol{x}_0|\boldsymbol{x})$, so that

$$\psi(\boldsymbol{x}) = \underbrace{\int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0}_{\text{volume integral over } \mathcal{R}} + \underbrace{\oint_{\partial\mathcal{R}} [G(\boldsymbol{x}|\boldsymbol{x}_0)\, \nabla_{\boldsymbol{x}_0}\psi(\boldsymbol{x}_0) - \psi(\boldsymbol{x}_0)\, \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0)] \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0}_{\text{boundary area integral over } \partial\mathcal{R}}. \tag{5.114}$$

We have thus established ψ as a volume integral of the Green's function with the source, Λ, plus a boundary integral of the Green's function with the boundary data. This expression holds for either the Dirichlet condition or Neumann condition, whereby the distinction occurs only for the boundary integral. Furthermore, note that the Green's function is independent of the source, Λ, and the boundary data, so that $G(\boldsymbol{x}|\boldsymbol{x}_0)$ can be used to express ψ for arbitrary source functions and boundary data.

5.6.6 Properties of the solution

Specializing the general solution (5.114) to Dirichlet boundary conditions results in

$$\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0 - \oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0)\, \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0. \tag{5.115}$$

Notice how the boundary integral involves the normal gradient of the Green's function, which is consistent with the one-dimensional case (5.77) derived in Section 5.5.1. We refer to the inward normal gradient of the Green's function as the *boundary Green's function*

$$G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) \equiv -\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0} = -\frac{\partial G(\boldsymbol{x}|\boldsymbol{x}_0)}{\partial \hat{n}_{\boldsymbol{x}_0}}, \tag{5.116}$$

in which case the Dirichlet solution takes the form

$$\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0 + \oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0)\, G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}\mathcal{S}_0. \tag{5.117}$$

This form for the solution emphasizes the role of the Green's function as the mediator between the distributed source, Λ, and all surrounding points $\boldsymbol{x} \in \mathcal{R}$, whereas the boundary Green's function mediates between information prescribed along the boundary, $\boldsymbol{x} \in \partial\mathcal{R}$, and interior points. In this subsection we summarize certain properties of the solution (5.115) and (5.117), and infer (through insisting on self-consistency) corresponding properties of the Green's function and boundary Green's function.

Linear superposition

The Dirichlet solution (5.115) manifests the linear superposition principle by writing $\psi = \psi_1 + \psi_2$ as given by Table 5.1. By construction, ψ_1 satisfies Poisson's equation with homogeneous Dirichlet boundary conditions, whereas ψ_2 satisfies Laplace's equation with inhomogeneous Dirichlet boundary conditions.

PDE: $\boldsymbol{x} \in \mathcal{R}$	BC: $\boldsymbol{x} \in \partial\mathcal{R}$	SOLUTION $\psi = \psi_1 + \psi_2$
$-\nabla^2\psi_1 = \Lambda$	$\psi_1 = 0$	$\psi_1(\boldsymbol{x}) = \int_{\mathcal{R}} G(\boldsymbol{x}\vert\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x}_0)\,\mathrm{d}V_0$
$-\nabla^2\psi_2 = 0$	$\psi_2 = \sigma$	$\psi_2(\boldsymbol{x}) = \oint_{\partial\mathcal{R}} G^{\mathrm{bd}}(\boldsymbol{x}\vert\boldsymbol{x}_0)\,\sigma(\boldsymbol{x}_0)\,\mathrm{d}\mathcal{S}_0$

TABLE 5.1: Decomposing the Dirichlet solution (5.115) into $\psi = \psi_1 + \psi_2$, with ψ_1 and ψ_2 satisfying the properties shown in this table. For the boundary contribution we made use of the boundary Green's function, $G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) = -\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}$, as given by equation (5.116).

Verifying the partial differential equation for $\boldsymbol{x} \in \mathcal{R}$

We derived the Dirichlet solution (5.115) with manipulations that are reversible; i.e., equal signs were used at every step. Hence, we know that the expression (5.115) indeed satisfies the Dirichlet boundary value problem (5.93). Even so, the exercise of verifying the solution reveals valuable insights into the Green's function.

To verify that the partial differential equation is satisfied for points within the interior of the region, $\boldsymbol{x} \in \mathcal{R}$, operate with $-\nabla^2_{\boldsymbol{x}}$ on equation (5.117) to find

$$-\nabla^2_{\boldsymbol{x}}\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\,[-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}V_0 + \oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0)\,[-\nabla^2_{\boldsymbol{x}} G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}\mathcal{S}_0. \tag{5.118}$$

For the first term on the right hand side, make use of the Green's function identity $-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0)$ and then use the sifting property of the Dirac delta, $\int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0)\,\mathrm{d}V_0 = \Lambda(\boldsymbol{x})$. To show that the boundary contribution vanishes, make use of the following

$$\nabla^2_{\boldsymbol{x}} G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) = \nabla^2_{\boldsymbol{x}}[-\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}] \tag{5.119a}$$

$$= \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\cdot\nabla_{\boldsymbol{x}_0}[-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)] \tag{5.119b}$$

$$= \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\cdot\nabla_{\boldsymbol{x}_0}\delta(\boldsymbol{x}-\boldsymbol{x}_0), \tag{5.119c}$$

and, without loss of generality, let the unit normal direction be parallel to the vertical, $\hat{\boldsymbol{n}}_{\boldsymbol{x}_0} = \hat{\boldsymbol{z}}$, so that

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\cdot\nabla_{\boldsymbol{x}_0}\delta(\boldsymbol{x}-\boldsymbol{x}_0) = \partial_{z_0}[\delta(x-x_0)\,\delta(y-y_0)\,\delta(z-z_0)] = \delta(x-x_0)\,\delta(y-y_0)\,\frac{\mathrm{d}\,[\delta(z-z_0)]}{\mathrm{d}z_0}. \tag{5.120}$$

With $\boldsymbol{x}_0 \in \partial\mathcal{R}$ yet $\boldsymbol{x} \notin \partial\mathcal{R}$, the Dirac delta never fires, thus eliminating the boundary contribution. We have thus verified that $-\nabla^2_{\boldsymbol{x}}\psi = \Lambda$ for points $\boldsymbol{x} \in \mathcal{R}$.

Verifying the Dirichlet boundary condition for $\boldsymbol{x} \in \partial\mathcal{R}$

To verify that the boundary conditions are satisfied by the Dirichlet solution (5.115), bring the field point, $\boldsymbol{x}$, onto the boundary

$$\boldsymbol{x} \to \boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}. \tag{5.121}$$

For such boundary points, the volume integral in the solution (5.115) vanishes since the Dirichlet Green's function vanishes on the boundary, $G(\boldsymbol{x}_{\partial\mathcal{R}}|\boldsymbol{x}_0) = 0$. Self-consistency with the Dirichlet boundary data, $\psi(\boldsymbol{x}_{\partial\mathcal{R}}) = \sigma(\boldsymbol{x}_{\partial\mathcal{R}})$, leads to

$$\sigma(\boldsymbol{x}) = \oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0)\,G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)\,\mathrm{d}\mathcal{S}_0 = -\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0)\,\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}_{\partial\mathcal{R}}|\boldsymbol{x}_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\,\mathrm{d}\mathcal{S}_0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.122}$$

This integral equation is consistent so long as the boundary Green's function satisfies the boundary condition

$$G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) = -\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0} = \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}, \tag{5.123}$$

where $\delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0)$ is the surface Dirac delta with physical dimensions of inverse area. This property of the boundary Green's function is consistent with the jump condition (5.126) found for the one-dimensional Poisson equation. It furthermore leads to the corresponding integral identity

$$\oint_{\partial\mathcal{R}} G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}\mathcal{S}_0 = \oint_{\partial\mathcal{R}} \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0)\, \mathrm{d}\mathcal{S}_0 = 1 \quad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}. \tag{5.124}$$

We emphasize[15] that the expressions (5.123) and (5.124) are found by first placing the source point, $\boldsymbol{x}_0$, on the boundary and thereafter moving the field point to the boundary, $\boldsymbol{x} \to \boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}$.

5.6.7 Boundary Green's function

Boundary value problem for the boundary Green's function

As part of the development in Section 5.6.6, we revealed that the boundary Green's function satisfies the following boundary value problem

$$-\nabla^2_{\boldsymbol{x}} G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \quad \text{for } \boldsymbol{x} \in \mathcal{R} \quad \text{and} \quad G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0) = \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{for} \quad \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}. \tag{5.125}$$

As seen by equation (5.99), the Dirichlet Green's function, $G(\boldsymbol{x}|\boldsymbol{x}_0)$, feels the Dirac source in the interior of the domain, $\boldsymbol{x} \in \mathcal{R}$, and satisfies homogeneous Dirichlet boundary conditions for $\boldsymbol{x} \in \partial\mathcal{R}$. As a complement, the boundary Green's function, $G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)$, is harmonic everywhere in the domain interior and yet equals to the Dirac source along the boundary. By construction, the boundary Green's function incorporates boundary information into the region as part of the Dirichlet solution (5.117). We make further use of the boundary Green's function when studying the diffusion equation in Section 5.8 and the advection-diffusion equation in Section 64.10, at which point the boundary Green's function is referred to as the *boundary propagator*.

Normalization of the boundary Green's function

Consider the special case of constant boundary data, $\sigma = \sigma_{\mathrm{const}}$, in which case the harmonic function in Table 5.1 is itself a constant, $\psi_B(\boldsymbol{x}) = \sigma_{\mathrm{const}}$. Consequently, the boundary Green's function satisfies

$$-\oint_{\partial\mathcal{R}} \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}|\boldsymbol{x}_0) \cdot \hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0 = \oint_{\partial\mathcal{R}} G^{\mathrm{bd}}(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}\mathcal{S}_0 = 1. \tag{5.126}$$

This relation is built by placing Dirac delta sources along the boundary, $\boldsymbol{x}_0 \in \partial\mathcal{R}$, and then area integrating over the boundary area. It holds for any field point, $\boldsymbol{x} \in \mathcal{R}$. Although derived by considering the special case of constant boundary data, equation (5.126) holds in general since the Green's function is independent of the boundary data.

To help understand the identity (5.126), consider the Green's function to be the steady state temperature or tracer concentration resulting from a Dirac delta source placed within the domain interior. The area integrated condition (5.126) acts to maintain the homogeneous Dirichlet boundary condition, $G(\boldsymbol{x}_{\partial\mathcal{R}}|\boldsymbol{x}_0) = 0$, for every point $\boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}$. It does so by providing a boundary flux, via the normal gradient, whose area integral precisely cancels the unit positive source from the Dirac delta. We encountered this property for the one-dimensional equation studied

[15] As per page 801 of *Morse and Feshbach* (1953).

in Section 5.5.3 and the three-dimensional Poisson equation with Dirichlet boundaries in Section 5.6.1.

Equation (5.126) represents a normalization of the boundary Green's function at each point within the region interior, and it is consistent with the boundary condition given in equation (5.125). If we place Dirac delta sources along the boundary and integrate over the boundary, then every point within the domain feels a net unit source from these boundary sources, which is reflected by the normalization of the boundary Green's function. We return to this normalization when considering the boundar propagator for the diffusion equation in Section 5.8.8.

5.7 Poisson's equation with Neumann boundaries

We now switch from the Dirichlet boundary conditions in Section 5.6 to the Poisson equation with *Neumann boundary conditions*

$$-\nabla^2\psi = \Lambda, \quad \text{for } \boldsymbol{x} \in \mathcal{R} \qquad \text{and} \qquad \hat{\boldsymbol{n}} \cdot \nabla\psi = \Sigma, \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.127}$$

Rather than specifying the value of ψ along the boundary, the Neumann condition specifies the normal derivative. Although much is shared between the Dirichlet and Neumann problems, there are distinctions that arise in the present section.

5.7.1 Constraints on the source and boundary data

As in our discussion of Dirichlet boundary conditions in Section 5.6.1, we can realize a solution to the boundary value problem (5.127) only so long as the constraint (5.95) is satisfied. For Neumann boundary conditions, we specify the normal derivative along the boundary so that the constraint (5.95) is now imposed on the volume source and boundary data[16]

$$\oint_{\partial\mathcal{R}} \Sigma \, \mathrm{d}S = -\int_{\mathcal{R}} \Lambda \, \mathrm{d}V. \tag{5.128}$$

If the source and boundary data do not satisfy this constraint, then there is no solution to the Poisson problem (5.127). If the Poisson problem arises physically from steady state tracer diffusion, then the constraint (5.128) imposes a balance between the diffusive flux integrated around the boundary (left hand side) with the volume integrated tracer source (right hand side). In the absence of this balance, there is no solution to the Poisson problem thus indicating the presence of transients (i.e., time dependent diffusion). If the Poisson problem arises from Newtonian gravity, then the condition (5.128) means that the area integrated gravitational acceleration specified on the boundary must be consistent with the volume integrated mass source distributed within the domain.

5.7.2 Uniqueness of the solution up to a constant

As in Section 5.6.2, we consider the uniqueness of the solution to the boundary value problem (5.127). We do so, again, by considering two functions, ψ_A and ψ_B, each satisfying the boundary value problem (5.127) and noting that their difference, $\Psi = \psi_A - \psi_B$, satisfies the homogeneous problem

$$-\nabla^2\Psi = 0, \quad \text{for } \boldsymbol{x} \in \mathcal{R} \qquad \text{and} \qquad \hat{\boldsymbol{n}} \cdot \nabla\Psi = 0, \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.129}$$

[16] To be self-contained, we here repeat the discussion of the constraint (5.128) that is also provided in Section 3.4.6.

The same arguments we used in Section 5.6.2 lead us to conclude that $\nabla\Psi = 0$, but for the Neumann problem this result is consistent with Ψ being an arbitrary spatial constant. We can understand this arbitrariness since the Neumann boundary condition involves a derivative, with the derivative of a constant vanishing. We thus conclude that the solution to the boundary value problem (5.127) is unique up to an arbitrary constant.

5.7.3 The Green's function problem

The Green's function corresponding to the Poisson boundary value problem (5.127) is the solution to the Poisson equation with a Dirac delta source and a homogeneous Neumann boundary condition

$$-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) \quad \text{for } \boldsymbol{x},\boldsymbol{x}_0 \in \mathcal{R} \quad \text{and} \quad \hat{\boldsymbol{n}}\cdot\nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = 0, \quad \text{for } \boldsymbol{x}\in\partial\mathcal{R}. \tag{5.130}$$

Linearity enables us to write the Green's function as the sum of the free space Green's function plus a harmonic function

$$G(\boldsymbol{x}|\boldsymbol{x}_0) = \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) + H(\boldsymbol{x}|\boldsymbol{x}_0), \tag{5.131}$$

where

$$-\nabla^2_{\boldsymbol{x}} \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) \qquad \text{for} \quad \boldsymbol{x},\boldsymbol{x}_0 \in \mathbb{R}^3 \tag{5.132a}$$

$$-\nabla^2_{\boldsymbol{x}} H(\boldsymbol{x}|\boldsymbol{x}_0) = 0 \qquad \text{for} \quad \boldsymbol{x},\boldsymbol{x}_0 \in \mathcal{R} \tag{5.132b}$$

$$-\hat{\boldsymbol{n}}\cdot\nabla_{\boldsymbol{x}} H(\boldsymbol{x}|\boldsymbol{x}_0) = \hat{\boldsymbol{n}}\cdot\nabla_{\boldsymbol{x}} \mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0) \quad \text{for} \quad \boldsymbol{x}\in\partial\mathcal{R}. \tag{5.132c}$$

5.7.4 Properties of the solution

Specializing the general solution (5.114) to Neumann boundary conditions results in

$$\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0 + \oint_{\partial\mathcal{R}} \Sigma(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}\mathcal{S}_0. \tag{5.133}$$

In this section we summarize certain properties of the solution (5.133) along with properties of the Green's function that are inferred (through insisting on self-consistency) from the solution.

Linear superposition

This Green's function solution (5.133) manifests the linear superposition principle by writing $\psi = \psi_1 + \psi_2$ as given by Table 5.2. By construction, ψ_1 satisfies Poisson's equation with homogeneous Neumann boundary conditions, whereas ψ_2 satisfies Laplace's equation with inhomogeneous Neumann boundary conditions.

PDE: $\boldsymbol{x}\in\mathcal{R}$	BC: $\boldsymbol{x}\in\partial\mathcal{R}$	SOLUTION $\psi = \psi_1 + \psi_2$
$-\nabla^2\psi_1 = \Lambda$	$\psi_1 = 0$	$\psi_1(\boldsymbol{x}) = \int_{\mathcal{R}} G(\boldsymbol{x}\|\boldsymbol{x}_0)\,\Lambda(\boldsymbol{x}_0)\,\mathrm{d}V_0$
$-\nabla^2\psi_2 = 0$	$\hat{\boldsymbol{n}}\cdot\nabla\psi_2 = \Sigma$	$\psi_2(\boldsymbol{x}) = \oint_{\partial\mathcal{R}} \Sigma(\boldsymbol{x}_0)\, G(\boldsymbol{x}\|\boldsymbol{x}_0)\,\mathrm{d}\mathcal{S}_0$

TABLE 5.2: Decomposing the Neumann solution (5.133) into $\psi = \psi_1 + \psi_2$, with ψ_1 and ψ_2 satisfying the properties shown here. The function ψ_1 is identical to ψ_1 appearing for the Dirichlet problem (see Table 5.1), whereas the function ψ_2 is distinct since it is determined by the respective boundary conditions.

Transforming the boundary data to the interior

The Neumann solution (5.133) allows for a dual formulation of the boundary data. To motivate this formulation, assume the only nontrivial Neumann boundary data appears along the constant geopotential surface $z = z_{\rm b}$, with all other boundaries maintaining the homogeneous boundary condition, $\hat{\boldsymbol{n}} \cdot \nabla \psi = 0$. In this special case the Neumann solution (5.133) takes the form

$$\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0 + \int_{z=z_{\rm b}} \Sigma(x_0, y_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}x_0\, \mathrm{d}y_0 \tag{5.134a}$$

$$= \int_{\mathcal{R}} [\Lambda(\boldsymbol{x}_0) + \Sigma(x_0, y_0)\, \delta(z_0 - z_{\rm b})]\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0 \tag{5.134b}$$

$$= \int_{\mathcal{R}} \Lambda^*(\boldsymbol{x}_0)\, G(\boldsymbol{x}|\boldsymbol{x}_0)\, \mathrm{d}V_0. \tag{5.134c}$$

These manipulations have absorbed the non-homogeneous Neumann boundary condition into a modified source, $\Lambda^*(\boldsymbol{x})$. We are thus led to two equivalent formulations for the Poisson boundary value problem with Neumann conditions. The first is given by equation (5.127), whereby ψ is the solution to the Poisson equation with source, Λ, and with inhomogeneous Neumann boundary data, Σ. The second formulation considers ψ to be the solution to Poisson's equation with homogeneous Neumann boundary conditions yet with a modified source function

$$\Lambda^*(\boldsymbol{x}) = \Lambda(\boldsymbol{x}) + \Sigma(x, y)\, \delta(z - z_{\rm b}) = \Lambda(\boldsymbol{x}) + \partial_z \psi(\boldsymbol{x})\, \delta(z - z_{\rm b}). \tag{5.135}$$

As a check, note that the physical dimensionality of $\Lambda^*(\boldsymbol{x})$ is indeed correct since the Dirac delta, $\delta(z - z_{\rm b})$, has dimensions of inverse length. We interpret the term $\Sigma(x, y)\, \delta(z - z_{\rm b})$ as a flux or *Dirac delta sheet* that sits just inside the boundary (at $z = z_{\rm b} - \epsilon$ with $\epsilon \to 0$), which allows this data to be incorporated into the volume source data rather than be part of the boundary data. The specific form (5.135) can be generalized to the expression

$$\Lambda^*(\boldsymbol{x}) = \Lambda(\boldsymbol{x}) + \Sigma(\boldsymbol{x})\, \delta[\hat{\boldsymbol{n}} \cdot (\boldsymbol{x} - \boldsymbol{x}_{\partial\mathcal{R}})] = \Lambda(\boldsymbol{x}) + \hat{\boldsymbol{n}} \cdot \nabla \psi(\boldsymbol{x})\, \delta[\hat{\boldsymbol{n}} \cdot (\boldsymbol{x} - \boldsymbol{x}_{\partial\mathcal{R}})], \tag{5.136}$$

where the argument to the Dirac delta picks out the coordinates in the direction of the outward unit normal. The transformed Neumann problem thus takes the generic form

$$-\nabla^2 \psi = \Lambda^*, \quad \text{for } \boldsymbol{x} \in \mathcal{R} \qquad \text{and} \qquad \hat{\boldsymbol{n}} \cdot \nabla \psi = 0, \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.137}$$

Again, the solution to the boundary value problem (5.137) is identical to the solution of the original problem (5.127).

Notably, the same data, Σ, is needed for both equations (5.137) and (5.127), so there is nothing fundamentally special or efficient about one formulation or the other. Rather, it is a matter of convenience. For example, the formulation using Λ^* has found some favor in the study of quasi-geostrophic potential vorticity (*Bretherton*, 1966). We also make use of a similar construct in Section 68.4.3 for studies of boundary buoyancy fluxes in water mass transformation analysis.

5.7.5 Verifying the solution

We verify that the solution (5.133) solves the Poisson boundary value problem (5.127). First consider a point in the interior of the region, $\boldsymbol{x} \in \mathcal{R}$, and apply $-\nabla^2_{\boldsymbol{x}}$ on equation (5.133) to find

$$-\nabla^2_{\boldsymbol{x}} \psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\, [-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\, \mathrm{d}V_0 + \oint_{\partial\mathcal{R}} \Sigma(\boldsymbol{x}_0)\, [-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\, \mathrm{d}\mathcal{S}_0 = \Lambda(\boldsymbol{x}). \tag{5.138}$$

To reach this result we used $-\nabla^2_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta(\boldsymbol{x} - \boldsymbol{x}_0)$ and noted that the boundary integral vanishes for $\boldsymbol{x} \notin \partial\mathcal{R}$.

To verify the boundary condition, act with the gradient, $\nabla_{\boldsymbol{x}}$, on the solution (5.133)

$$\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) = \int_{\mathcal{R}} \Lambda(\boldsymbol{x}_0)\,[\nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}V_0 + \oint_{\partial\mathcal{R}} \Sigma(\boldsymbol{x}_0)\,[\nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}\mathcal{S}_0. \tag{5.139}$$

Now move the field point onto the boundary, $\boldsymbol{x} \to \boldsymbol{x}_{\boldsymbol{x}_{\partial\mathcal{R}}} \in \partial\mathcal{R}$, and project the gradient onto the unit normal direction, $\hat{\boldsymbol{n}}_{\boldsymbol{x}}$, at the point $\boldsymbol{x}_{\partial\mathcal{R}}$. This projection leads to $\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) = \Sigma(\boldsymbol{x})$ on the left hand side, and it annihilates the volume term on the right hand side since $\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = 0$ for $\boldsymbol{x} \in \partial\mathcal{R}$. We are thus left with

$$\hat{\boldsymbol{n}} \cdot \nabla_{\boldsymbol{x}}\psi(\boldsymbol{x}) = \Sigma(\boldsymbol{x}) = \oint_{\partial\mathcal{R}} \Sigma(\boldsymbol{x}_0)\,[\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)]\,\mathrm{d}\mathcal{S}_0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.140}$$

Again, both arguments of the Green's function are on the boundary, $\boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}$, with the Dirac source point, $\boldsymbol{x}_0$, integrated around the boundary whereas the field point, $\boldsymbol{x}$, is an arbitrary point on the boundary. Equation (5.122) is the analogous integral equation for the solution with Dirichlet boundary conditions. As for the Dirichlet case, we are ensured a solution to the integral equation (5.140) if the Green's function satisfies the property

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0) = \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{for } \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}, \tag{5.141}$$

which takes on the integral expression

$$\oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}|\boldsymbol{x}_0)\,\mathrm{d}\mathcal{S}_0 = \oint_{\partial\mathcal{R}} \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0)\,\mathrm{d}\mathcal{S}_0 \quad \text{for } \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.142}$$

Table 5.3 compares the boundary properties of the respective Green's functions.

BOUNDARY CONDITION	GREEN'S FUNCTION PROPERTY	EQUATION
Dirichlet	$\partial G/\partial\hat{n}_0 = \hat{\boldsymbol{n}}_{\boldsymbol{x}_0} \cdot \nabla_{\boldsymbol{x}_0} G(\boldsymbol{x}\|\boldsymbol{x}_0) = -\delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0)$	(5.123)
Neumann	$\partial G/\partial\hat{n} = \hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}\|\boldsymbol{x}_0) = \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0)$	(5.141)

TABLE 5.3: Comparing the boundary normal derivatives for the Poisson equation Green's function with Dirichlet and Neumann boundary conditions. Each point is on the boundary, $\boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}$, and the Dirac delta is two-dimensional so it has dimensions of inverse area. The properties satisfied by these Green's functions are realized by first placing the source point, $\boldsymbol{x}_0$, on the boundary and then moving the field point to the boundary, $\boldsymbol{x} \to \boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}$. For the Dirichlet condition, the normal derivative is computed at the source point, whereas the Neumann condition computes the normal derivative at the field point.

5.8 The diffusion equation

We continue building our understanding of Green's function methods by now studying the *diffusion equation*, also known as the *heat equation*. We first encountered the diffusion equation in Section 3.5, where it served as the canonical parabolic partial differential equation. It is more thoroughly explored in Chapter 64, with much of the current chapter a foundation for the Green's function treatment of the advection-diffusion equation in Section 64.10. Time dependence appearing in the diffusion equation is the new feature relative to the elliptic Poisson equation encountered in the previous sections.

The traditional Green's function formalism for the diffusion equation, and the one pursued in

this chapter, assumes that the spatial domain, $\mathcal{R}$, is static. Doing so ensures that space and time operations commute, such as differentiation and integration. Although time independent domains are suitable for many applications, certain geophysical applications of interest in this book make use of time dependent boundaries, with the ocean free surface the key example. We examine time dependent boundaries when studying the advection-diffusion equation in Section 64.10, with that generality best confronted only after nurturing our Green's function brain muscle in the current chapter.

5.8.1 Causal free space Green's function

Consider a Dirac delta tracer source at $(\boldsymbol{x}_0, t_0)$ and assume a continuous media where there is no advection, such as found in a stagnent fluid or elastic solid. The simplest solution to the diffusion equation is known as the *causal free space Green's function*, $\mathcal{G}$, which is defined for $t \in (-\infty, \infty)$ and satisfies

$$(\partial_t - \kappa \nabla^2_{\boldsymbol{x}})\, \mathcal{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = \delta(t - t_0)\, \delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad \boldsymbol{x} \in \mathbb{R}^n \tag{5.143a}$$

$$\mathcal{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) \to 0 \qquad |\boldsymbol{x} - \boldsymbol{x}_0| \to \infty \tag{5.143b}$$

$$\mathcal{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x} \in \mathbb{R}^n, \;\; t < t_0, \tag{5.143c}$$

where $\mathbb{R}^n$ is Euclidean space with $n = 1, 2, 3$ for a line, plane, and volume, respectively, and where $\kappa > 0$ is a constant diffusivity (dimensions $\mathrm{L}^2\ \mathrm{T}^{-1}$). Equation (5.143b) ensures that the free space Green's function decays as the field point gets further away from the source point. The *causality condition* (5.143c) means that the Green's function vanishes for times prior to the time, t_0, at which the Dirac source occurs. Given the dimensions of the Dirac source, we see that the Green's function has dimensions of L^{-n}.

The causal free-space Green's function is given by[17]

$$\mathcal{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = \frac{H(t - t_0)}{[4\,\pi\,\kappa\,(t - t_0)]^{n/2}} e^{-|\boldsymbol{x} - \boldsymbol{x}_0|^2/[4\,\kappa\,(t - t_0)]}, \tag{5.144}$$

where the Heaviside step function (equation (5.18)) enforces causality. The amplitude of the Green's function exponentially decays when moving away from the source location, thus satisfying the condition (5.143b). Additionally, as time progresses beyond the source time, the Green's function decays according to the pre-factor, $(t - t_0)^{-n/2}$. Each of these properties of the causal free space Green's function are reflected in solutions to more general diffusion processes.

5.8.2 Causal Green's function

Moving beyond the free space solution, we next introduce the *causal Green's function* for the diffusion equation. This Green's function is defined for $t \in (-\infty, \infty)$ and satisfies the following equations when assuming Neumann boundary conditions

$$\frac{\partial[G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)]}{\partial t} - \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)] = \delta(t - t_0)\, \delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad \boldsymbol{x} \in \mathcal{R} \tag{5.145a}$$

$$\hat{\boldsymbol{n}} \cdot \mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.145b}$$

$$G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \;\; t < t_0. \tag{5.145c}$$

The Neumann boundary condition is relevant when one knows the boundary flux of heat or tracer concentration. Alternatively, Dirichlet conditions are used when knowing the boundary values for

[17] See Section 5.8 of *Stakgold* (2000b) for a derivation of the free space solution (5.144).

the field, in which case the corresponding causal Green's function satisfies

$$\frac{\partial[G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)]}{\partial t} - \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] = \delta(t-t_0)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0) \qquad \boldsymbol{x} \in \mathcal{R} \tag{5.146a}$$

$$G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.146b}$$

$$G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t < t_0. \tag{5.146c}$$

The Dirichlet condition is particularly relevant for passive tracers in the atmosphere and ocean, such as those studied in Section 64.10. In both the Neumann and Dirichlet cases, we generalized the free space solution from Section 5.8.1 by introducing a space-time dependent diffusivity tensor, $\mathbb{K}(\boldsymbol{x},t)$, which is a symmetric second order tensor with dimensions $\mathrm{L}^2\ \mathrm{T}^{-1}$ (we study such diffusion tensors in Chapter 64 and 66). The Green's function has dimensions of inverse volume, L^{-3}, which is implied since the Dirac delta source has dimensions of inverse volume times inverse time, $\mathrm{L}^{-3}\ \mathrm{T}^{-1}$.

In the presence of boundaries, the spatial position of the Dirac delta source impacts the value of the causal Green's function. In contrast, the causality condition (5.145c) means that the Green's function is dependent only on the time since the introduction of the source, $t - t_0$. Hence, there is no added generality afforded by setting the source time, t_0, to be distinct from $t_0 = 0$. Even so, we retain t_0 to maintain symmetry with the spatial location $\boldsymbol{x}_0$. Doing so also helps to distinguish the Dirac source time, t_0, from the initial time, t_{init}, with the intitial time introduced in Section 5.8.6.

5.8.3 Adjoint causal Green's function

We make use of the *adjoint causal Green's function* for solving initial-boundary value problems for the diffusion equation. The adjoint causal Green's function is defined for $t \in (-\infty, \infty)$ and satisfies the following boundary value problem for the Neumann conditions, with these equations representing the adjoint to the Green's function equations (5.145a)-(5.145c)

$$-\frac{\partial[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)]}{\partial t} - \nabla_{\boldsymbol{x}} \cdot \left[\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\right] = \delta(t-t_0)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0) \quad \boldsymbol{x} \in \mathcal{R} \tag{5.147a}$$

$$\hat{\boldsymbol{n}} \cdot \mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.147b}$$

$$\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_0. \tag{5.147c}$$

Similarly, the adjoint Green's function satisfying Dirichlet boundary conditions is determined by

$$-\frac{\partial[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)]}{\partial t} - \nabla_{\boldsymbol{x}} \cdot \left[\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\right] = \delta(t-t_0)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0) \quad \boldsymbol{x} \in \mathcal{R} \tag{5.148a}$$

$$\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.148b}$$

$$\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_0. \tag{5.148c}$$

Note the sign change on the time derivative in equations (5.147a) and (5.148a) relative to equations (5.145a) and (5.146a). This change results since the single partial time derivative is not a self-adjoint operator, reflecting the lack of time symmetry of the diffusion equation (i.e., the diffusion equation distinguishes between past and future). Also note the backward causal condition, equations (5.147c) and (5.148c). Pondering the physics of these equations, we propose that the adjoint Green's function provides a solution to the *concentration equation*, which is the diffusion equation run backwards in time.

5.8.4 Reciprocity of the Green's function and its adjoint

When studying Poisson's equation we made use of reciprocity (5.103) satisfied by the Poisson equation Green's function, and we will require a corresponding reciprocity for the diffusion equation Green's function. Deriving reciprocity requires a bit more work for the diffusion equation due to the added time derivative term, which renders the adjoint diffusion operator distinct from the diffusion operator. That is, the diffusion operator is not *self-adjoint* due to sign change on the time derivative, whereas the Laplacian operator is self-adjoint (even with the symmetric diffusion tensor).

Before starting this derivation, note that we did not derive the adjoint in Section 5.8.3, instead we merely wrote it down. However, introduction of the adjoint Green's function is largely motivated by the following derivation of the reciprocity relation, where we see that the Green's function for the diffusion equation satisfies a reciprocity relation with the adjoint Green's function. Hence, as part of the following derivation we indirectly see how to construct the adjoint problem.

Setting up the derivation

To derive reciprocity, consider the partial differential equation (5.145a) with a Dirac delta source $\delta(t-t_1)\,\delta(\boldsymbol{x}-\boldsymbol{x}_1)$, and the adjoint partial differential equation (5.147a) with a distinct Dirac delta source $\delta(t-t_2)\,\delta(\boldsymbol{x}-\boldsymbol{x}_2)$. Multiply each of these equations by the complement Green's function and subtract

$$\begin{aligned}
&\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)(\partial_t G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)-\nabla_{\boldsymbol{x}}\cdot[\mathbb{K}\cdot\nabla_{\boldsymbol{x}}G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)])\\
&-G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)(-\partial_t\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)-\nabla_{\boldsymbol{x}}\cdot[\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)])\\
&\quad=\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)\,\delta(t-t_1)\,\delta(\boldsymbol{x}-\boldsymbol{x}_1)-G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)\,\delta(t-t_2)\,\delta(\boldsymbol{x}-\boldsymbol{x}_2).
\end{aligned}\tag{5.149}$$

The Dirac delta source locations, $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, are arbitrary, so long as they are within the domain $\mathcal{R}$. Likewise, the source times, t_1 and t_2, are arbitrary. In the following, we find it useful to introduce an arbitrarily large time, T, so that

$$-T<t_1,t_2<T,\tag{5.150}$$

with T later dropping out from the results through use of the causality conditions.

Integration and use of the sifting property

An integral of the right hand side of equation (5.149) over the domain $\mathcal{R}$ and over time, both for the observational space-time points $(\boldsymbol{x},t)$, leads to

$$\begin{aligned}
\int_{-T}^{T}\int_{\mathcal{R}}\Big[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_2,t_2)\,\delta(t-t_1)\,\delta(\boldsymbol{x}-\boldsymbol{x}_1)-G(\boldsymbol{x},t|\boldsymbol{x}_1,t_1)\,\delta(t-t_2)\,\delta(\boldsymbol{x}-\boldsymbol{x}_2)\Big]\,\mathrm{d}V\,\mathrm{d}t&\\
=\widetilde{G}(\boldsymbol{x}_1,t_1|\boldsymbol{x}_2,t_2)-G(\boldsymbol{x}_2,t_2|\boldsymbol{x}_1,t_1).&
\end{aligned}\tag{5.151}$$

As shown in the following, the same integral of the left hand side of equation (5.149) vanishes, which then establishes the reciprocity property between the Green's function and the adjoint Green's function.

Moving the time derivative from G to $\widetilde{G}$ and picking up a minus sign

The left hand side of equation (5.149) requires us to massage just the first term since, as we will show, this term equals to the second so that the left hand side of equation (5.149) vanishes. To prove this assertion, start by examining the time derivative. Since the spatial domain, $\mathcal{R}$, is assumed to be static, we can swap the time and space derivatives to find

$$\int_{-T}^{T} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \partial_t\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\ \mathrm{d}t$$
$$= \int_{-T}^{T} \left[\partial_t \left(\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right) - \partial_t \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\ G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right] \mathrm{d}t. \quad (5.152)$$

We now set

$$G(\boldsymbol{x}, t = -T|\boldsymbol{x}_1, t_1) = 0 \quad \text{and} \quad \widetilde{G}(\boldsymbol{x}, t = +T|\boldsymbol{x}_2, t_2) = 0, \quad (5.153)$$

which result from the causality conditions (5.145c) and (5.147c). Hence, in moving the time derivative from G to $\widetilde{G}$ we pick up a minus sign, which, again, means that the time derivative is not self-adjoint

$$\int_{-T}^{T} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \partial_t\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\ \mathrm{d}t = -\int_{-T}^{T} \partial_t \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\ G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, \mathrm{d}t. \quad (5.154)$$

The Laplacian is self-adjoint with a symmetric diffusion tensor

Consider next the spatial derivative term on the left hand side of equation (5.149)

$$-\int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)]\, \mathrm{d}V =$$
$$\int_{\mathcal{R}} \left[-\nabla_{\boldsymbol{x}} \cdot \left(\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right) + \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2) \cdot \mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right] \mathrm{d}V. \quad (5.155)$$

Use of the divergence theorem and either the homogeneous Neumann boundary condition (5.145b) or homogeneous Dirichlet condition (5.146b) allow us to drop the total derivative term. The same manipulation, with either the Neumann condition (5.147b) or Dirichlet condition (5.148b) satisfied by the adjoint Green's function $\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)$, allows us to seamlessly move the Laplacian operator from $G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)$ onto $\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)$, thus manifesting the self-adjoint nature of the Laplacian operator even in the presence of a symmetric diffusion tensor

$$\int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)]\, \mathrm{d}V$$
$$= \int_{\mathcal{R}} \nabla_{\boldsymbol{x}} \cdot \left[\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\right] G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, \mathrm{d}V. \quad (5.156)$$

Reciprocity of the Green's function and the adjoint Green's function

The above manipulations show that the space-time integral for the left hand side of equation (5.149) vanishes. Consequently, we are left with the reciprocity relation satisfied by the Green's function and adjoint Green's function for the diffusion equation

$$\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t). \quad (5.157)$$

The right hand side results from placing a Dirac source at $(\boldsymbol{x}, t)$ and using the forward diffusion equation to determine the effect at $(\boldsymbol{x}_0, t_0)$ with $t < t_0$. The left hand side results from placing a Dirac source at $(\boldsymbol{x}_0, t_0)$ and using the adjoint diffusion equation to determine the effect at $(\boldsymbol{x}, t)$, again with $t < t_0$. The reciprocity relation (5.157) proves the two approaches are identical. We emphasize that reciprocity is the concerted property of the differential operator, the boundary conditions, and causality conditions.

Reciprocity in the form of equation (5.157) means we have no need to bother solving the adjoint Green's function equation for $\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$ since the adjoint Green's function equals to the Green's function after swapping the space-time points for the field and source. Hence, it is sufficient to determine the Green's function, $G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$, and then use reciprocity to determine $\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$. The simplicity of the reciprocity relation (5.157) is central to the practical use of the Green's function method for the diffusion equation.

5.8.5 Composition property of the Green's function

Following from the reciprocity relation derived in Section 5.8.4, we here derive the *composition property* satisfied by the Green's functions for the diffusion equation. This property connects the Green's function to Markov processes, in which the composition property is known as the *Chapman-Kolmogorov relation* (*Gardiner*, 1985). The derivation closely follows that given in Section 5.8.4 for reciprocity, though it is a bit simpler. *Larson* (1999) and *Holzer* (2009) discuss the composition property in the context of the advection-diffusion equation, to which we return to in Section 64.10.6. *Holzer* (2009) also provides further connections to probability theory, thus promoting the interpretation of the Green's function as a transition probability.

Setting up the derivation

Consider again the Green's function partial differential equation (5.145a) with a Dirac delta source at $(t_1, \boldsymbol{x}_1)$,

$$\partial_t G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1) - \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)] = \delta(t - t_1)\, \delta(\boldsymbol{x} - \boldsymbol{x}_1), \tag{5.158}$$

and the adjoint Green's function partial differential equation (5.147a) with a distinct Dirac delta source at $(t_2, \boldsymbol{x}_2)$

$$\partial_t \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2) + \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)] = -\delta(t - t_2)\, \delta(\boldsymbol{x} - \boldsymbol{x}_2). \tag{5.159}$$

Multiply each of these equations by the complement Green's function and add the two equations.[18] Adding the time derivatives leads to

$$\begin{aligned} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \partial_t G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1) + G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, \partial_t \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2) \\ = \partial_t \left[\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right], \end{aligned} \tag{5.160}$$

and adding the space derivatives leads to

$$\begin{aligned} &- \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)] + G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, \nabla_{\boldsymbol{x}} \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)] \\ &\quad = \nabla_{\boldsymbol{x}} \cdot [-\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, \mathbb{K} \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1) + G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\, \mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)]. \end{aligned} \tag{5.161}$$

[18] Recall that in Section 5.8.4 we subtracted the two equations to derive the reciprocity relation.

Integrating over the full spatial domain and using the homogeneous Neumann or Dirichlet boundary conditions removes the space derivative terms, thus leaving

$$\int_{\mathcal{R}} \partial_t \left[\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, t|\boldsymbol{x}_1, t_1)\right] \mathrm{d}V \\ = \widetilde{G}(\boldsymbol{x}_1, t|\boldsymbol{x}_2, t_2)\, \delta(t - t_1) - G(\boldsymbol{x}_2, t|\boldsymbol{x}_1, t_1)\, \delta(t - t_2). \quad (5.162)$$

Time integration and use of causality

FIGURE 5.4: Two possible placements of the time steps used to derive the Green's function composition property.

Now integrate equation (5.162) over time, assuming the spatial domain is time independent as done for the reciprocity derivation, in which case

$$\int_{\mathcal{R}} [\widetilde{G}(\boldsymbol{x}, T_2|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, T_2|\boldsymbol{x}_1, t_1) - \widetilde{G}(\boldsymbol{x}, T_1|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, T_1|\boldsymbol{x}_1, t_1)] \,\mathrm{d}V \\ = \int_{T_1}^{T_2} [\widetilde{G}(\boldsymbol{x}_1, t|\boldsymbol{x}_2, t_2)\, \delta(t - t_1) - G(\boldsymbol{x}_2, t|\boldsymbol{x}_1, t_1)\, \delta(t - t_2)] \,\mathrm{d}t, \quad (5.163)$$

where $T_1 < T_2$ are time endpoints for the time integration. The causality conditions (5.145c) and (5.147c) lead to the following identities, depending on the placements of T_1, T_2 relative to t_1, t_2 as shown in Figure 5.4

$$\widetilde{G}(\boldsymbol{x}_1, t_1|\boldsymbol{x}_2, t_2) = \int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x}, T_2|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, T_2|\boldsymbol{x}_1, t_1) \,\mathrm{d}V \quad \text{if } T_1 < t_1 < T_2 < t_2 \quad (5.164a)$$

$$G(\boldsymbol{x}_2, t_2|\boldsymbol{x}_1, t_1) = \int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x}, T_1|\boldsymbol{x}_2, t_2)\, G(\boldsymbol{x}, T_1|\boldsymbol{x}_1, t_1) \,\mathrm{d}V \quad \text{if } t_1 < T_1 < t_2 < T_2. \quad (5.164b)$$

Use of the reciprocity relation (5.157) then leads to the composition relations

$$G(\boldsymbol{x}_2, t_2|\boldsymbol{x}_1, t_1) = \int_{\mathcal{R}} G(\boldsymbol{x}_2, t_2|\boldsymbol{x}, T_2)\, G(\boldsymbol{x}, T_2|\boldsymbol{x}_1, t_1) \,\mathrm{d}V \quad \text{if } T_1 < t_1 < T_2 < t_2 \quad (5.165a)$$

$$G(\boldsymbol{x}_2, t_2|\boldsymbol{x}_1, t_1) = \int_{\mathcal{R}} G(\boldsymbol{x}_2, t_2|\boldsymbol{x}, T_1)\, G(\boldsymbol{x}, T_1|\boldsymbol{x}_1, t_1) \,\mathrm{d}V \quad \text{if } t_1 < T_1 < t_2 < T_2. \quad (5.165b)$$

These equations are identical since both include an arbitrary intermediate time that is bounded by $t_1 < t_2$, thus allowing us to write the generic composition relation

$$G(\boldsymbol{x}_2, t_2|\boldsymbol{x}_1, t_1) = \int_{\mathcal{R}} G(\boldsymbol{x}_2, t_2|\boldsymbol{x}, \tau)\, G(\boldsymbol{x}, \tau|\boldsymbol{x}_1, t_1) \,\mathrm{d}V \quad \text{if } t_1 < \tau < t_2 \quad (5.166)$$

Interpreting the Green's function composition property

The left hand side of the Green's function composition property (5.166) is the response from a Dirac source diffused from $(\boldsymbol{x}_1, t_1)$ and measured at the field space-time point $(\boldsymbol{x}_2, t_2)$. The right

hand side says that this response is identical to the composition of a Green's function feeling the source at $(\boldsymbol{x}_1, t_1)$ but now sampled at an intermediate space-time position, $(\boldsymbol{x}, \tau)$, and then further diffused to $(\boldsymbol{x}_2, t_2)$, with integration over all possible intermediate positions $\boldsymbol{x}$. Furthermore, note that the intermediate sampling can occur at an arbitrary intermediate time, τ, so long as $t_1 < \tau < t_2$. The composition property allows us to conceive of a long-time interval Green's function as the composition of an arbitrary number of shorter time interval Green's functions.

5.8.6 The integral solution

Having established reciprocity (5.157), we are now ready to derive an integral expression for the field, $\psi(\boldsymbol{x}, t)$, satisfying the diffusion equation initial-boundary value problem with either the Neumann boundary conditions

$$\frac{\partial \psi(\boldsymbol{x}, t)}{\partial t} - \nabla \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \psi(\boldsymbol{x}, t)] = \Lambda(\boldsymbol{x}, t) \quad \boldsymbol{x} \in \mathcal{R} \tag{5.167a}$$

$$\hat{\boldsymbol{n}} \cdot \mathbb{K} \cdot \nabla_{\boldsymbol{x}} \psi(\boldsymbol{x}, t) = \Sigma(\boldsymbol{x}, t) \quad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.167b}$$

$$\psi(\boldsymbol{x}, t = t_{\text{init}}) = I(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}, \tag{5.167c}$$

or Dirichlet boundary conditions

$$\frac{\partial \psi(\boldsymbol{x}, t)}{\partial t} - \nabla \cdot [\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \psi(\boldsymbol{x}, t)] = \Lambda(\boldsymbol{x}, t) \quad \boldsymbol{x} \in \mathcal{R} \tag{5.168a}$$

$$\psi(\boldsymbol{x}, t) = \sigma(\boldsymbol{x}, t) \quad \boldsymbol{x} \in \partial\mathcal{R} \tag{5.168b}$$

$$\psi(\boldsymbol{x}, t = t_{\text{init}}) = I(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}. \tag{5.168c}$$

In these equations we introduced the initial time, $t = t_{\text{init}}$, which is distinct from the Dirac delta source time, $t = t_0$. Correspondingly, the Dirac delta source is fired *after* the initial time,

$$t_{\text{init}} < t_0, \tag{5.169}$$

which follows since we are interested in the evolution of ψ after specification of the initial data, $\psi(\boldsymbol{x}, t = t_{\text{init}}) = I(\boldsymbol{x})$. Correspondingly, t_{init} defines the lower limit on time integrals in the following. Use of the $\nabla_{\boldsymbol{x}}$ notation is not needed for these equations, since there is no source point, $\boldsymbol{x}_0$, in any of the expressions. However, writing $\nabla_{\boldsymbol{x}}$ helps us remain organized during the following manipulations. Finally, note that the diffusion tensor appearing in these equations means that the source function, $\Lambda(\boldsymbol{x}, t)$, in equations (5.167a) and (5.168a), as well as the boundary data, $\Sigma(\boldsymbol{x}, t)$, in equation (5.167b), have different dimensions from their counterparts found in the Poisson boundary value problems (5.93) and (5.127).

The following derivation emulates that for the Poisson equation in Section 5.6.5, yet with distinct features arising from time evolution and the corresponding need to use the adjoint causal Green's function, $\widetilde{G}$. We expose many details as doing so reveals general notions and tricks arising with Green's function methods for initial-boundary value problems.

Setting up the derivation

To start the derivation, multiply the diffusion equation (5.167a) by the adjoint Green's function, $\widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$, and the adjoint Green's function equation (5.147a) by $\psi(\boldsymbol{x}, t)$. Subtracting and rearranging leads to

$$\partial_t(\widetilde{G}\,\psi) + \nabla \cdot [\psi\,\mathbb{K} \cdot \nabla_{\boldsymbol{x}} \widetilde{G} - \widetilde{G}\,\mathbb{K} \cdot \nabla\psi] = \widetilde{G}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)\,\Lambda(\boldsymbol{x}, t) - \psi(\boldsymbol{x}, t)\,\delta(\boldsymbol{x} - \boldsymbol{x}_0)\,\delta(t - t_0), \tag{5.170}$$

where we temporarily suppressed arguments on the left hand side for brevity. Since the spatial domain is assumed to be static, we can integrate this equation over space and time without concern for the order of integration.

Time integration

A time integral of the first left hand side term in equation (5.170) leads to

$$\int_{t_{\text{init}}}^{T} \partial_t[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\psi(\boldsymbol{x},t)]\,\mathrm{d}t = \widetilde{G}(\boldsymbol{x},T|\boldsymbol{x}_0,t_0)\,\psi(\boldsymbol{x},T) - \widetilde{G}(\boldsymbol{x},t_{\text{init}}|\boldsymbol{x}_0,t_0)\,\psi(\boldsymbol{x},t_{\text{init}}) \tag{5.171a}$$

$$= -\widetilde{G}(\boldsymbol{x},t_{\text{init}}|\boldsymbol{x}_0,t_0)\,I(\boldsymbol{x}), \tag{5.171b}$$

where we made use of the backward causal condition (5.147c) satisfied by the adjoint Green's function to set $\widetilde{G}(\boldsymbol{x},t=T|\boldsymbol{x}_0,t_0)=0$, and used the initial condition (5.167c) to introduce the initial value data, $\psi(\boldsymbol{x},t_{\text{init}})=I(\boldsymbol{x})$.

Space integration

A space integral over all observation points, and use of the divergence theorem, brings the divergence term on the left side of equation (5.170) into

$$\int_{\mathcal{R}} \nabla\cdot[\psi\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\widetilde{G} - \widetilde{G}\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi]\,\mathrm{d}V$$
$$= \oint_{\partial\mathcal{R}} \Big[\psi(\boldsymbol{x},t)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) - \widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi\Big]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{5.172}$$

where we kept both boundary terms pending specification of whether the fields satisfy Dirichlet or Neumann conditions. This boundary integral has the same appearance as found for the Poisson equation in Section 5.6.5, with the added feature here of the diffusion tensor.

Integrating the right hand side of equation (5.170)

A space and time integral for the right hand side of equation (5.170), along with the sifting properties of the Dirac delta, render

$$\int_{t_{\text{init}}}^{T}\left[\int_{\mathcal{R}}[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x},t) - \psi(\boldsymbol{x},t)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0)\,\delta(t-t_0)]\,\mathrm{d}V\right]\mathrm{d}t$$
$$= -\psi(\boldsymbol{x}_0,t_0) + \int_{t_{\text{init}}}^{T}\left[\int_{\mathcal{R}}\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x},t)\mathrm{d}V\right]\mathrm{d}t. \tag{5.173}$$

Notice how this integration over the observation space-time points, $(\boldsymbol{x},t)$, serves to pick out the field, ψ, evaluated at the space-time point, $(\boldsymbol{x}_0,t_0)$, where the Dirac delta source is located.

Rearrangement and use of reciprocity

Bringing the above results together leads to the expression

$$\psi(\boldsymbol{x}_0,t_0) = \int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x},t_{\text{init}}|\boldsymbol{x}_0,t_0)\, I(\boldsymbol{x})\,\mathrm{d}V + \int_{t_{\text{init}}}^{t_0}\left[\int_{\mathcal{R}} \widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x},t)\,\mathrm{d}V\right]\mathrm{d}t$$
$$+\int_{t_{\text{init}}}^{t_0}\left[\oint_{\partial\mathcal{R}}\left[\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x},t) - \psi(\boldsymbol{x},t)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\widetilde{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}\right]\mathrm{d}t. \tag{5.174}$$

The time integrals are restricted to the range $t \in [t_{\text{init}}, t_0]$ through use of the causality condition (5.147c) for the adjoint Green's function. Hence, the arbitrary time, T, drops out from the solution and there is no dependence on fields at times later than t_0 nor before t_{init}.

Use of reciprocity (5.157) allows us to replace the adjoint Green's function with the Green's function to thus bring equation (5.174) to

$$\psi(\boldsymbol{x}_0,t_0) = \int_{\mathcal{R}} G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}})\, I(\boldsymbol{x})\,\mathrm{d}V + \int_{t_{\text{init}}}^{t_0}\left[\int_{\mathcal{R}} G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\,\Lambda(\boldsymbol{x},t)\,\mathrm{d}V\right]\mathrm{d}t$$
$$+\int_{t_{\text{init}}}^{t_0}\left[\oint_{\partial\mathcal{R}}\left[G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x},t) - \psi(\boldsymbol{x},t)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}}G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}\right]\mathrm{d}t. \tag{5.175}$$

Finally, it is convenient to relabel $(\boldsymbol{x}_0,t_0) \leftrightarrow (\boldsymbol{x},t)$ to write

$$\psi(\boldsymbol{x},t) = \underbrace{\int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_{\text{init}})\, I(\boldsymbol{x}_0)\,\mathrm{d}V_0}_{\text{space integral of } G \text{ times } I \text{ on } \mathcal{R}} + \underbrace{\int_{t_{\text{init}}}^{t}\left[\int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x}_0,t_0)\,\mathrm{d}V_0\right]\mathrm{d}t_0}_{\text{space-time integral of } G \text{ times } \Lambda \text{ over } \mathcal{R}}$$
$$+\underbrace{\int_{t_{\text{init}}}^{t}\left[\oint_{\partial\mathcal{R}}\left[G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}_0}\psi(\boldsymbol{x}_0,t_0) - \psi(\boldsymbol{x}_0,t_0)\,\mathbb{K}\cdot\nabla_{\boldsymbol{x}_0}G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\right]\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\,\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0}_{\text{space-time integral of boundary terms over } \partial\mathcal{R}}. \tag{5.176}$$

Specializing to Neumann boundary conditions leads to

$$\psi^{\text{Neumann}}(\boldsymbol{x},t) = \int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_{\text{init}})\, I(\boldsymbol{x}_0)\,\mathrm{d}V_0 + \int_{t_{\text{init}}}^{t}\left[\int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x}_0,t_0)\,\mathrm{d}V_0\right]\mathrm{d}t_0$$
$$+\int_{t_{\text{init}}}^{t}\left[\oint_{\partial\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Sigma(\boldsymbol{x}_0,t_0)\,\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0, \tag{5.177}$$

whereas the solution with Dirichlet boundary conditions is

$$\psi^{\text{Dirichlet}}(\boldsymbol{x},t) = \int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_{\text{init}})\, I(\boldsymbol{x}_0)\,\mathrm{d}V_0 + \int_{t_{\text{init}}}^{t}\left[\int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\Lambda(\boldsymbol{x}_0,t_0)\,\mathrm{d}V_0\right]\mathrm{d}t_0$$
$$-\int_{t_{\text{init}}}^{t}\left[\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0,t_0)\,\mathbb{K}(\boldsymbol{x}_0,t_0)\cdot\nabla_{\boldsymbol{x}_0}G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\,\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0. \tag{5.178}$$

5.8.7 Properties of the solution

Many of the properties of the solution (5.176) are also reflected in the Poisson equation solutions from Sections 5.6.6 and 5.7.4. In particular, the solution manifests the linear superposition principle, with the solution given by the sum of three terms arising from the initial conditions,

distributed volume source, and spatial boundary conditions. We expect to have this connection given that the steady state diffusion equation satisfies a generalized Poisson equation (generalized by the presence of a diffusion tensor). A fundamentally new piece of physics and maths arises from time dependence. In this section we exhibit properties of the Green's function as inferred (through insisting on self-consistency) by the initial and boundary conditions.

Uniqueness of the solution

Uniqueness of a solution to the diffusion boundary value problem follows as in the discussion of the Poisson equation in Sections 5.6.2 and 5.7.2. Namely, consider two solutions to the diffusion equation and take their difference, $\Psi = \psi_A - \psi_B$. We readily see that Ψ satisfies the homogeneous diffusion equation with homogeneous boundary conditions along with a zero initial condition. Ψ thus remains zero for both the Dirichlet and Neumann cases, thus proving that the solution to both problems is unique.

Initial conditions

By sampling the solution (5.176) as time decreases towards the initial time, $t \to t_{\text{init}}$, and noting the initial condition $\psi(\boldsymbol{x}, t_{\text{init}}) = I(\boldsymbol{x})$, we are led to[19]

$$\lim_{t \to t_{\text{init}}} \psi(\boldsymbol{x}, t) = I(\boldsymbol{x}) = \lim_{t \to t_{\text{init}}} \int_{\mathcal{R}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0. \tag{5.179}$$

This temporal sampling of the field time is distinguished from the source time, t_0, which here is fixed at the initial time, $t_0 = t_{\text{init}}$. Self-consistency in equation (5.179) implies that the Green's function for both Neumann and Dirichlet boundary conditions satisfies the initial condition

$$\lim_{t \to t_{\text{init}}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}}) = \delta(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{with } \boldsymbol{x}, \boldsymbol{x}_0 \in \mathcal{R}. \tag{5.180}$$

That is, the Green's function is initialized by a Dirac delta pulse at the source point, $\boldsymbol{x}_0$, which then leads to

$$\lim_{t \to t_{\text{init}}} \int_{\mathcal{R}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 = \int_{\mathcal{R}} \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 = I(\boldsymbol{x}). \tag{5.181}$$

Neumann boundary conditions

Acting with $\mathbb{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}}$ on the Neumann solution (5.177); evaluating the expression on the boundary $\boldsymbol{x} = \boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}$; and then projecting onto the outward unit normal, $\hat{\boldsymbol{n}}_{\boldsymbol{x}}$, serves to annihilate the volume integrals as per the homogeneous Neumann conditions satisfied by the Green's function. We are thus left with

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \mathbb{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}} \psi(\boldsymbol{x}, t) = \Sigma(\boldsymbol{x}, t) = \int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \mathbb{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0)\, \Sigma(\boldsymbol{x}_0, t_0)\, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0. \tag{5.182}$$

Self-consistency implies that the Green's function for the Neumann problem, when evaluated on the spatial boundary, satisfies

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}} \cdot \mathbb{K}(\boldsymbol{x}, t) \cdot \nabla_{\boldsymbol{x}} G(\boldsymbol{x}, t | \boldsymbol{x}_0, t_0) = \delta(t - t_0)\, \delta^{(2)}(\boldsymbol{x} - \boldsymbol{x}_0) \quad \text{with } \boldsymbol{x}, \boldsymbol{x}_0 \in \partial\mathcal{R}, \tag{5.183}$$

which is a generalization of the property (5.141) holding for the Poisson equation Green's function.

[19] Since t_{init} is the initial time, the limit $t \to t_{\text{init}}$ is taken from above so that $t = t_{\text{init}} + \epsilon$ with $\epsilon \to 0$.

Transforming the Neumann boundary data to the interior

In Section 5.7.4, we saw how to transform the Neumann boundary condition into the interior by modifying the source function. The diffusion equation Neumann solution (5.177) allows for the same transformation by writing

$$\psi^{\text{Neumann}}(\boldsymbol{x},t) = \int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_{\text{init}})\, I(\boldsymbol{x}_0)\, \mathrm{d}V_0 + \int_{t_{\text{init}}}^{t} \left[\int_{\mathcal{R}} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\, \Lambda^*(\boldsymbol{x}_0,t_0)\, \mathrm{d}V_0\right] \mathrm{d}t_0, \quad (5.184)$$

where the modified source function follows from that used for the Poisson equation (5.136)

$$\Lambda^*(\boldsymbol{x}_0,t_0) = \Lambda(\boldsymbol{x}_0,t_0) + \Sigma(\boldsymbol{x}_0,t_0)\, \delta[\hat{\boldsymbol{n}}\cdot(\boldsymbol{x}_0 - \boldsymbol{x}_{\partial\mathcal{R}})]. \quad (5.185)$$

Dirichlet boundary conditions

Evaluating the Dirichlet solution (5.178) on a spatial boundary, $\boldsymbol{x} = \boldsymbol{x}_{\partial\mathcal{R}} \in \partial\mathcal{R}$, eliminates both of the volume integrals so that we are left with

$$\psi^{\text{dirichlet}}(\boldsymbol{x}_{\partial\mathcal{R}},t) = \sigma(\boldsymbol{x}_{\partial\mathcal{R}},t) = -\int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0,t_0)\, \mathbb{K}\cdot\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0\right] \mathrm{d}t_0. \quad (5.186)$$

Self-consistency implies that the Green's function for the Dirichlet problem, when evaluated on the spatial boundary, satisfies

$$\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\cdot\mathbb{K}(\boldsymbol{x}_0,t_0)\cdot\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = -\delta(t-t_0)\,\delta^{(2)}(\boldsymbol{x}-\boldsymbol{x}_0) \quad \text{with } \boldsymbol{x},\boldsymbol{x}_0 \in \partial\mathcal{R}, \quad (5.187)$$

which is a generalization of the property (5.123) holding for the Poisson equation Green's function.

5.8.8 Boundary propagator

In Sections 5.6.6 and 5.6.7 we studied the boundary Green's function for the Poisson equation. Here we extend those ideas to the *boundary propagator* for the diffusion equation, with the boundary propagator mediating the transfer of Dirichlet boundary information into the interior. Boundary propagators for diffusion and advection-diffusion (Section 64.10) have extensive use in geophysical fluids given that many tracers have no interior sources.

Defining the boundary propagator

To focus on the role of the boundary propagator, consider a tracer in which the initial conditions and interior source both vanish: $I(\boldsymbol{x}) = 0$ and $\Lambda(\boldsymbol{x},t) = 0$. Assuming Dirichlet boundary conditions, the initial-boundary value problem (5.167a)-(5.167c) simplifies to

$$\frac{\partial\psi(\boldsymbol{x},t)}{\partial t} - \nabla_{\boldsymbol{x}}\cdot[\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi(\boldsymbol{x},t)] = 0 \qquad \boldsymbol{x}\in\mathcal{R} \quad (5.188a)$$

$$\psi(\boldsymbol{x},t) = \sigma(\boldsymbol{x},t) \qquad \boldsymbol{x}\in\partial\mathcal{R} \quad (5.188b)$$

$$\psi(\boldsymbol{x},t=t_{\text{init}}) = 0 \qquad \boldsymbol{x}\in\mathcal{R}, \quad (5.188c)$$

with the corresponding Dirichlet Green's function solution (5.178) taking the form

$$\psi(\boldsymbol{x},t) = -\int_{t_{\text{init}}}^{t} \left[\oint_{\partial\mathcal{R}} \sigma(\boldsymbol{x}_0,t_0)\, \mathbb{K}(\boldsymbol{x}_0,t_0)\cdot\nabla_{\boldsymbol{x}_0} G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0}\, \mathrm{d}\mathcal{S}_0\right] \mathrm{d}t_0. \quad (5.189)$$

We define the *boundary propagator* as the kernel in this equation

$$G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) \equiv -\mathbb{K}(\boldsymbol{x}_0,t_0)\cdot\nabla_{\boldsymbol{x}_0}G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\cdot\hat{\boldsymbol{n}}_{\boldsymbol{x}_0} \quad \text{with } \boldsymbol{x}_0\in\partial\mathcal{R}, \tag{5.190}$$

with this definition giving $G^{\rm bp}$ the dimensions of $\mathrm{L}^{-2}\,\mathrm{T}^{-1}$. Use of the boundary propagator brings the solution (5.189) into the succinct form

$$\psi(\boldsymbol{x},t) = \int_{t_{\rm init}}^{t}\left[\oint_{\partial\mathcal{R}}\sigma(\boldsymbol{x}_0,t_0)\,G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)\,\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0. \tag{5.191}$$

Boundary value problem for the boundary propagator

If we know the Green's function, $G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)$, then we can compute the boundary propagator through the definition (5.190). Alternatively, we can directly determine the boundary propagator by solving its boundary value problem. Following from the definition (5.190) and the boundary condition (5.187), we know that

$$G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(t-t_0)\,\delta^{(2)}(\boldsymbol{x}-\boldsymbol{x}_0) \quad \text{with } \boldsymbol{x},\boldsymbol{x}_0\in\partial\mathcal{R}. \tag{5.192}$$

Hence, the boundary propagator, when evaluated along the boundary, is a Dirac delta source that fires at time $t=t_0$ at the location $\boldsymbol{x}=\boldsymbol{x}_0\in\partial\mathcal{R}$. To determine the partial differential equation satisfied by the boundary propagator, make use of the solution (5.191) and compute its time derivative

$$\frac{\partial\psi(\boldsymbol{x},t)}{\partial t} = \oint_{\partial\mathcal{R}}\sigma(\boldsymbol{x}_0,t)\,G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t)\,\mathrm{d}\mathcal{S}_0 + \int_{t_{\rm init}}^{t}\left[\oint_{\partial\mathcal{R}}\sigma(\boldsymbol{x}_0,t_0)\,\frac{\partial G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)}{\partial t}\,\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0. \tag{5.193}$$

The first right hand side term vanishes since the boundary propagator satisfies causality just like the Green's function when sampled at interior points

$$G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \quad \text{if } t\le t_0 \text{ and } \boldsymbol{x}\notin\partial\mathcal{R}. \tag{5.194}$$

We are thus left with

$$\begin{aligned}\frac{\partial\psi(\boldsymbol{x},t)}{\partial t} &- \nabla_{\boldsymbol{x}}\cdot(\mathbb{K}\cdot\nabla_{\boldsymbol{x}}\psi)\\ &= \int_{t_{\rm init}}^{t}\left[\oint_{\partial\mathcal{R}}\sigma(\boldsymbol{x}_0,t_0)\left[\frac{\partial G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)}{\partial t} - \nabla_{\boldsymbol{x}}\cdot[\mathbb{K}\cdot\nabla_{\boldsymbol{x}}G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)]\right]\mathrm{d}\mathcal{S}_0\right]\mathrm{d}t_0.\end{aligned} \tag{5.195}$$

Since the left hand side vanishes via the partial differential equation (5.188a), and since the boundary data, σ, is arbitrary, we are led to the causal boundary value problem for the boundary propagator

$$\frac{\partial G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)}{\partial t} - \nabla_{\boldsymbol{x}}\cdot[\mathbb{K}\cdot\nabla_{\boldsymbol{x}}G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)] = 0 \qquad \boldsymbol{x}\in\mathcal{R} \tag{5.196a}$$

$$G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x}\notin\partial\mathcal{R}, t\le t_0 \tag{5.196b}$$

$$G^{\rm bp}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(t-t_0)\,\delta^{(2)}(\boldsymbol{x}-\boldsymbol{x}_0) \quad \boldsymbol{x},\boldsymbol{x}_0\in\partial\mathcal{R}. \tag{5.196c}$$

In words, we see that upon firing the Dirac delta source on the boundary at time $t=t_0$ and point $\boldsymbol{x}=\boldsymbol{x}_0\in\partial\mathcal{R}$, the boundary propagator diffuses the Dirac source into the region interior. We thus

see that whereas the Dirichlet Green's function, $G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$, is zero along the boundary and yet feels the Dirac delta sources within the interior, the boundary propagator, $G^{\text{bp}}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$, places the Dirac delta sources just on the boundary and feels no sources within the interior. Just as the causality condition means that the Green's function is a function of $t - t_0$, so too is the boundary propagator. Furthermore, a focus on the boundary propagator rather than the Green's function allows us to dispense with the need to compute the normal gradient of the Green's function at the boundary, with that calculation rather awkward in practice.

Normalization of the boundary propagator

Consider the special case of a uniform constant Dirichlet boundary data, $\sigma = \sigma_{\text{constant}}$ in the solution (5.191). Diffusion will act on this constant boundary value to spread it throughout the region. After sufficient time the solution will reach a steady state whereby $\psi = \sigma_{\text{constant}}$ at every point withing the domain. This result means that the boundary Green's function satisfies the normalization condition

$$\lim_{t_{\text{init}} \to -\infty} \int_{t_{\text{init}}}^{t} \left[\oint_{\partial \mathcal{R}} G^{\text{bp}}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) \, \mathrm{d}\mathcal{S}_0 \right] \mathrm{d}t_0 = 1, \tag{5.197}$$

where the lower time limit is meant to indicate some arbitrary time sufficiently far in the past so that a steady state has been reached. Again, this normalization condition holds for every point within the domain and for any time. It corresponds to the normalization condition (5.126) satisfied by the boundary Green's function for the Poisson equation.

5.9 The wave equation

The linear wave equation from Section 3.6 describes the motion of non-dispersive waves such as the acoustic waves of Chapter 49 and shallow water gravity waves of Section 53.5. These are a small subset of the waves encountered in geophysical fluid mechanics, most of which are dispersive. Even so, it is useful to here introduce the Green's function formalism for non-dispersive waves both because of its intrinsic interest, and because it offers a step towards the dispersive waves. Much of the development in this section emulates that for the diffusion equation in Section 5.8, in particular the details of causality that are shared between the diffusion equation and wave equation.

5.9.1 Initial-boundary value problem for the wave equation

Consider the following initial-boundary value problem for a wave function satisfying the linear non-dispersive wave equation

$$(\partial_{tt} - c^2 \nabla^2)\, \psi(\boldsymbol{x}, t) = \Lambda(\boldsymbol{x}, t) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_{\text{init}} \tag{5.198a}$$

$$\psi(\boldsymbol{x}, t) = I(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.198b}$$

$$\partial_t \psi(\boldsymbol{x}, t) = J(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.198c}$$

$$\psi(\boldsymbol{x}, t) = \sigma(\boldsymbol{x}, t) \qquad \boldsymbol{x} \in \partial \mathcal{R}, \tag{5.198d}$$

where $\mathcal{R}$ is a spatial region, and with Λ, I, J, and σ known functions. We choose to focus on the Dirichlet boundary problem here, though note that the Neumann boundary condition is handled

similarly.[20] Compatiability between the boundary conditions and initial conditions is ensured if

$$\sigma(\boldsymbol{x}, t) = I(\boldsymbol{x}) \qquad \boldsymbol{x} \in \partial\mathcal{R}, \;\; t = t_{\text{init}}. \tag{5.199}$$

As for the diffusion equation in Section 5.8.6, we introduced the initial time, $t = t_{\text{init}}$, which is distinct from the Dirac delta source time, $t = t_0$, appearing in the Green's function equations. Correspondingly, the Dirac delta source is fired *after* the initial time,

$$t_{\text{init}} < t_0, \tag{5.200}$$

which follows since we are interested in evolution of ψ after specification of the initial data. Correspondingly, t_{init} defines the lower limit on time integrals in the following. For the upper limit we introduce an arbitrary time $T > t_0$, with T dropping out due to causality in a manner just like it did for the diffusion equation in Section 5.8.6.

5.9.2 Uniqueness of the solution

In Section 5.5.5 we proved uniqueness for the diffusion equation with Dirichlet boundary conditions, and we here display the analogous proof for the wave equation. If there are two distinct solutions, ψ_1 and ψ_2, that each solve the initial-boundary value problem (5.198a)–(5.198d), then their difference, $\Psi = \psi_1 - \psi_2$, must solve the following homogeneous system

$$(\partial_{tt} - c^2\nabla^2)\,\Psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \;\; t > t_{\text{init}} \tag{5.201a}$$

$$\Psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \;\; t = t_{\text{init}} \tag{5.201b}$$

$$\partial_t\Psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \;\; t = t_{\text{init}} \tag{5.201c}$$

$$\Psi(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.201d}$$

Now multiply the homogeneous wave equation (5.201a) by $\partial_t\Psi$ and integrate over the domain, with integration by parts leading to and energy equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} [(\partial_t\Psi)^2 + c^2\,\nabla\Psi\cdot\nabla\Psi]\,\mathrm{d}V = 2\,c^2\int_{\partial\mathcal{R}} (\partial_t\Psi)\,\nabla\Psi\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{5.202}$$

Since $\Psi = 0$ on the boundary (equation (5.201d)), we know that $\partial_t\Psi = 0$ also holds on the boundary, so that the right hand side vanishes, meaning that the energy integral is a constant

$$\int_{\mathcal{R}} [(\partial_t\Psi)^2 + c^2\,\nabla\Psi\cdot\nabla\Psi]\,\mathrm{d}V = C. \tag{5.203}$$

At the initial condition both $\Psi = 0$ and $\partial_t\Psi = 0$, in which case $\nabla\Psi = 0$ as well, which means that $C = 0$. Since the integrand is non-negative, we can only satisfy this constraint if Ψ is a space-time constant. With $\Psi = 0$ as the initial condition, then $\Psi = 0$ holds for all time, which then proves our assertion that the wave equation solution is unique.

[20] See Section 8.5 of *Duchateau and Zachmann* (1986) for the general Robin boundary value problem.

5.9.3 Relating modified initial condition solutions

Consider the following initial-boundary value problem

$$(\partial_{tt} - c^2\nabla^2)\, u(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_{\text{init}} \tag{5.204a}$$
$$u(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.204b}$$
$$\partial_t u(\boldsymbol{x}, t) = F(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.204c}$$
$$u(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}, \quad t \geq 0, \tag{5.204d}$$

as well as the slightly modified problem

$$(\partial_{tt} - c^2\nabla^2)\, v(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_{\text{init}} \tag{5.205a}$$
$$v(\boldsymbol{x}, t) = F(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.205b}$$
$$\partial_t v(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_{\text{init}} \tag{5.205c}$$
$$v(\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}, , \quad t \geq 0 \tag{5.205d}$$

where the only difference appears in the initial conditions. Compatibility between the initial condition and boundary condition requires that $F(\boldsymbol{x}) = 0$ on $\partial\mathcal{R}$. In the following we show that

$$v = \partial_t u, \tag{5.206}$$

so that finding u is sufficient for finding v. Furthermore, by superposition we can handle any arbitrary initial displacement and time derivative.

For the proof, introduce the function

$$\beta = \partial_t u, \tag{5.207}$$

with our goal to show that β satisfies the same equations as v and then, from the uniqueness theorem in Section 5.9.2, we will be able to conclude that $\beta = v$. First observe that

$$(\partial_{tt} - c^2\,\nabla^2)\beta = (\partial_{tt} - c^2\,\nabla^2)\partial_t u = \partial_t(\partial_{tt} - c^2\,\nabla^2)u = 0, \tag{5.208}$$

so that β satisfies the homogeneous wave equation. Since u vanishes on $\partial\mathcal{R}$ for all time, $t \geq 0$, then it has a vanishing time derivative there as well, which means that $\beta = 0$ on $\partial\mathcal{R}$. For the initial condition, observe that

$$\beta(\boldsymbol{x}, 0) = \partial_t u(\boldsymbol{x}, 0) = F(\boldsymbol{x}). \tag{5.209}$$

Finally, we have

$$\partial_t\beta(\boldsymbol{x}, t) = \partial_{tt} u(\boldsymbol{x}, t) = c^2\nabla^2 u(\boldsymbol{x}, t). \tag{5.210}$$

Since $u(\boldsymbol{x}, t = 0) = 0$, we know that $\nabla^2 u(\boldsymbol{x}, t = 0) = 0$, which means that

$$\partial_t\beta(\boldsymbol{x}, 0) = 0. \tag{5.211}$$

We have thus established that β satisfies the same initial-boundary value problem as v, which means that $\beta = v$.

5.9.4 Causal free space Green's function

The causal free space Green's function for the wave equation satisfies

$$(\partial_{tt} - c^2\nabla^2_{\boldsymbol{x}})\,\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(t-t_0)\,\delta(\boldsymbol{x}-\boldsymbol{x}_0) \qquad \boldsymbol{x},\boldsymbol{x}_0 \in \mathbb{R}^n \tag{5.212a}$$

$$\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x},\boldsymbol{x}_0 \in \mathbb{R}^n,\ \ t \le t_0 \tag{5.212b}$$

$$\partial_t\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0) \qquad \boldsymbol{x},\boldsymbol{x}_0 \in \mathbb{R}^n,\ \ t = t_0, \tag{5.212c}$$

where $c > 0$ is a constant wave speed (dimensions L T^{-1}). An initial condition (5.212c) on the time derivative is needed since the wave equation has two time derivatives, and it is chosen as a Dirac source. Note that we do not impose a regularity condition at infinity, in contrast to equation (5.143b) for the diffusion equation free space Green's function. The reason is that we can conceive, at least in principle, of waves reaching out to infinity at time infinity. Finally, given the dimensions of the Dirac source, we see that the Green's function has dimensions of T L^{-n}.

Consider the slightly simpler Green's function problem by focusing on times $t > t_0$ and setting $t_0 = 0$ and $\boldsymbol{x}_0 = 0$, in which case we have

$$(\partial_{tt} - c^2\nabla^2)\,g(\boldsymbol{x},t) = 0 \qquad \boldsymbol{x} \in \mathbb{R}^n,\ \ t > 0 \tag{5.213a}$$

$$g(\boldsymbol{x},t) = 0 \qquad \boldsymbol{x} \in \mathbb{R}^n,\ \ t = 0+ \tag{5.213b}$$

$$\partial_t g(\boldsymbol{x},t) = \delta(\boldsymbol{x}) \qquad \boldsymbol{x} \in \mathbb{R}^n,\ \ t = 0+, \tag{5.213c}$$

where $t = 0+$ refers to a time that is arbitrarily close to, but greater than, $t = 0$. We now show that

$$\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0 = 0, t_0 = 0) = \mathcal{H}(t)\,g(\boldsymbol{x},t), \tag{5.214}$$

or more generally

$$\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \mathcal{H}(t-t_0)\,g(\boldsymbol{x},t|\boldsymbol{x}_0,t_0). \tag{5.215}$$

This result is not too surprising since, by causality, $\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0)$ vanishes for times prior to the Dirac delta is fired, so we suspect it should be proportional to a Heaviside step function.

A proof of equation (5.215) requires the time derivatives (dropping the $\boldsymbol{x}$ label for brevity)

$$\partial_t\mathcal{G}(t) = \delta(t)\,g(t) + \mathcal{H}(t)\,\partial_t g(t) \tag{5.216a}$$

$$\partial_{tt}\mathcal{G}(t) = (\mathrm{d}\delta(t)/\mathrm{d}t)\,g(t) + 2\,\delta(t)\,\partial_t g(t) + \mathcal{H}(t)\,\partial_{tt} g(t). \tag{5.216b}$$

To massage the second derivative term, introduce a prime symbol for time derivative so that[21]

$$\delta'(t)\,g(t) + \delta(t)\,\partial_t g(t) = \delta'(t)\,g(t) - t\,\delta'(t)\,\partial_t g(t) \qquad \text{dipole identity (5.28)} \tag{5.217a}$$

$$= \delta'(t)\,[g(t) - t\,\partial_t g(t)] \qquad \text{reorganize} \tag{5.217b}$$

$$= \delta'(t)\,[g(t) - g(t) + g(0)] \qquad \text{Taylor series around } t = 0 \tag{5.217c}$$

$$= \delta'(t)\,g(0). \tag{5.217d}$$

Causality, along with the initial condition (5.213b), means that $g(t = 0) = 0$, so that

$$\partial_{tt}\mathcal{G}(t) = \delta(t)\,\partial_t g(t) + \mathcal{H}(t)\,\partial_{tt} g(t). \tag{5.218}$$

When multiplying a function and the Dirac delta, it is sufficient to evaluate that function at the

[21] These manipulations are motivated from page 61 of *Stakgold* (2000b), including his footnote.

place where the Dirac fires, so that

$$\delta(t)\,\partial_t g(\boldsymbol{x},t) = \delta(t)\,\partial_t g(\boldsymbol{x},0) = \delta(t)\,\delta(\boldsymbol{x}), \tag{5.219}$$

where the final equality made use of the initial condition (5.213c). Bringing all the pieces together leads to

$$(\partial_{tt} - c^2\,\nabla^2)\mathcal{G} = \mathcal{H}(t)\,(\partial_{tt} - c^2\,\nabla^2)g + \delta(t)\,\delta(\boldsymbol{x}) = \delta(t)\,\delta(\boldsymbol{x}), \tag{5.220}$$

with the final equality holding since $(\partial_{tt} - c^2\,\nabla^2)g = 0$ as per equation (5.213a). We have thus shown that the causal free-space Green's function for the wave equation can be decomposed as in equation (5.215), in which case it is sufficient to solve equations (5.213a)-(5.213c).

5.9.5 Expressions for the free space Green's functions

Following the methods from Section 28.4 of *Dennery and Krzywicki* (1967), Section 8.5 of *Duchateau and Zachmann* (1986), and Section 5.8 of *Stakgold* (2000b), the causal free-space Green's function for the wave equation is given by[22]

$$\mathcal{G}(x,t|x_0,t_0) = \frac{\mathcal{H}[c\,(t-t_0) - |x-x_0|]}{2c} \qquad n = 1 \text{ space dimension} \tag{5.221a}$$

$$\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \frac{\mathcal{H}[c\,(t-t_0) - |\boldsymbol{x}-\boldsymbol{x}_0|]}{2\,\pi\,c\,\sqrt{[c\,(t-t_0)]^2 - |\boldsymbol{x}-\boldsymbol{x}_0|^2}} \qquad n = 2 \text{ space dimensions} \tag{5.221b}$$

$$\mathcal{G}(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \frac{\delta[c\,(t-t_0) - |\boldsymbol{x}-\boldsymbol{x}_0|]}{4\,\pi\,c\,|\boldsymbol{x}-\boldsymbol{x}_0|} \qquad n = 3 \text{ space dimensions.} \tag{5.221c}$$

These wave solutions manifest causality since they vanish for regions in space-time that are unconnected to the source, as accords with the domain of influence shown by Figure 3.3.

There is an essential distinction between the three-dimensional Green's function (5.221c) relative to the one and two dimensional Green's functions (5.221a) and (5.221b). Namely, in three dimensions the Green's function is a spherical front that is infinitely sharp (i.e., a Dirac front) that propagates outward at speed c from the source point at $\boldsymbol{x} = \boldsymbol{x}_0$. The one and two dimensional Green's function fronts also move with speed c, yet these fronts are trailed by a wake as realized by the Heaviside step function. Furthermore, observe that the two dimensional wake decays according to the inverse distance from the front.

5.9.6 Causal Green's function for the wave equation

The causal Green's function corresponding to the initial-boundary value problem (5.198a)-(5.198d) is given by

$$(\partial_{tt} - c^2\nabla^2)\,G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = \delta(\boldsymbol{x}-\boldsymbol{x}_0)\,\delta(t-t_0) \qquad \boldsymbol{x},\boldsymbol{x}_0 \in \mathcal{R} \tag{5.222a}$$

$$G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R},\;\; t < t_0 \tag{5.222b}$$

$$G(\boldsymbol{x},t|\boldsymbol{x}_0,t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.222c}$$

We observe the following properties that are of use in the following.

- The time dependence only appears as the difference, $t - t_0$, so that there is no real need to

[22] Recall from Section 5.3.5 that the Heaviside step function is a non-dimensional function, whereas the Dirac delta has dimensions given by the inverse dimensions of its argument. These properties are key to checking that the given Green's functions in equations (5.221a)-(5.221c) have dimensions T L^{-n}.

retain both time variables. Correspondingly,

$$\partial_t G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = -\partial_{t_0} G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0). \tag{5.223}$$

- The wave operator is self-adjoint. Even so, swapping t and t_0 results in a swapped causality relation so that if $G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$ is the causal Green's function that satisfies equations (5.222a)-(5.222c), then $G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t)$ represents and *anti-causal* Green's function in that it satisfies

$$(\partial_{tt} - c^2\nabla^2)\, G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t) = \delta(\boldsymbol{x} - \boldsymbol{x}_0)\, \delta(t - t_0) \qquad \boldsymbol{x}, \boldsymbol{x}_0 \in \mathcal{R} \tag{5.224a}$$

$$G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t > t_0 \tag{5.224b}$$

$$G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.224c}$$

- By the same arguments used in Section 5.9.4, we can determine the causal Green's function by solving the following initial-boundary value problem

$$(\partial_{tt} - c^2\nabla^2)\, g(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x}, \boldsymbol{x}_0 \in \mathcal{R} \quad t > t_0 \tag{5.225a}$$

$$g(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_0 \tag{5.225b}$$

$$\partial_t g(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = \delta(\boldsymbol{x} - \boldsymbol{x}_0) \qquad \boldsymbol{x} \in \mathcal{R}, \quad t = t_0 \tag{5.225c}$$

$$g(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = 0 \qquad \boldsymbol{x} \in \partial\mathcal{R}. \tag{5.225d}$$

As in equation (5.215) for the free space Green's function, we have

$$G(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0) = \mathcal{H}(t - t_0)\, g(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0). \tag{5.226}$$

5.9.7 Green's function solution to the wave equation

The self-adjoint nature of the wave operator simplifies the derivation of the Green's function solution relative that needed for the diffusion equation in Section 5.8. To proceed, multiply the swapped Green's function equation (5.224a) by the wave function and integrate over the space-time domain

$$\psi(\boldsymbol{x}_0, t_0) = \int_{\mathcal{R}} \int_{t_{\text{init}}}^{T} \psi(\boldsymbol{x}, t)\, (\partial_{tt} - c^2\nabla^2)\, G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t)\, \mathrm{d}t\, \mathrm{d}V_{\boldsymbol{x}}. \tag{5.227}$$

Dropping arguments for brevity, we move the wave operator from acting on the Green's function to the wave function leads to

$$\psi\, (\partial_{tt} - c^2\nabla^2)\, G = G\, (\partial_{tt} - c^2\, \nabla^2)\psi + \partial_t(\psi\, \partial_t G - G\, \partial_t\psi) - c^2\, \nabla \cdot (\psi\, \nabla G - G\, \nabla\psi). \tag{5.228}$$

Making use of the partial differential equation (5.198a) satisfied by the wave equation brings the first right hand side term to

$$G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t)\, (\partial_{tt} - c^2\, \nabla^2)\psi(\boldsymbol{x}, t) = G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t)\, \Lambda(\boldsymbol{x}, t). \tag{5.229}$$

The space integral of the space derivative term in equation (5.228) is given by

$$\int_{\mathcal{R}} \nabla_{\boldsymbol{x}} \cdot (\psi\, \nabla_{\boldsymbol{x}} G - G\, \nabla_{\boldsymbol{x}}\psi)\, \mathrm{d}V_{\boldsymbol{x}} = \int_{\partial\mathcal{R}} \sigma(\boldsymbol{x}, t)\, \nabla_{\boldsymbol{x}} G(\boldsymbol{x}_0, t_0|\boldsymbol{x}, t) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}_{\boldsymbol{x}}, \tag{5.230}$$

where we used the Dirichlet boundary condition (5.198d) satisfied by ψ and the homogeneous Dirichlet condition (5.224c) satisfied by the Green's function.

We need to do a bit more work for the time integral of the time derivative term in equation (5.228), which is given by

$$\int_{t_{\text{init}}}^{T} \partial_t(\psi\,\partial_t G - G\,\partial_t\psi)\,\mathrm{d}t = [\psi(\boldsymbol{x},t)\,\partial_t G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t) - G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\,\partial_t\psi(\boldsymbol{x},t)]\Big|_{t_{\text{init}}}^{T}. \tag{5.231}$$

The initial conditions (5.198b) and (5.198c), along with the anti-causality condition (5.224b), render

$$\int_{t_{\text{init}}}^{T} \partial_t(\psi\,\partial_t G - G\,\partial_t\psi)\,\mathrm{d}t = -I(\boldsymbol{x})\,\partial_t G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}}) + J(\boldsymbol{x})\,G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}}) \tag{5.232a}$$

$$= I(\boldsymbol{x})\,\partial_{t_0} G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}}) + J(\boldsymbol{x})\,G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}}), \tag{5.232b}$$

where the second equality used the property (5.223) of the time derivatives acting on the Green's function. Notice that the upper time limit, T, drops out due to the anti-causality condition.

Bringing terms together leads to the Green's function solution to the wave equation

$$\begin{aligned}\psi(\boldsymbol{x}_0,t_0) = &\int_{\mathcal{R}}\int_{t_{\text{init}}}^{t_0} \Lambda(\boldsymbol{x},t)\,G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\,\mathrm{d}t\,\mathrm{d}V_{\boldsymbol{x}}\\ &- c^2\int_{\partial\mathcal{R}}\int_{t_{\text{init}}}^{t_0} \sigma(\boldsymbol{x},t)\nabla_{\boldsymbol{x}}G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t)\cdot\boldsymbol{n}\,\mathrm{d}\mathcal{S}_{\boldsymbol{x}}\\ &+ \int_{\mathcal{R}} [I(\boldsymbol{x})\,\partial_{t_0}G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}}) + J(\boldsymbol{x})\,G(\boldsymbol{x}_0,t_0|\boldsymbol{x},t_{\text{init}})]\,\mathrm{d}V_{\boldsymbol{x}}.\end{aligned} \tag{5.233}$$

Again notice that the upper time limit, T, drops out due to the anti-causality condition. Hence, the Green's function solution (5.233) only depends on processes happening between the initial time, t_{init}, and current time, t_0, thus manifesting causality. This solution shares much with the diffusion equation in Section 5.8, but here with the addition of a second initial condition due to the second order time derivative appearing in the wave equation, whereas there is only a single time derivative in the diffusion equation.

5.9.8 The Helmholtz equation

Consider the wave equation (5.198a) in unbounded space

$$(\partial_{tt} - c^2\,\nabla^2)\,\psi = \lambda. \tag{5.234}$$

Now introduce the time-frequency Fourier transforms, $\Psi(\boldsymbol{x},\omega)$ and $\Lambda(\boldsymbol{x},\omega)$ (see equations (4.101a) and (4.101b)) whereby

$$\psi(\boldsymbol{x},t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Psi(\boldsymbol{x},\omega)\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}\,\mathrm{d}\omega \quad\text{and}\quad \lambda(\boldsymbol{x},t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Lambda(\boldsymbol{x},\omega)\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}\,\mathrm{d}\omega, \tag{5.235}$$

thus yielding the frequency domain version of the wave equation

$$[\nabla^2 + (\omega/c)^2]\,\Psi = -\Lambda/c^2. \tag{5.236}$$

This is the *Helmholtz equation* first introduced in Section 3.6.3, and its corresponding free space Green's function satisfies the singular elliptic problem

$$[\nabla^2 + (\omega/c)^2]\,\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0;\omega) = -\delta(\boldsymbol{x}-\boldsymbol{x}_0). \tag{5.237}$$

Observe that the Helmholtz operator, $\nabla^2 + (\omega/c)^2$, differs from the screened Poisson operator, $\nabla^2 - \mu^2$ (equation (5.67)), due to the differing signs on the constant. One may relate the two by setting

$$\mu = -\mathrm{i}\,\omega/c. \tag{5.238}$$

This connection proves rather important for both the physics and the maths, yet with details involving aspects of causality and complex analysis that are beyond our scope.[23] It is satisfying that the details do confirm that the Helmholtz free space Green's function is related to the screened Poisson Green's function (5.72c) simply by setting $\mu = -\mathrm{i}\,\omega/c$, so that

$$\mathcal{G}(\boldsymbol{x}|\boldsymbol{x}_0;\omega) = \frac{\mathrm{e}^{\mathrm{i}\,|\boldsymbol{x}-\boldsymbol{x}_0|\,\omega/c}}{4\,\pi\,|\boldsymbol{x}-\boldsymbol{x}_0|}. \tag{5.239}$$

5.10 Initial value problems and response functions

In this section we focus on initial value problems and study the response functions that help to characterize a dynamical system. For this purpose, consider the first order ordinary differential equation

$$[\mathrm{d}/\mathrm{d}t + \lambda(t)]\,\psi(t) = F(t) \quad \text{with } \psi(t \le t_{\text{init}}) = 0, \tag{5.240}$$

where ψ is some geophysical field, such as the anomalous sea surface temperature, λ is a feedback parameter that is positive for a damped system, and F is a forcing function such as that introduced by atmospheric variability on the surface ocean. We are only concerned with temporal behavior so that all spatial information is ignored. This equation has found widespread use in the climate dynamics community, largely following the work from *Hasselmann* (1976).

The material in this section could well have been used near the start of this chapter since it only involves ordinary differential equations. However, placing it at the end helps to tie together some of the material sprinkled throughout this chapter, and to connect to applications of Green's function technology for studies of climate dynamics.

5.10.1 Impulse response function

Consider the system (5.240) with $\lambda > 0$ a time-independent feedback parameter damping the system back to zero, and with the forcing given by a Dirac delta

$$[\mathrm{d}/\mathrm{d}t + \lambda]\,G(t|t_0) = \alpha\,\delta(t-t_0) \quad \text{with } G(t|t_0) = 0 \text{ for } t < t_0, \tag{5.241}$$

where $\alpha > 0$ is a constant dimensionless scaling coefficient. We refer to the resulting causal Green's function, $G(t|t_0)$, as the *impulse response function* since it represents the response of the dynamical system to an impulse provided by the Dirac delta.[24]

Initial condition for the impulse response function

To determine the initial condition for the Green's function, integrate equation (5.241) over an interval containing the source time, t_0, to render

$$\lim_{\epsilon\to 0}\left[G(t_0+\epsilon|t_0) - G(t_0-\epsilon|t_0) + \int_{t_0-\epsilon}^{t_0+\epsilon} \lambda\,G(t|t_0)\,\mathrm{d}t\right] = \alpha. \tag{5.242}$$

[23] We recommend for the curious reader to study Section 50 of *Fetter and Walecka* (2003), who provide a lucid discussion of the role of causality, as well as Section 5.8 and 7.12 of *Stakgold* (2000b), for a precise discussion of the mathematical derivations.

[24] Recall our discussion of impulse in Section 5.3.7.

Causality means that $G(t_0 - \epsilon|t_0) = 0$ so that

$$\lim_{\epsilon\to 0} G(t_0 + \epsilon|t_0) + \lim_{\epsilon\to 0} \int_{t_0}^{t_0+\epsilon} \lambda\, G(t|t_0)\, \mathrm{d}t = \alpha. \tag{5.243}$$

We assume that the integral vanishes in the limit of $\epsilon \to 0$, which is a sensible assumption since the only means to have a nonzero integral is if the Green's function had a singularity similar to a Dirac delta. We are thus led to the initial condition for the Green's function

$$G(t = t_0|t_0) = \alpha. \tag{5.244}$$

Solution for the impulse response function

The causality condition $G(t < t_0|t_0) = 0$ can be satisfied by introducing the Heaviside step function from Section 5.3.5

$$G(t|t_0) = \mathcal{H}(t - t_0)\, g(t) \quad \text{with} \quad [\mathrm{d}/\mathrm{d}t + \lambda]\, g = 0 \quad \text{and} \quad g(t = t_0) = \alpha, \tag{5.245}$$

with the solution readily determined to be the damped exponential

$$G(t|t_0) = \mathcal{H}(t - t_0)\, \alpha\, e^{-\lambda\,(t-t_0)}. \tag{5.246}$$

We verify this function satisfies the initial value problem (5.241) by noting that

$$\mathrm{d}G(t|t_0)/\mathrm{d}t = \alpha\, \delta(t - t_0)\, e^{-\lambda\,(t-t_0)} - \lambda\, G(t|t_0) = \alpha\, \delta(t - t_0) - \lambda\, G(t|t_0) \tag{5.247}$$

as per the discussion leading to equation (5.17). As illustrated in Figure 5.5, the impulse response function (5.246) has a particularly simple interpretation as the damped exponential response of the dynamical system to a Dirac impulse fired at $t = t_0$.

FIGURE 5.5: Left panel: Dirac delta that is fired at time $t = t_0$. Right panel: The impulse response function (5.246) resulting from the Dirac delta impulse as realized for the damped linear system (5.241).

5.10.2 Step response function

Rather than hit the system at a particular moment in time with a Dirac delta, we may choose to impose a force that turns on and remains on after some initial time, as per a Heaviside step function. The *step response function*, $S(t|t_0)$, measures the response of the dynamical system to this step forcing and it satisfies the differential equation

$$[\mathrm{d}/\mathrm{d}t + \lambda]\, S(t|t_0) = \alpha\, \mathcal{H}(t - t_0) \quad \text{with } S(t|t_0) = 0 \text{ for } t < t_0. \tag{5.248}$$

Note that in the steady state at $t \to \infty$, the step response function asymptotes to the constant

$$\lim_{t\to\infty} S(t|t_0) = \alpha/\lambda. \tag{5.249}$$

Connection to the impulse response function

The time derivative $\mathrm{d}/\mathrm{d}t_0$ acting on the step response function equation (5.248) leads to

$$[\mathrm{d}/\mathrm{d}t + \lambda]\,\mathrm{d}S(t|t_0)/\mathrm{d}t_0 = \alpha\,\mathrm{d}\mathcal{H}(t-t_0)/\mathrm{d}t_0. \tag{5.250}$$

The derivative of the Heaviside step function equals to the Dirac delta as per equation (5.21), in which

$$\mathrm{d}\mathcal{H}(t-t_0)/\mathrm{d}t_0 = -\mathrm{d}\mathcal{H}(t-t_0)/\mathrm{d}t = -\delta(t-t_0). \tag{5.251}$$

Use of this result in equation (5.250), and comparison to the impulse response function equation (5.241), yields the identity

$$\frac{\mathrm{d}S(t|t_0)}{\mathrm{d}t_0} = -G(t|t_0). \tag{5.252}$$

This identity holds even when the feedback parameter is a function of time, $\lambda = \lambda(t)$, since the time derivative operator, $\mathrm{d}/\mathrm{d}t_0$, has no effect on $\lambda(t)$.

Initial condition for the step response function

To determine the initial condition for the step response function, integrate equation (5.248) over an interval bounding t_0 and take the limit as that interval vanishes

$$\lim_{\epsilon\to 0}\left[S(t_0+\epsilon|t_0) - S(t_0-\epsilon|t_0) + \int_{t_0-\epsilon}^{t_0+\epsilon} \lambda\, S(t|t_0)\,\mathrm{d}t = \int_{t_0-\epsilon}^{t_0+\epsilon} \mathcal{H}(t-t_0)\,\mathrm{d}t\right]. \tag{5.253}$$

Causality means that $S(t_0-\epsilon|t_0) = 0$. Furthermore, the integral of the Heaviside is given by

$$\lim_{\epsilon\to 0}\int_{t_0-\epsilon}^{t_0+\epsilon} \mathcal{H}(t-t_0)\,\mathrm{d}t = \lim_{\epsilon\to 0}\int_{t_0}^{t_0+\epsilon} \mathcal{H}(t-t_0)\,\mathrm{d}t = \lim_{\epsilon\to 0}\epsilon = 0, \tag{5.254}$$

so that

$$\lim_{\epsilon\to 0} S(t_0+\epsilon|t_0) = \epsilon\,\lambda \Longrightarrow S(t=t_0|t_0) = 0. \tag{5.255}$$

That is, the step response function starts at zero and then grows in time in response to the Heaviside step function forcing.

Solution for the step response function

It is straightforward to show that the causal step response function is given by the saturating exponential

$$S(t|t_0) = \frac{\alpha}{\lambda}\left[1 - e^{-\lambda\,(t-t_0)}\right]\mathcal{H}(t-t_0). \tag{5.256}$$

Figure 5.6 depicts this function along with the Heaviside step forcing. Furthermore, we verify the connection between $S(t|t_0)$ and $G(t|t_0)$ by computing

$$\mathrm{d}S(t|t_0)/\mathrm{d}t_0 = -\alpha\,\mathcal{H}(t-t_0)\,e^{-\lambda\,(t-t_0)} - \frac{\alpha}{\lambda}\left[1 - e^{-\lambda\,(t-t_0)}\right]\delta(t-t_0) \tag{5.257a}$$

$$= -G(t|t_0) - \frac{\alpha}{\lambda}\left[1 - e^{-\lambda\,(t-t_0)}\right]\delta(t-t_0). \tag{5.257b}$$

The second term on the right hand side vanishes since

$$\int_{t_0-\epsilon}^{t_0+\epsilon} \left[1 - e^{-\lambda\,(t-t_0)}\right] \delta(t-t_0)\,\mathrm{d}t = 0, \tag{5.258}$$

in which case we have

$$\mathrm{d}S(t|t_0)/\mathrm{d}t_0 = -G(t|t_0). \tag{5.259}$$

FIGURE 5.6: Left panel: Heaviside step function is fired at time $t = t_0$ and stays on afterward. Right panel: The step response function (5.256) resulting from the Heaviside step forcing impulse as realized for the damped linear system (5.241).

5.10.3 Reciprocity relation

The initial value problem (5.240) is not self-adjoint. Hence, we need to develop a reciprocity condition for the impulse response function and its adjoint, following the procedure used for the diffusion equation in Section 5.8.4. Again, the impulse response function satisfies

$$[\mathrm{d}/\mathrm{d}t + \lambda]\,G(t|t_1) = \alpha\,\delta(t-t_1) \quad \text{with } G(t|t_1) = 0 \text{ for } t < t_1 \text{ and } G(t_1|t_1) = \alpha, \tag{5.260}$$

and the adjoint impulse response function satisfies

$$[-\mathrm{d}/\mathrm{d}t + \lambda]\,\widetilde{G}(t|t_2) = \alpha\,\delta(t-t_2) \quad \text{with } \widetilde{G}(t|t_2) = 0 \text{ for } t > t_2 \text{ and } \widetilde{G}(t_2|t_2) = \alpha. \tag{5.261}$$

We here introduced two Dirac delta source times, t_1, t_2, which both occur after the initial time and before the end time

$$t_{\text{init}} < t_1, t_2 < T. \tag{5.262}$$

As we will see, causality eliminates the final time, T, from the solution for ψ. We retain it merely for bookeeping.

Determining the reciprocity relation between $\widetilde{G}$ and G follows by multiplying equation (5.260) by $\widetilde{G}(t|t_2)$ and multiplying equation (5.261) by $G(t|t_1)$ and then subtracting

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[G(t|t_1)\,\widetilde{G}(t|t_2)\right] = \alpha\,[\widetilde{G}(t|t_2)\,\delta(t-t_1) - G(t|t_1)\,\delta(t-t_2)]. \tag{5.263}$$

Now integrate this equation over the time range $t_{\text{init}} \le t \le T$. For the right hand side we assume α to be a constant, which then leads to the difference $\widetilde{G}(t_1|t_2) - G(t_2|t_1)$. For the left hand side,

use of the causality conditions in equations (5.260) and (5.261) render

$$\int_{t_{\text{init}}}^{T} \frac{\mathrm{d}}{\mathrm{d}t}\left[G(t|t_1)\,\widetilde{G}(t|t_2)\right]\mathrm{d}t = 0, \tag{5.264}$$

thus yielding the reciprocity relation

$$\widetilde{G}(t|t_0) = G(t_0|t). \tag{5.265}$$

The feedback parameter, λ, dropped out from the derivation, with the reciprocity relation holding even if λ is time dependent. However, we again needed to assume the coefficient α to be constant.

5.10.4 Response function for general forcing

We now return to the initial value problem (5.240) and determine the response, ψ, to a general forcing function, $F(t)$, that turns on at some initial time $t = t_0 > t_{\text{init}}$. As for our earlier discussions of Green's functions, we express the general response function as an integral over impulse responses. For this purpose, multiply equation (5.240) by $\widetilde{G}(t|t_0)$ and the adjoint equation (5.261) by $\psi(t)$, subtract, and then integrate to find

$$\alpha\,\psi(t_0) = \int_{t_{\text{init}}}^{T} \widetilde{G}(t|t_0)\,F(t)\,\mathrm{d}t - \int_{t_{\text{init}}}^{T} \frac{\mathrm{d}}{\mathrm{d}t}\left[\widetilde{G}(t|t_0)\,\psi(t)\right]\mathrm{d}t. \tag{5.266}$$

Making use of the causality condition $\widetilde{G}(t|t_0) = 0$ for since $t > t_0$ leads to

$$\alpha\,\psi(t_0) = \widetilde{G}(t_{\text{init}}|t_0)\,\psi(t_{\text{init}}) + \int_{t_{\text{init}}}^{t_0} \widetilde{G}(t|t_0)\,F(t)\,\mathrm{d}t, \tag{5.267}$$

where we retained the possibility of $\psi(t_{\text{init}}) \neq 0$ for a bit of generality. The reciprocity condition (5.265) brings this equation to the form

$$\alpha\,\psi(t_0) = G(t_0|t_{\text{init}})\,\psi(t_{\text{init}}) + \int_{t_{\text{init}}}^{t_0} G(t_0|t)\,F(t)\,\mathrm{d}t, \tag{5.268}$$

and swapping symbols, $t \leftrightarrow t_0$, yields

$$\alpha\,\psi(t) = G(t|t_{\text{init}})\,\psi(t_{\text{init}}) + \int_{t_{\text{init}}}^{t} G(t|t_0)\,F(t_0)\,\mathrm{d}t_0. \tag{5.269}$$

As anticipated, the general response is written as an initial response plus the integral of the general forcing with the impulse response function. Causality ensures that ψ is dependent only on forcing that is active between the initial time, t_{init}, and current time, t. To garner further insights into the general expression (5.269), consider the special case of constant feedback parameter, λ, in which the impulse response function is (5.246) so that

$$\psi(t) = e^{-\lambda\,(t-t_{\text{init}})}\,\psi(t_{\text{init}}) + \int_{t_{\text{init}}}^{t} e^{-\lambda\,(t-t_0)}\,F(t_0)\,\mathrm{d}t_0. \tag{5.270}$$

5.10.5 Connection to the boundary propagator

Recall our discussion in Section 5.8.8 of the boundary propagator for the diffusion equation, which solves the causal boundary value problem (5.196a)-(5.196c). Again, the boundary propogator,

$G^{\text{bp}}(\boldsymbol{x}, t|\boldsymbol{x}_0, t_0)$, measures the response of the system at $(\boldsymbol{x}, t)$ to a Dirac delta space-time source imposed along the surface boundary. The details of the diffusion process are encoded into the boundary propagator so that the propagator is able to build up the response, ψ, to a general boundary forcing function, σ, as per equation (5.191). The discussion in the current section thus prompts us to consider the boundary propagator as an impulse response function for spatially distributed sources whose influence is mediated by diffusion.

5.10.6 Comments and further study

Many applications of Green's function methods in geophysical fluid mechanis and climate dynamics do not make use of analytical methods to solve for the Green's function. Instead, they make use of numerical estimates based on time stepping passive tracers in ocean and atmospheric models, with source functions approximating Dirac delta sources. Many applications have focused on boundary propagators, which as shown in this section are equivalant to impulse response functions for boundary sources. We return to this point when discussing the passive tracer equation in Section 64.10.

Hasselmann et al. (1993) introduced the impulse response function and step response function to the study of climate model drift. *Marshall et al.* (2014) and *Zanna et al.* (2019) presented further studies using this framework. Some of the mathematical formulation of impulse response and step response functions as presented here follow that offered in Exercise 1.52 of *Stakgold* (2000a).

Chapter 6

Calculus of variations

The *calculus of variations* or *variational calculus* provides a mathematical framework to determine what function produces an extremum to an integral, with the integral typically built from a *functional*, which is a function of functions. *Yourgrau and Mandelstam* (1968) discuss the intellectual origins of variational methods, which started from extremum questions posed by the ancient Greeks and then found its modern realization in the work of Fermat in optics and in mechanics by Newton, the Bernoulli brothers, Euler, Legendre, Lagrange, and Hamilton. Variational methods are central to nearly all of modern physics, including classical and quantum field theory. In addition to physics, the calculus of variations is central to methods of optimization, information theory, and data assimilation, with an internet search exposing any number of treatments for these topics.

Various treatments of the calculus of variations are given in classical mechanics texts, with the present chapter building from Chapter 2 of *Goldstein* (1980), Chapter 5 of *Marion and Thornton* (1988), Chapter 2 of *Basdevant* (2007), and Appendix B of *Tracy et al.* (2014). Our treatment is relatively brief, first working through the derivation of the *Euler equation* and then providing a few analytical examples. Variational methods can handle constraints that modify the solution to the extremum problem. We do not consider constraints in this chapter, leaving their treatment for analytical mechanics as studied in Chapter 12.

READER'S GUIDE TO THIS CHAPTER

The calculus of variations is fundamental to various parts of this book through the use of *Hamilton's Principle*, with applications to analytical mechanics in Chapter 12, continuum field theory in Chapter 16, and wave mechanics in Chapter 48 (and other waves chapters in Part IX). In these mechanical examples, the functional is known as the *Lagrangian* and the integral is the *action*.

When making use of variational methods in other chapters of this book, we typically provide background to the calculus of variations sufficient to deal with the problem at hand. Consequently, the present chapter can be readily skipped. Even so, we offer this chapter for those wanting a bit more understanding of the method's foundations, as well as some analytical examples from the numerous problems whose solutions are enabled by variational methods.

6.1 Mathematical formulation

The fundamental goal of the calculus of variations concerns the determination of a function that extremizes the integral of a given functional. For example, what is the shortest path between two points on a plane? Experience indicates that the shortest path is a straight line, and with the formalism of the calculus of variations supporting this experience (Section 6.2). The question is non-local, involving the ingral statement for the distince between two distinct points. The answer, as we will see, is the solution to a differential equation that determines a specific function at each point in space.

Let (x, y) be a point in $\mathbb{R}^2$, and assume that $y = y(x)$ specifies y as a differentiable function of x. In this chapter we focus on functions of one variable, with extensions to higher dimensions straightforward and are presented where needed later in this book. Now consider an integral of the form

$$\mathcal{J} = \int_{x_1}^{x_2} L[y(x), y'(x), x]\,\mathrm{d}x, \tag{6.1}$$

where L is a functional and

$$y'(x) = \frac{\mathrm{d}y}{\mathrm{d}x} \tag{6.2}$$

is the first derivative of $y(x)$. Functionals dependent on higher derivatives of y can be considered, but in mechanics (i.e., Hamilton's principle) we do not encounter higher than the first derivative and so do not consider anything higher in this book. We thus seek a function, y, that extremizes the integral, $\mathcal{J}$, for a given functional, L, and with specified end points, x_1 and x_2. The calculus of variations provides a systematic method to determine this extremal function. Note that we write x, which typically means space point in this book. However, it can also mean time, t, which is typicallly the case in mechanics.

In formulating the solution to the extremum problem, it is important to recognize that the functional, L, depends implicitly on x as realized through its dependence on $y(x)$ and $y'(x)$. It also depends explicitly on x, as indicated by the final argument in equation (6.1). This tandem implicit and explicit dependence makes it important to clearly state how derivatives of L are taken, with this point further explained in Section 6.1.4.

6.1.1 Variation of a function

Assume that $y(x)$ is the particular function that extremizes $\mathcal{J}$, and assume this function is unique. As a result, any function distinct from $y(x)$ is not an extremum of $\mathcal{J}$. One means to consider such non-extremal functions functions is by introducing a non-dimensional parameter, α, that defines

$$Y(x, \alpha) = y(x) + \alpha\,\eta(x), \tag{6.3}$$

where $\eta(x)$ is an arbitrary smooth function that vanishes at the endpoints

$$\eta(x_1) = \eta(x_2) = 0. \tag{6.4}$$

Specifying these endpoint conditions means that $Y(x,\alpha)$ equals to the extremum function at the endpoints

$$Y(x_1,\alpha) = y(x_1) \quad \text{and} \quad Y(x_2,\alpha) = y(x_2). \tag{6.5}$$

Furthermore, by definition,

$$Y(x,0) = y(x) \tag{6.6}$$

is the extremum function for all x. We say that $Y(x,\alpha)$ is a function of the spatial point, x, and the parameter, α. It follows that varying α allows $Y(x,\alpha)$ to sample the space of functions that are close, but not identical, to the extreme function, $y(x)$.

6.1.2 The δ variation operator acting on a function

As a notational shorthand, it is very useful to make use of the non-dimensional *variation operator*, δ, defined so that

$$Y(x,\alpha) = y(x) + \alpha\,\eta(x) = y(x) + \delta y(x) = (1+\delta)\,y(x), \tag{6.7}$$

where $\delta y(x)$ defines the variation of the function. Notably, δ acts only on the function and not the space point, so that x remains unchanged upon acting with δ. Correspondingly, δ commutes with the derivative operator

$$\delta[y'(x)] = \delta[\mathrm{d}y(x)/\mathrm{d}x] = \mathrm{d}[\delta y(x)]/\mathrm{d}x. \tag{6.8}$$

As a final shorthand, we often write

$$y(x) \to y(x) + \delta y(x), \tag{6.9}$$

to indicate that a function, y, is to be replaced by $(1+\delta)\,y$ each place it is found. In Figure 6.1 we illustrate $y(x)+\delta y(x)$, where $y(x)$ is a straight line whereas $\delta y(x)$ are arbitrary curved paths for which $\delta y(x_1) = \delta y(x_2) = 0$.

FIGURE 6.1: Illustrating some variations to the function, $y(x)$, here depicted as a straight line whereas $y(x)+\delta y(x)$ are curved paths. Note that each variation satisfies $\delta y(x_1) = \delta y(x_2) = 0$.

6.1.3 Derivative of the integral

Introducing the function, $Y(x,\alpha)$, into the integral (6.1) yields

$$\mathcal{J}(\alpha) = \int_{x_1}^{x_2} L[Y(x,\alpha), Y'(x,\alpha), x]\,\mathrm{d}x, \tag{6.10}$$

where we exposed the α dependence of the integral by writing $\mathcal{J}(\alpha)$, and where

$$Y'(\alpha, x) = \frac{\partial Y(x,\alpha)}{\partial x} = y'(x) + \alpha\, \eta'(x). \tag{6.11}$$

By construction, the integral, $\mathcal{J}(\alpha)$, is an extremum at $\alpha = 0$, which means that its derivative vanishes there

$$\left.\frac{\mathrm{d}\mathcal{J}}{\mathrm{d}\alpha}\right|_{\alpha=0} = 0. \tag{6.12}$$

The integration limits in equation (6.10) are independent of α, so that the chain rule renders

$$\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha} = \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial Y}\frac{\partial Y}{\partial \alpha} + \frac{\partial L}{\partial Y'}\frac{\partial Y'}{\partial \alpha}\right] \mathrm{d}x. \tag{6.13}$$

Making use of the identities

$$\frac{\partial Y}{\partial \alpha} = \eta \quad \text{and} \quad \frac{\partial Y'}{\partial \alpha} = \eta' \tag{6.14}$$

leads to

$$\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha} = \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial Y}\eta + \frac{\partial L}{\partial Y'}\eta'\right] \mathrm{d}x \tag{6.15a}$$

$$= \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial Y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial Y'}\right)\right] \eta\, \mathrm{d}x + \int_{x_1}^{x_2} \frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{\partial L}{\partial Y'}\eta\right] \mathrm{d}x, \tag{6.15b}$$

where the second equality follows from integration by parts. Since $\eta(x_1) = \eta(x_2) = 0$, the total derivative term vanishes from equation (6.15b), thus leaving

$$\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha} = \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial Y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial Y'}\right)\right] \eta\, \mathrm{d}x. \tag{6.16}$$

We emphasize the importance of distinguishing the derivative operators as they appear in equation (6.16), whereby

$$\frac{\partial L}{\partial Y'} = \left(\frac{\partial L}{\partial Y'}\right)_{Y,x} \tag{6.17a}$$

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{\partial L}{\partial Y'}\right] = \left[\frac{\partial Y}{\partial x}\frac{\partial}{\partial Y}\Big)_{Y',x} + \frac{\partial Y'}{\partial x}\frac{\partial}{\partial Y'}\Big)_{Y,x} + \frac{\partial}{\partial x}\Big)_{Y,Y'}\right]\frac{\partial L}{\partial Y'}. \tag{6.17b}$$

The ∂_Y and $\partial_{Y'}$ terms arise from the implicit x dependence through Y and Y', with the explicit x dependence leading to the ∂_x term. Being mindful of these operations greatly reduces confusion when manipulating the equations of variational calculus. In the following, we typically drop the subscripts to reduce notational clutter.

6.1.4 Variation of the integral and the Fréchet derivative

Rather than computing the derivative of the integral as in Section 6.1.3, it is common in the physics literature to compute the variation of the integral through use of the δ operator, which in turn motivates defining the *functional derivative*, or sometimes called the *Fréchet derivative*. In

this approach we write

$$\delta\mathcal{J} = \delta\int_{x_1}^{x_2} L[y(x), y'(x), x]\,\mathrm{d}x = \int_{x_1}^{x_2} \delta L[y(x), y'(x), x]\,\mathrm{d}x, \tag{6.18}$$

where the variation operator commutes with the spatial integral since, as noted in Section 6.1.2, δ does not touch the space coordinate. To compute the variation of the functional, L, we make use of the chain rule and by noting that $\delta x = 0$, so that

$$\begin{aligned}
\delta\mathcal{J} &= \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial y}\,\delta y + \frac{\partial L}{\partial y'}\delta y'\right]\mathrm{d}x && \text{(6.19a)}\\
&= \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right]\delta y\,\mathrm{d}x + \int_{x_1}^{x_2} \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\,\delta y\right)\mathrm{d}x && \text{(6.19b)}\\
&= \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right]\delta y\,\mathrm{d}x && \text{(6.19c)}\\
&= \alpha\left[\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha}\right]_{\alpha=0}, && \text{(6.19d)}
\end{aligned}$$

where the penultimate equality holds since $\delta y(x_1) = \delta y(x_2) = 0$, and the final equality set $\delta y = \alpha\,\eta$ and used equation (6.16) for $\mathrm{d}\mathcal{J}(\alpha)/\mathrm{d}\alpha$. Evidently, equation (6.19d) provides a direct connection between the variation of the integral to the derivative of the integral via

$$\delta\mathcal{J} = \alpha\left[\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha}\right]_{\alpha=0}. \tag{6.20}$$

The variation operator formalism in equation (6.19c) suggests we define the functional derivative, also known as the Fréchet derivative, via

$$\frac{\delta\mathcal{J}}{\delta y(x^*)} = \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right]\frac{\delta y(x)}{\delta y(x^*)}\,\mathrm{d}x = \left[\frac{\partial L}{\partial y(x^*)} - \frac{\mathrm{d}}{\mathrm{d}x^*}\left(\frac{\partial L}{\partial y'(x^*)}\right)\right]\mathrm{d}x^*, \tag{6.21}$$

where

$$\frac{\delta y(x)}{\delta y(x^*)} = \delta(x - x^*)\,\mathrm{d}x^*, \tag{6.22}$$

with $\delta(x - x^*)$ the Dirac delta introduced in Section 5.3, and with x^* an arbitrary space point. It is notable that the $\mathrm{d}x^*$ factor appearing in equation (6.22) is typically ignored in most treatments, since it plays no role in the Euler equations that follow from setting $\delta\mathcal{J}/\delta y(x^*) = 0$ (Section 6.1.5). However, this factor is necessary for dimensional consistency since the Dirac delta has dimensions of inverse length.[1] So in summary, the Fréchet derivative of the integral is given by

$$\frac{\delta\mathcal{J}}{\delta y} = \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right]\mathrm{d}x. \tag{6.23}$$

The Fréchet derivative provides the functional analog to the gradient operator, with this derivative vanishing at an extremum of $\mathcal{J}$.

[1] Use of the δ symbol for both the variational operator as well as the Dirac delta is unfortunate but universal.

6.1.5 The Euler equation

The derivative (6.16) vanishes when $\alpha = 0$, by construction, in which case

$$0 = \left.\frac{\mathrm{d}\mathcal{J}(\alpha)}{\mathrm{d}\alpha}\right|_{\alpha=0} = \int_{x_1}^{x_2} \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right] \eta \,\mathrm{d}x, \tag{6.24}$$

where the derivatives are now taken with respect to y since $Y(0, x) = y(x)$. Since $\eta(x)$ is an arbitrary function, this equation is satisfied only if the integrand vanishes, which leads to *Euler's equation*

$$\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right) \Longleftrightarrow y(x) \text{ extremizes } \mathcal{J}[y(x), y'(x), x]. \tag{6.25}$$

Euler's equation is equivalently found by setting the Fréchet derivative (6.23) to zero

$$\frac{\delta \mathcal{J}}{\delta y} = 0 \Longrightarrow \left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right] = 0. \tag{6.26}$$

Note that in our study of mechanics in Chapter 12, we refer to the Euler equation as the *Euler-Lagrange equation*, given work done by Lagrange to extend variational methods to mechanics.

6.1.6 The second form of Euler's equation

The total derivative of the functional is given, through the chain rule, by

$$\frac{\mathrm{d}L}{\mathrm{d}x} = \left[\frac{\partial L}{\partial x}\right]_{y,y'} + \frac{\mathrm{d}y}{\mathrm{d}x}\left[\frac{\partial L}{\partial y}\right]_{y',x} + \frac{\mathrm{d}^2 y}{\mathrm{d}x^2}\left[\frac{\partial L}{\partial y'}\right]_{y,x} \tag{6.27a}$$

$$= \frac{\partial L}{\partial x} + y'\frac{\partial L}{\partial y} + y''\frac{\partial L}{\partial y'}, \tag{6.27b}$$

where the second equality dropped the subscript notation to reduce clutter. In turn, we have

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[y'\frac{\partial L}{\partial y'}\right] = y''\frac{\partial L}{\partial y'} + y'\frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{\partial L}{\partial y'}\right], \tag{6.28}$$

with substitution from equation (6.27b) rendering

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[L - y'\frac{\partial L}{\partial y'}\right] = \frac{\partial L}{\partial x} + y'\left[\frac{\partial L}{\partial y} - \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\partial L}{\partial y'}\right)\right]. \tag{6.29}$$

The final term on the right hand side vanishes due to Euler's equation (6.25), thus leading to the *second form of Euler's equation*

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[L - y'\frac{\partial L}{\partial y'}\right] = \frac{\partial L}{\partial x}. \tag{6.30}$$

This equation is particularly useful when the functional, L, has no explicit dependence on x, in which case the right hand side vanishes. Furthermore, when applied to mechanics, the term $y'\,\partial L/\partial y' - L$ is the Hamiltonian (e.g., see Section 12.9.4).

6.1.7 Nature of the extremum

The Euler equation (6.25) has a solution, $y(x)$, that is an extremum to the integral $\mathcal{J}[y(x), y'(x), x]$. In this manner, we connect a question about the extremum to an integral to the solution of a differential equation. However, is the extremum a minimum, maximum, or inflection? To answer

that question requires taking the second derivative of the integral,

$$\delta^2 \mathcal{J} = \alpha^2 \left[\frac{\mathrm{d}^2 \mathcal{J}(\alpha)}{\mathrm{d}\alpha^2} \right]_{\alpha=0}. \tag{6.31}$$

In practice this is a rather difficult calculation to perform. Furthermore, in many cases the nature of the extremum is apparent by inspection. For example, in Section 6.2 we determine the path between any two points on a plane, with a straight line an extremum that is the minimum path since one is free to consider an alternative path this is arbitrarily longer.

6.2 Shortest path between two points on a plane

Let (x, y) be a point in $\mathbb{R}^2$, where $y = y(x)$ specifies y as a differentiable function of x. We seek an expresion for the function, $y(x)$, that represents the shortest path between two arbitrary points in $\mathbb{R}^2$. The answer is a straight line

$$y = y_1 + \frac{x - x_1}{x_2 - x_1}(y_2 - y_1) = \frac{y_1(x_2 - x) + y_2(x - x_1)}{x_2 - x_1}, \quad \text{with } y_1 = y(x_1) \text{ and } y_2 = y(x_2), \tag{6.32}$$

with the calculus of variations unnecessary to determine this function. Even so, we find it useful to consider a question whose answer is known in order to garner experience and confidence with the formalism.

On the plane, the distance between two points is given by Pythagoras' theorem

$$\mathrm{d}s = [(\mathrm{d}x)^2 + (\mathrm{d}y)^2]^{1/2} = \sqrt{1 + (y')^2}\,\mathrm{d}x, \tag{6.33}$$

so that the distance between two points is the integral

$$\mathcal{J} = \int_{x_1}^{x_2} \mathrm{d}s = \int_{x_1}^{x_2} \sqrt{1 + (y')^2}\,\mathrm{d}x = \int_{x_1}^{x_2} L\,\mathrm{d}x, \tag{6.34}$$

where the functional is

$$L = \sqrt{1 + (y')^2}. \tag{6.35}$$

Terms in the Euler equation (6.25) are thus given by

$$\frac{\partial L}{\partial y} = 0 \quad \text{and} \quad \frac{\partial L}{\partial y'} = \frac{y'}{\sqrt{1 + (y')^2}}, \tag{6.36}$$

so that the Euler equation is

$$\frac{\mathrm{d}}{\mathrm{d}x}\left[\frac{y'}{\sqrt{1 + (y')^2}}\right] = 0, \tag{6.37}$$

whose solution is indeed the straight line given by equation (6.32).

6.3 Shortest time falling between two points

The *brachistochrone* is a smooth curve upon which a frictionless bead moves under the effects from gravity and travels in the shortest time between two points, A and B, where these two points

are not underneath one another.[2] We illustrate the physical system in Figure 6.2. The integral expression for time of the excursion is given by

$$T = \int_A^B \mathrm{d}t = \int_{s_A}^{s_B} \frac{\mathrm{d}s}{v(s)}, \tag{6.38}$$

where s is the arc length and $v(s)$ is the speed of the bead as a function of the arc length. The minimal time is achieved by the particle moving in a single plane, which we set as the x-z plane without loss of generality. In this case the differential arc length is given by

$$\mathrm{d}s = \sqrt{(\mathrm{d}x)^2 + (\mathrm{d}z)^2} = \sqrt{1 + (z')^2}\,\mathrm{d}x, \tag{6.39}$$

where we assumed that the vertical position, z, is a monotonic function of the horizontal position, x, thus enabling a functional expression $z = z(x)$ for the curve.[3]

FIGURE 6.2: A bead falls along a frictionless wire from point A to point B. It traverses this path in the least amount of time if the wire is in the shape of a *cycloid*. This brachistochrone problem is readily solved using variational methods.

Mechanical energy of the bead is constant since the bead is frictionless.[4] If the bead starts from rest at point A, then the mechanical energy at this point is just given by the gravittional potential energy, $g\,m\,z_A$, where m is the mass of the bead, z_A is its vertical position, and we choose the zero for potential energy at $z = 0$. We thus find that the speed at any point along the path is given by

$$v^2/2 + g\,z = g\,z_A \Longrightarrow v = \sqrt{2\,g\,(z_A - z)}, \tag{6.40}$$

in which the time integral (6.38) becomes

$$T = \int_{s_A}^{s_B} \frac{\mathrm{d}s}{v(s)} = \int_{x_A}^{x_B} \frac{\sqrt{1 + (z')^2}}{\sqrt{2\,g\,(z_A - z)}}\,\mathrm{d}x. \tag{6.41}$$

The functional appearing in the time integral (6.41) is given by

$$L = L[z(x), z'(x)] = \frac{\sqrt{1 + (z')^2}}{\sqrt{2\,g\,(z_A - z)}}. \tag{6.42}$$

[2]If the two points A and B are vertically oriented, then the brachistochrone is the straight vertical line connecting these two points.

[3]Some treatments, such as Example 5.2 of *Marion and Thornton* (1988), solve for $x = x(z)$, which is possible since the is a one-to-one relation between x and z.

[4]In Section 11.1.5 we prove this property of conservative classical discrete systems.

With no explicit dependence on x, the second form of Euler's equation, given by equation (6.30), leads to the identity

$$L - z' \frac{\partial L}{\partial z'} = \frac{1}{\sqrt{2\,g\,(z_A - z)\,(1 + (z')^2)}} = c^{-1}, \tag{6.43}$$

where c is a constant with dimensions of speed ($\mathrm{L\ T^{-1}}$). We can write the solution to this equation by introducing the angle parameter θ, so that

$$x = [c^2/(4g)]\,(\sin\theta - \theta) \quad \text{and} \quad z_A - z = [c^2/(4g)]\,(1 - \cos\theta) \tag{6.44a}$$

$$\mathrm{d}x/\mathrm{d}\theta = [c^2/(4g)]\,(\cos\theta - 1) \quad \text{and} \quad \mathrm{d}(z_A - z)/\mathrm{d}\theta = [c^2/(4g)]\sin\theta. \tag{6.44b}$$

This is the equation for a *cycloid*, which is the curve shown in Figure 6.3 that is traced by a point on a circle that is rolling (without slipping) along a straight line on a plane.[5]

FIGURE 6.3: A cycloid is the curve traced by a point on a circle that is rolling (without slipping) along a straight line on a plane. As per equation (6.44a), the radius of the circle is $c^2/(4g)$ so that its circumference is $2\,\pi\,c^2/(4g)$. We depict the circle each quarter rotation as it moves along the line, with the black dot fixed relative to the circle and tracing out the cycloid.

6.4 Shape of a hanging massive string

Consider a string or cable with uniform mass per length, σ, which is suspended from each end as depicted in Figure 6.4. What is the shape of the string when in mechanical equilibrium? To answer this question one can make use of mechanics through studying the tensile forces acting within the string and the gravitational forces acting on the string, with equilibrium realized when the net forces and torques sum to zero. Alternatively, we can assume the shape minimizes the gravitational potential energy of the string, in which case there is no need to determine any of the forces. Instead we make use of variational calculus to determine the minimum potential energy state.

The variational problem arises from writing the gravitational potential energy as

$$P = g\,\sigma \int_{s(x_1)}^{s(x_2)} z(x)\,\mathrm{d}s, \tag{6.45}$$

where s is the arc distance along the curve and g is the constant gravitational acceleration. Along the curve, the arc-length differential is

$$\mathrm{d}s = \sqrt{(\mathrm{d}x)^2 + (\mathrm{d}z)^2} = \sqrt{1 + (z')^2}\,\mathrm{d}x, \tag{6.46}$$

where $z'(x) = \mathrm{d}z/\mathrm{d}x$ is the derivative. Hence, the potential energy is

$$P = g\,\sigma \int_{x_1}^{x_2} z(x)\,\sqrt{1 + (z')^2}\,\mathrm{d}x = g\,\sigma \int_{x_1}^{x_2} L[z(x), z'(x)]\,\mathrm{d}x, \tag{6.47}$$

[5]See Example 5-2 of *Marion and Thornton* (1988) for more details of the cycloid.

FIGURE 6.4: A massive string or cable is supported at its two ends at a vertical position $z_1 = z(x_1) = z_2 = z(x_2)$. The string is placed in a vertically directed gravitational field with acceleration, $\boldsymbol{g} = -g\,\hat{\boldsymbol{z}}$, where g is the constant gravitational acceleration. Variational methods determine the shape of the string as given by the hyperbolic cosine in equation (6.50), which is known as a *catenary*. This is the shape taken by power lines, spider webs, clothes lines, and chains, for example.

where we introduced the functional

$$L[z(x), z'(x)] = z(x)\,\sqrt{1 + (z')^2}. \tag{6.48}$$

This functional is reminiscent of that found for the shortest path problem as given by equation (6.35), yet here there is an extra $z(x)$ factor multiplying the square root term.

Since the functional (6.48) has no explicit x dependence, we make use of the second form of the Euler equation, in which

$$L - y'\,\frac{\partial L}{\partial y'} = z\,\sqrt{1 + (z')^2}\left[1 - \frac{(z')^2}{1 + (z')^2}\right] = \ell \Longrightarrow z/\ell = 1 + (z')^2, \tag{6.49}$$

where ℓ is a constant of integration with dimensions of length. The solution to this differential equation that satisfies the two endpoint conditions $z(x_1) = z(x_2)$ is given by

$$z = \ell\cosh[(2\,x - x_1 - x_2)/(2\ell)], \tag{6.50}$$

which is referred to as a *catenary* and is depicted in Figure 6.4. The constant, ℓ, is the vertical position of the midpoint of the curve, which is also the lowest point

$$z = \ell \quad \text{at } x = (x_1 + x_2)/2. \tag{6.51}$$

6.5 Minimal surface of revolution

Figure 6.5 shows an axially symmetric surface that is bounded by two circles with distinct radii and that are aligned along the $\hat{\boldsymbol{z}}$ axis. This surface is formed by connecting two points in the x-z plane, (x_1, z_1) and (x_2, z_2), and then revolving the curve around the z-axis. What is the shape of the surface that results in the minimum surface area? One guess is that the surface is a cone built from straight lines extending from the lower circle to the upper circle. In fact, it turns out to be built from catenaries; i.e., the same shape as found in Section 6.4 for the hanging massive string, with the resulting surface known as a *catenoid*.

Given the rotational symmetry assumed for the surface, it is sufficient to fix attention to the x-z plane. Furthermore, we assume there is a monotonic relation between z and x, so that we can write $z = z(x)$ for any point on the surface in the x-z plane. In this case the surface area is

FIGURE 6.5: This figure shows an axially symmetric surface that connects two circles aligned along the $\hat{\boldsymbol{z}}$ axis. The thickness of a strip along the surface and within the x-z plane is given by $\mathrm{d}s = \sqrt{(\mathrm{d}x)^2 + (\mathrm{d}z)^2} = \sqrt{1 + (z')^2}\,\mathrm{d}x$. The shape of the minimal surface that connects the two circles is known as a *catenoid*. The catenoid is built from connecting the two circles with a catenary and then rotating the catenary around the vertical axis.

given by

$$A = 2\,\pi \int_{x_1}^{x_2} x\,\sqrt{1 + (z')^2}\,\mathrm{d}x, \tag{6.52}$$

where the 2π factor arises from the angular integral and circular symmetry. The x factor is the radius of the circle and

$$\mathrm{d}s = \sqrt{1 + (z')^2}\,\mathrm{d}x \tag{6.53}$$

is the thickness of a tiny strip along the surface and in the x-z plane (see Figure 6.5). The integrand to the surface area in equation (6.52) is identical to the integrand in equation (6.47) for the potential energy of a hanging string. Hence, the minimal surface is constructed from catenaries. That is, in any particular plane passing through the center of the circles (e.g., the x-z plane), use a catenary to connect a point on the upper surface to a point on the lower surface, and then spin this catenary around the vertical axis. The resulting surface of revolution has the minimal surface area and it is known as a catenoid.

As noted in Section 2-2 of *Goldstein* (1980), a more thorough treatment of this problem identifies those configurations in which there is no catenary that can connect the circles, or when the minimal surface is discontinuous rather than continuous. Such cases might represent inflection points rather than minimal surfaces. Also note that circles with similar or identical radii, then the function $z(x)$ is not monotonic, in which case the problem can be split into two regions over which $z(x)$ is monotonic.

Chapter 7

Curves and surfaces

We encounter curves and surfaces throughout the study of geophysical fluid mechanics, with fluid particle pathlines through space-time and isopycnal/isentropic surfaces providing two examples. Indeed, curves and surfaces are encountered throughout physics. Hence, there is a well developed mathematical framework to describe the geometric properties of these objects. Our goal in this chapter is to introduce some of the basics of curves and surfaces embedded in Euclidean space.

Although the curves and surfaces of geophysical fluid mechanics are commonly moving as part of the fluid flow, we are concerned in this chapter with describing their instantaneous spatial properties. Hence, time does not appear in this chapter. Furthermore, although curves and surfaces can overturn and intersect themselves, we restrict attention to orientable curves and surfaces whose normal direction has a nonzero projection onto the vertical; i.e., they have no overhangs and no wrapping (Figure 7.1). This constraint is satisfied by the surfaces of constant generalized vertical coordinates (e.g., isopycnal surfaces) considered in Chapter 59 and in many other places in this book. It allows us to make use of coordinates known as the *Monge gauge* in condensed matter physics

READER'S GUIDE TO THIS CHAPTER

This chapter requires an understanding of the Cartesian calculus of Chapter 2. The differential geometry presented here is of some use throughout this book, and yet the casual reader need not penetrate the material. Conversely, the interested reader can find far more development of the mathematics, along with physical applications, by studying the physics of fluctuating membranes, with Section 10.4 of the condensed matter physics textbook from *Chaikin and Lubensky* (1995) providing a starting point.

7.1 Definitions and notation

The basic notions of curves and surfaces embedded in Euclidean space are rather intuitive. Nonetheless, it is important to be precise in our usage. For this purpose we here offer some notation and definitions.

7.1.1 Definitions

We assume the notion of a curve and surface embedded in Euclidean space to be self-evident, offering analytical expressions for curves in Section 7.2 and surfaces in Section 7.3. Given such, we here define some related notions used in our study of fluid mechanics.

- ORIENTABLE: An *orientable curve* is a curve that allows for normal and tangent directions to specify directions and sides to the curve. Likewise, an *orientable surface* has two sides, allowing one to choose a positive side and a negative side. A Möbius strip is the canonical surface that is not orientable since it only has one side. Likewise, the boundary of a Möbius strip is a non-orientable curve. We only consider orientable objects in this book.

- PATH or CONTOUR: A path or contour is a continuous piecewise smooth oriented curve. A *simple path* or *simple contour* does not cross itself. We already encountered contours when considering path integrals in Chapter 2.

- CIRCUIT: A circuit is a path that closes, and a *simple circuit* is a circuit that does not cross itself. Finally, a *reducible circuit* is a circuit that can be continuously deformed to a point within the domain without leaving the domain. For example, a circuit within the ocean that encloses an island or continent cannot be deformed to a point since doing so requires the circuit to cross onto land and thus to leave the ocean.

7.1.2 Notation

In this chapter we write the Cartesian position of a point on a surface as

$$\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + \eta(x,y)\,\hat{\boldsymbol{z}} \qquad \text{position on surface,} \tag{7.1}$$

with the vertical position written as

$$z = \eta(x,y) \qquad \text{vertical position on surface.} \tag{7.2}$$

If we are instead referring to a point on a planar curve in the x-z-plane, then we drop the y-dependence to have

$$\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + \eta(x)\,\hat{\boldsymbol{z}} \qquad \text{position on planar curve.} \tag{7.3}$$

Time dependence is dropped throughout this chapter since we focus on the spatial geometry of curves and surfaces at a particular time instance.

We assume the outward normal direction on the curve or the surface has a nonzero projection into the vertical as shown in Figure 7.1. Indeed, we are only able to write the vertical position as $z = \eta(x,y)$ so long as there are no overturns in the surface, in which case the outward unit normal direction is

$$\hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{\sqrt{1+|\nabla\eta|^2}}. \tag{7.4}$$

Figure 7.2 provides an example surface along with the notation.

FIGURE 7.1: Two sample curves on the x-z plane. The left panel shows a curve whose outward unit normal, $\hat{\boldsymbol{n}}$, encounters points where $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} = 0$ and where $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}}$ changes sign. This curve, and its generalization to a surface, are not treated in this chapter. The right panel shows a more gently undulating curve where $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} \neq 0$ everywhere, and thus where $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}}$ is single signed. For curves such as the right panel, we can express the vertical position as a 1-to-1 function of the horizontal position, $z = \eta(x)$. Again, this curve has its natural generalization to a gently undulating surface whereby $z = \eta(x, y)$ provides a unique mapping between horizontal position and vertical. The assumption regarding no overhanging curves and surfaces is consistent with our study of surfaces defined by a constant generalized vertical coordinate (e.g., isopycnals or isentropes) in Chapter 59.

7.1.3 Surfaces with $x = \gamma(y, z)$ or $y = \psi(x, z)$

We generally find it most useful to specify a point on a surface according to equation (7.1), whereby we write $z = \eta(x, y)$ for the vertical position as a function of the horizontal position. This approach is typical for our applications since the surfaces we encounter most commonly in stratified geophysical flows have a normal direction that has a non-zero projection into the $\hat{\boldsymbol{z}}$ direction. However, there are occasions where it is more convenient to define a point on a surface according to

$$\boldsymbol{S} = \gamma(y, z)\, \hat{\boldsymbol{x}} + y\, \hat{\boldsymbol{y}} + z\, \hat{\boldsymbol{z}} \qquad \text{alternative specification.} \tag{7.5}$$

Here, we specify the x position on the surface as a function of y and z via the function $\gamma(y, z)$. The unit normal is thus specified by

$$\hat{\boldsymbol{n}} = \frac{\nabla(x - \gamma)}{|\nabla(x = \gamma)|} = \frac{\hat{\boldsymbol{x}} - \hat{\boldsymbol{y}}\, \partial_y \gamma - \hat{\boldsymbol{z}}\, \partial_z \gamma}{1 + \sqrt{(\partial_y \gamma)^2 + (\partial_z \gamma)^2}}. \tag{7.6}$$

Hence, this specification is useful for those surfaces with normal direction having a non-zero $\hat{\boldsymbol{x}}$ component everywhere on the surface, in which case we are afforded the ability to define $\gamma(y, z)$. Alternatively, if the surface instead has a normal direction with a non-zero $\hat{\boldsymbol{y}}$ component everywhere, then we would find it more suitable to define a point on the surface according to

$$\boldsymbol{S} = x\, \hat{\boldsymbol{x}} + \psi(x, z)\, \hat{\boldsymbol{y}} + z\, \hat{\boldsymbol{z}}, \tag{7.7}$$

where $y = \psi(x, z)$ provides the y position of a point on the surface as a function of x, z.

For the remainder of this chapter we return to the specification (7.1) whereby $z = \eta(x, y)$. However, there are occasions when we find it more suitable to define the surface using either equation (7.5) or (7.7). For example, we make use of the specification (7.5) in Section 22.7 when studying the meridional-depth overturning streamfunction.

FIGURE 7.2: An example of a surface embedded in Euclidean space. The position of a point on the surface is given by the Cartesian position vector $\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + \eta(x,y)\,\hat{\boldsymbol{z}}$. The relation $z = \eta(x,y)$ provides a 1-to-1 mapping between the horizontal position and the vertical position of a point on the surface. Correspondingly, the surface is uniquely specified by finding the envelope of points where $z - \eta(x,y) = 0$. The lightly shaded region represents the projection of the curved surface onto the flat horizontal x-y plane below.

7.2 Planar curves in 2D Euclidan space

We here describe the geometry of a curve on the x-z-plane (a *planar curve*) as depicted in Figure 7.3. These curves are one-dimensional objects living in a two-dimensional Euclidean space. Extensions to curves on non-Euclidean surfaces, such as the sphere or an isopycnal, are straightforward when those surfaces are embedded in a background Euclidean space (which is typical for Newtonian physics).

7.2.1 Differential increments along the curve

As a one-dimensional geometric object, an arbitrary curve can be parameterized by a single coordinate, referred to here as φ. Let $\boldsymbol{S}(\varphi)$ specify the position of a point along the curve. Correspondingly, the differential increment between two infinitesimally close points on the curve is given by

$$\boldsymbol{S}(\varphi + \mathrm{d}\varphi) - \boldsymbol{S}(\varphi) = \mathrm{d}\boldsymbol{S} = \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}\varphi}\,\mathrm{d}\varphi \equiv \boldsymbol{t}\,\mathrm{d}\varphi, \tag{7.8}$$

where

$$\boldsymbol{t} = \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}\varphi} \tag{7.9}$$

is tangent to the curve. If $\varphi = s$ is the arc length along the curve, then $\boldsymbol{t} = \hat{\boldsymbol{t}}$ is a unt vector

$$\hat{\boldsymbol{t}} \cdot \hat{\boldsymbol{t}} = \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}s} \cdot \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}s} = 1. \tag{7.10}$$

In some treatments in this book we also write

$$\hat{\boldsymbol{s}} = \hat{\boldsymbol{t}} \tag{7.11}$$

to correspond to s for arc length. Recall we made use of the arc length along a curve in Section 2.4 when describing path integration.

FIGURE 7.3: An orientable path in the x-z plane defined by a planar curve that does not intersect itself. The Cartesian position of a point on the curve is given by $\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + \eta(x)\,\hat{\boldsymbol{z}}$, where $z = \eta(x)$ provides the vertical position of the point as a function of the horizontal position. The projection of the curve onto the horizontal x-axis occupies a range $x_A \leq x \leq x_B$. One way to define the curve is by finding the envelope of points where $z - \eta(x) = 0$, in which case we can readily find the unit normal direction pointing upward as $\hat{\boldsymbol{n}} = \nabla(z-\eta)/|\nabla(z-\eta)| = [\hat{\boldsymbol{z}} - (\mathrm{d}\eta/\mathrm{d}x)\,\hat{\boldsymbol{x}}]\,[1 + (\mathrm{d}\eta/\mathrm{d}x)^2\,]^{-1/2}$, and the unit tangent vector $\hat{\boldsymbol{t}} = [\hat{\boldsymbol{x}} + (\mathrm{d}\eta/\mathrm{d}x)\,\hat{\boldsymbol{z}}]\,[1 + (\mathrm{d}\eta/\mathrm{d}x)^2\,]^{-1/2}$.

7.2.2 Length along the curve

As in equation (7.3) we can represent the position of a point along the curve using Cartesian coordinates

$$\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + \eta(x)\,\hat{\boldsymbol{z}}. \tag{7.12}$$

Hence, letting $\varphi = x$ parameterize the curve leads to the representation of the tangent direction

$$\boldsymbol{t} = \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}x} = \hat{\boldsymbol{x}} + \frac{\mathrm{d}\eta}{\mathrm{d}x}\,\hat{\boldsymbol{z}}, \tag{7.13}$$

which has the magnitude

$$\boldsymbol{t}\cdot\boldsymbol{t} = 1 + (\mathrm{d}\eta/\mathrm{d}x)^2, \tag{7.14}$$

so that the unit tangent vector is

$$\hat{\boldsymbol{t}} = \frac{\hat{\boldsymbol{x}} + (\mathrm{d}\eta/\mathrm{d}x)\,\hat{\boldsymbol{z}}}{\sqrt{1 + (\mathrm{d}\eta/\mathrm{d}x)^2}}. \tag{7.15}$$

Likewise, the curve's unit normal vector is given by

$$\hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{\hat{\boldsymbol{z}} - (\mathrm{d}\eta/\mathrm{d}x)\,\hat{\boldsymbol{x}}}{\sqrt{1 + (\mathrm{d}\eta/\mathrm{d}x)^2}}, \tag{7.16}$$

with orthogonality manifest

$$\hat{\boldsymbol{t}}\cdot\hat{\boldsymbol{n}} = 0. \tag{7.17}$$

The squared length of an infinitesimal segment along the curve is given by

$$(\mathrm{d}s)^2 = \mathrm{d}\boldsymbol{S}\cdot\mathrm{d}\boldsymbol{S} = \left[\frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}x}\cdot\frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}x}\right]\mathrm{d}x\,\mathrm{d}x, \tag{7.18}$$

so that the finite length of the curve is determined by the integral

$$L = \int_0^L \mathrm{d}s = \int_{x_A}^{x_B} |\mathrm{d}\boldsymbol{S}/\mathrm{d}x|\,\mathrm{d}x = \int_{x_A}^{x_B} \sqrt{1 + (\mathrm{d}\eta/\mathrm{d}x)^2}\,\mathrm{d}x, \tag{7.19}$$

where $x_A \leq x \leq x_B$ is the range over which x runs for the projection of the curve onto the x-axis (see Figure 7.3).

7.2.3 Curvature of a curve

Curvature measures the amount that the unit normal changes along the curve. For a planar curve, the curvature at a point equals to the inverse radius of a circle that shares the same tangent plane to the curve at the point (see Figure 7.4). We refer to the radius as the *radius of curvature* and the corresponding circle as the *curvature circle*. To formulate an analytic expression for the radius of curvature at a point on a curve, orient the Cartesian coordinate axes so that the point is at the origin and the tangent plane sits along the x-axis as in Figure 7.4. Consequently, the outward unit normal, $\hat{\boldsymbol{n}}$, is parallel to the $\hat{\boldsymbol{z}}$ direction.

A Taylor series expansion about the origin tells us that the vertical position of a point along the curve and near to the origin can be written

$$\eta(x) = \eta(0) + x\left[\frac{\mathrm{d}\eta}{\mathrm{d}x}\right]_{x=0} + \frac{x^2}{2}\left[\frac{\mathrm{d}^2\eta}{\mathrm{d}x^2}\right]_{x=0} + \mathcal{O}(x^3) \tag{7.20a}$$

$$= \frac{x^2}{2}\left[\frac{\mathrm{d}^2\eta}{\mathrm{d}x^2}\right]_{x=0} + \mathcal{O}(x^3). \tag{7.20b}$$

This result follows since we placed the origin so that $\eta(0) = 0$, and aligned the x-axis so that it is tangent at the origin, in which case $\mathrm{d}\eta/\mathrm{d}x = 0$ at $x = 0$. Hence, η has a quadratic behavior near the origin.

FIGURE 7.4: The radius of curvature at a point on a curve, P, equals to the radius of the curvature circle that shares the same tangent plane as the curve at the point P. When constructing the curvature circle we make use of the angle, ϑ, to measure the height of a point along the circle, $h(x) = R\,(1 - \cos\vartheta) \approx R\,\vartheta^2/2 \approx x^2/(2R)$. Setting $R^{-1} = \mathrm{d}^2\eta/\mathrm{d}x^2$ provides a second order accurate fit of the curvature circle to the curve at the point P.

Now place a circle with center along the z-axis so that it is tangent to the curve at the origin, as depicted in Figure 7.4. What is the radius, R, of the circle that best fits the curve at the origin? To answer this question note that the height of a point on the circle is given by $h(x) = R\,(1-\cos\vartheta)$, where $\vartheta = 0$ for a point at the origin and $\vartheta = \pi$ at the diametrically opposite point. For small ϑ this height takes the form

$$h(x) \approx R\,[1 - 1 + \vartheta^2/2] = x^2/(2R), \tag{7.21}$$

where $\vartheta = x/R$ near the origin. For the height of a point on the curve (equation (7.20b)) to match the height along the circle, to second order accuracy, requires us to set the circle's radius to

$$\frac{1}{R} = \frac{\mathrm{d}^2\eta}{\mathrm{d}x^2}. \tag{7.22}$$

Equation (7.22) thus provides an expression for the radius of curvature, R, whose inverse is the

curvature

$$\text{curvature} = \frac{1}{R}. \tag{7.23}$$

This result supports our expectation that the second derivative measures the curvature. As radius, R, gets larger the curvature decreases since local regions along the circle appear more flat. In the opposite limit the curvature grows as R decreases. Note that we could have chosen to orient the circle on the opposite side of the tangent (on the convex side), in which case the radius of curvature is negative. That is, $R > 0$ when the unit normal points towards the concave side (side where the curve rises towards $\hat{\boldsymbol{n}}$), whereas $R < 0$ when the unit normal points towards the convex side (side where the curve falls away from $\hat{\boldsymbol{n}}$).

In closing this section we note that

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{\mathrm{d}^2\eta/\mathrm{d}x^2}{[1 + (\mathrm{d}\eta/\mathrm{d}x)^2\,]^{3/2}}. \tag{7.24}$$

When evaluated at the point of interest along the curve, we set $\mathrm{d}\eta/\mathrm{d}x = 0$ so that

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{\mathrm{d}^2\eta}{\mathrm{d}x^2} = \frac{1}{R}. \tag{7.25}$$

This result supports our earlier statement that curvature measures the change in the normal direction along the curve. In fact, the identity

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{1}{R} \tag{7.26}$$

holds for an arbitrary point along the curve since it is a coordinate invariant statement.

Equation (7.25) provides a useful means to check the sign of the radius of curvature. Namely, the point of interest in Figure 7.4 is a local minimum, so that $\mathrm{d}^2\eta/\mathrm{d}x^2 > 0$ and the radius of curvature is thus positive, $R > 0$. In contrast, the radius of curvature is negative at points where $\mathrm{d}^2\eta/\mathrm{d}x^2 < 0$.

7.3 Surfaces embedded in 3D Euclidean space

We now extend the previous discussion to a two-dimensional surface embedded in three-dimensional Euclidean space such as in Figure 7.2. In general, a 2D surface in 3D space can be parameterized by two variables, φ_1 and φ_2, so that infinitesimal increments along the surface satisfy

$$\mathrm{d}\boldsymbol{S} = \frac{\partial \boldsymbol{S}}{\partial \varphi_1}\,\mathrm{d}\varphi_1 + \frac{\partial \boldsymbol{S}}{\partial \varphi_2}\,\mathrm{d}\varphi_2 = \boldsymbol{t}_1\,\mathrm{d}\varphi_1 + \boldsymbol{t}_2\,\mathrm{d}\varphi_2. \tag{7.27}$$

The vectors $\boldsymbol{t}_1$ and $\boldsymbol{t}_2$ are tangent to the surface at the point (φ_1, φ_2), and yet they are not generally orthogonal to one another.

Making use of the Cartesian expression (7.1)

$$\boldsymbol{S} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + \eta(x, y)\,\hat{\boldsymbol{z}} \tag{7.28}$$

brings the two tangent directions and the unit tangent directions into the form

$$\boldsymbol{t}_1 = \frac{\partial \boldsymbol{S}}{\partial x} = \hat{\boldsymbol{x}} + \frac{\partial \eta}{\partial x}\,\hat{\boldsymbol{z}} \quad \text{and} \quad \hat{\boldsymbol{t}}_1 = \frac{\hat{\boldsymbol{x}} + (\partial\eta/\partial x)\,\hat{\boldsymbol{z}}}{\sqrt{1+(\partial\eta/\partial x)^2}} \tag{7.29a}$$

$$\boldsymbol{t}_2 = \frac{\partial \boldsymbol{S}}{\partial y} = \hat{\boldsymbol{y}} + \frac{\partial \eta}{\partial y}\,\hat{\boldsymbol{z}} \quad \text{and} \quad \hat{\boldsymbol{t}}_2 = \frac{\hat{\boldsymbol{y}} + (\partial\eta/\partial y)\,\hat{\boldsymbol{z}}}{\sqrt{1+(\partial\eta/\partial y)^2}}. \tag{7.29b}$$

Likewise, the surface unit normal vector is given by

$$\hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{|\hat{\boldsymbol{z}} - \nabla\eta|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{\sqrt{1+|\nabla\eta|^2}}, \tag{7.30}$$

and it is straightforward to show orthogonality with the two tangent vectors

$$\hat{\boldsymbol{t}}_1 \cdot \hat{\boldsymbol{n}} = \hat{\boldsymbol{t}}_2 \cdot \hat{\boldsymbol{n}} = 0. \tag{7.31}$$

7.3.1 Area on the surface

Recall from Section 1.4.5 that the magnitude of a vector product of two vectors equals to the area of the parallelogram subtended by the vectors. Hence, the area of an infinitesimal surface element with sides $\mathrm{d}\varphi_1$ and $\mathrm{d}\varphi_2$ is given by

$$\mathrm{d}\mathcal{S} = \left|\frac{\partial \boldsymbol{S}}{\partial \varphi_1} \times \frac{\partial \boldsymbol{S}}{\partial \varphi_2}\right| \mathrm{d}\varphi_1\,\mathrm{d}\varphi_2. \tag{7.32}$$

Making use of Cartesian coordinates brings the area element to

$$\mathrm{d}\mathcal{S} = \sqrt{1+|\nabla\eta|^2}\,\mathrm{d}x\,\mathrm{d}y = \sqrt{1+|\nabla\eta|^2}\,\mathrm{d}A, \tag{7.33}$$

where

$$\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y \tag{7.34}$$

is the area of the surface projected onto the horizontal plane. Hence, the area of a finite region is given by the integral

$$\mathcal{S} = \int \mathrm{d}\mathcal{S} = \int |\nabla(z-\eta)|\,\mathrm{d}A = \int \sqrt{1+|\nabla\eta|^2}\,\mathrm{d}x\,\mathrm{d}y, \tag{7.35}$$

where the second and third integrals extend over the region defined by the projection of the surface onto the horizontal (see Figure 7.2).

7.3.2 Curvature of a surface

We now seek an expression for the curvature of a point on the surface. Since the surface has two dimensions, we expect the curvature to be measured by two numbers rather than the single curvature for the curve discussed in Section 7.2.3. The method for developing the curvature is analogous to that used for a curve, yet with a bit more mathematics needed to allow for the extra dimension. Figure 7.5 depicts the situation.

Let $\boldsymbol{x} = (x_1, x_2) = (x, y)$ be Cartesian coordinates on a tangent plane local to an arbitrary point on the surface, with the origin of the coordinate system taken at the point. Near to the point, we can estimate the vertical distance of a point on the surface from the tangent plane

FIGURE 7.5: Depicting the elements needed to construct the curvature of a surface at an arbitrary point, P. The local unit normal direction is given by $\hat{\boldsymbol{n}}$, along with the two tangent vectors $\boldsymbol{t}_1$ and $\boldsymbol{t}_2$. The tangent vectors span the space of the tangent plane, $\mathcal{T}$, shown as a flat surface that is tangent at the chosen point on the surface. In this case the surface falls away from the normal direction, as per a convex surface, so that the two radii of curvature are negative. Other surfaces can be concave, whereby both radii of curvature are positive, or hyperbolic (saddle), whereby one is positive and another negative.

according to the quadratic form

$$\eta \approx \frac{1}{2}\, x_m\, \mathbb{C}_{mn}\, x_n, \tag{7.36}$$

where $\mathbb{C}$ is the matrix of second partial derivatives evaluated at the point

$$\mathbb{C} = \begin{bmatrix} \dfrac{\partial^2 \eta}{\partial x_1^2} & \dfrac{\partial^2 \eta}{\partial x_1 \partial x_2} \\ \dfrac{\partial^2 \eta}{\partial x_1 \partial x_2} & \dfrac{\partial^2 \eta}{\partial x_2^2} \end{bmatrix}. \tag{7.37}$$

As a symmetric matrix, $\mathbb{C}$ is diagonalizable and it has two eigenvalues, R_1^{-1} and R_2^{-1}, along with its associated eigenvectors, $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$. The quadratic form (7.36) can thus be written as

$$\eta \approx \frac{1}{2}\, R_1^{-1}\, (\boldsymbol{x} \cdot \boldsymbol{e}_1)^2 + \frac{1}{2}\, R_2^{-1}\, (\boldsymbol{x} \cdot \boldsymbol{e}_2)^2. \tag{7.38}$$

R_1 and R_2 are the principle radii of curvature for the surface at the point P. They correspond, respectively, to the radii of the curvature circles in the $\hat{\boldsymbol{n}}$-$\boldsymbol{e}_1$ and $\hat{\boldsymbol{n}}$-$\boldsymbol{e}_2$ planes. If the radius of curvature R_m is positive, then the surface curves towards $\hat{\boldsymbol{n}}$ along the $\hat{\boldsymbol{n}}$-$\boldsymbol{e}_i$ plane, and conversely if R_m is negative. The surface takes the shape of a saddle when the two radii of curvature have opposite signs.

There are two scalar invariants of the matrix $\mathbb{C}$ that commonly arise in applications.

- $\mathrm{Tr}(\mathbb{C}) = R_1^{-1} + R_2^{-1}$, which is twice the mean curvature for the surface. With the unit normal vector given by equation (7.4), one can show that

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{\nabla^2 \eta}{[1 + (\nabla \eta)^2\,]^{3/2}}. \tag{7.39}$$

A bit of algebra leads us to conclude that

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{\nabla^2 \eta}{[1 + (\nabla \eta)^2\,]^{3/2}} = \frac{1}{R_1} + \frac{1}{R_2}, \tag{7.40}$$

for any point along the surface, thus generalizing the result (7.25) found for a curve. Furthermore, if $|\nabla \eta| \ll 1$ then we have

$$\nabla^2 \eta \approx \frac{1}{R_1} + \frac{1}{R_2}, \tag{7.41}$$

with this result proving useful in the study of surface tension in Section 26.11.

- $\det(\mathbb{C}) = 1/(R_1\, R_2)$ is known as the *Gaussian curvature*, which is the product of the two curvatures.

7.3.3 Curves on the surface $z = \eta(x, y)$

FIGURE 7.6: Geometry depicting a contour along a particular line of constant $z = \eta(x, y)$, such as for a constant elevation path along a mountain or valley. The along-contour unit tangent direction is $\hat{\boldsymbol{t}} = \mathrm{d}\boldsymbol{x}/\mathrm{d}s$, with s the arc length along the contour. The unit normal direction pointing to the left of the contour direction is $\hat{\boldsymbol{n}}$, with $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0$ and $\hat{\boldsymbol{t}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$. Both $\hat{\boldsymbol{n}}$ and $\hat{\boldsymbol{t}}$ are horizontal unit vectors.

We now consider a curve, as in Section 7.2, defined along a two dimensional surface, $z = \eta(x, y)$, with the curve defined by lines of constant $z = \eta(x, y)$. For example, if $\eta(x, y)$ is the solid earth topography, then lines of constant η are contours of constant topography. By definition, these contours have no projection into the vertical direction (i.e., they do not go uphill or downhill), and they are determined by

$$\mathrm{d}\eta = 0 = \nabla \eta \cdot \mathrm{d}\boldsymbol{x}, \tag{7.42}$$

where $\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{x}}\,\mathrm{d}x + \hat{\boldsymbol{y}}\,\mathrm{d}y$ is the horizontal space increment along the contour. Following the introduction of arc length in Section 7.2.1, we write

$$\mathrm{d}\eta = 0 = \nabla \eta \cdot \mathrm{d}\boldsymbol{x} = \nabla \eta \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\,\mathrm{d}s = \nabla \eta \cdot \hat{\boldsymbol{t}}\,\mathrm{d}s, \tag{7.43}$$

where $\hat{\boldsymbol{t}}$ is a unit vector pointing in the direction of the contour. To build an orthogonal triad of coordinates, we then define an orthogonal unit vector, $\hat{\boldsymbol{n}}$, that points to the left of the contour direction so that

$$\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0 \quad \text{and} \quad \hat{\boldsymbol{t}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}, \tag{7.44}$$

as depicted in Figure 7.6. We provide an example use of this formalism in Exercise 7.1.

7.4 Exercises

EXERCISE 7.1: JACOBIAN EVALUATED ALONG A CONTOUR
Consider the vector cross product of two functions, $\psi(x, y)$ and $Q(x, y)$

$$\hat{\boldsymbol{z}} \cdot (\nabla\psi \times \nabla Q) = \partial_x\psi\, \partial_y Q - \partial_y\psi\, \partial_x Q \equiv J(\psi, Q), \tag{7.45}$$

where the final equality defined the Jacobian operator. Show that when evaluated along a contour of constant Q, the Jacobian is given by

$$J(\psi, Q) = -(\hat{\boldsymbol{n}} \cdot \nabla Q)\,(\hat{\boldsymbol{t}} \cdot \nabla\psi) \tag{7.46}$$

where $\hat{\boldsymbol{t}}$ is the unit tangent along the contour and $\hat{\boldsymbol{n}}$ is a unit vector pointing to the left of the tangent (e.g., see Figure 7.6).

EXERCISE 7.2: CURVATURE OF A CIRCLE
Make use of equation (7.26), as well as the polar coordinates from Section 10.3, to show that for a circle of radius r we have

$$-\nabla \cdot \hat{\boldsymbol{n}} = \frac{1}{r}, \tag{7.47}$$

where $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{r}}$ points to the left when moving around the circle in a counterclockwise direction. Hence, the radius of curvature for the circle equals to the circle's radius.

Chapter 8

General tensors in brief

Vector calculus, as formalized by the Cartesian tensor analysis of Chapters 1 and 2, is sufficient for many areas of geophysical fluid mechanics. However, there are a number of applications where general tensors helps the physics to shine through the maths. We are thus motivated to move beyond Cartesian tensor analysis to here consider general tensors, thus enabling a more versatile and precise mathematical formalism. Besides enhancing our tools for geophysical fluid mechanics, general tensor analysis is found throughout physics so that understanding the formalism, if only its rudiments, can grealy help to understand the broader physics literature.

Geophysical fluid mechanics applications require only a modest level of new formalism in the transition from Cartesian tensors to general tensors. The following reasons support a somewhat minimalist use of general tensor analysis and differential geometry.

- Geophysical fluids are embedded within the same Euclidean space used for Newtonian particle mechanics (Chapter Part 11). Notably, Euclidean space has zero intrinsic curvature so we say that it is a *flat space*. So although we are concerned with fluid motion on curved static manifolds (e.g., spherical planets); motion on curved and fluctuating manifolds (e.g., isopycnals); and in describing motion using non-orthogonal coordinates (e.g., generalized vertical coordinates), the fluid remains embedded within a background Euclidean space. Through that embedding, the local geometry inherits features from the Euclidean space. In particular, we continue to measure distance between points in space via the Pythagorean theorem and the associated Kronecker metic.

- We make use of universal *Newtonian time*. Hence, time is measured the same by all observers and reference frames. So although the spatial coordinates used by geophysical fluid mechanics can be a function of time, the time coordinate is always independent of space.

- We assume that the position of a fluid particle is described by a vector extending from an origin, typically assumed to be the center of the planet. In so doing, we retain the notion of a position vector as a directed line segment starting from an origin, just as for Cartesian tensor analysis in Section 1.2. Alternative treatments dispense with the notion of an origin and corresponding position vector. Instead, these treatments generalize the concept of a vector to a directed partial derivative operator. We briefly motivate this generalization in Section 8.4.3.[1] Such treatments are essential in some areas of continuum mechanics, particularly when working with arbitrary manifolds where there is no special point that can serve as the origin. Even so, we retain the notion of an origin for our purposes since it is needed to discuss motion on a rotating planet. Namely, on a rotating planet the planet's center

[1] For a thorough discussion of this general approach to defining vectors and tensors, the reader can refer to one of the many books on mathematical physics, such as *Schutz* (1980) (see his Section 2.7) or *Frankel* (2004) (see his Section 1.3).

provides a natural coordinate origin and the rotational axis breaks the isotropy of space. It follows that to understand the planetary Coriolis acceleration and planetary centrifugal acceleration, which arise from a rotating terrestrial observer's description of planetary fluid motion, requires an acknowledgement of the rotational axis and planetary center.

Each of these features of the space and time used for geophysical fluid mechanics means that our mathematical needs are far less than the general relativist who studies fluids moving in strong gravity fields and/or over galactic distances. Even so, we do need some of the tools, and that is the goal for this chapter as well as Chapter 9.

Throughout our study of general tensor analysis it is useful to keep in mind the central goal is to uncover objective statements about how physical systems operate. In particular, we aim to make use of a formalism that does the following:

- suports computations to allow for the comparison of theory with measurements;
- provides a systematic technology to transform between coordinate representations, since there are many occasions where such transformations are useful to develope physical insight and support calculations;
- provides physics equations that are independent of coordinate system.

These goals are realized by general tensor analysis so that the technology reflects the underlying objective nature of physical relationships while allowing for a quantitative realization of those relationships in particular situations.

READER'S GUIDE TO THIS CHAPTER

This brief chapter offers an overview sufficient to appreciate why we need general tensors for certain subjects in this book. We do so by offering a conceptual platform for general tensor analysis, with details presented in Chapter 9. We focus on tensor analysis on spatial manifolds endowed with a metric, thus touching on the rudiments of *Riemannian differential geometry*. Furthermore, we restrict attention to manifolds embedded in Euclidean space, thus providing a natural extension of the Cartesian tensor analysis from Chapters 1 and 2.

8.1 Coordinate independent physical relations

Physical relations are independent of subjective choices for their mathematical representations. This principle motivates us to seek mathematical expressions between objects whose meaning transcends a particular coordinate representation. At its most profound level, there is no *a priori* notion of the underlying geometry, with an insistence on such generalities leading to general relativity and the notion of *general covariance*. General covariance means that the physical equations take on the same form regardless the coordinates, even though when unpacked into coordinate components the terms in these equations generally are effected by coordinate choice. We are not going to insist on general covariance in this book, given that we accept the notion of a background Euclidean space on which the fluid moves, and we make use of a universal Newtonian time measured by all observers. Nonetheless, within the restricted class of Euclidean space and Newtonian time, we do insist that the mathematical expression of a physical relation in an inertial reference frame be independent of the choice of coordinates.

We refer to this property of the physical equations as *Newtonian covariance*, or more specifically *coordinate invariance*. This property is ensured when the equations of mathematical physics are relations between geometric objects such as points, vectors, and tensors. We thus focus in this chapter and in Chapter 9 with the operational goal of laying down the foundations for expressing the continuum equations of fluid mechanics in a form that exposes their underlying geometric foundation. Doing so allows us to avoid being distracted by coordinate dependent statements, while also offering a framework for the practice of using specific coordinates as well as non-inertial reference frames.

Although physics does not care about coordinates, physicists often do. Namely, it is convenient, and sometimes necessary, to work with specific coordinates suited to the symmetry of the physical system, particularly when comparing theory to experiment. After deriving a physical law in one set of coordinates, it is often of interest to establish the form of the law in another set of coordinates. How does the physical law, typically represented as a differential equation, transform into other coordinates? So long as the equations are written in a proper tensorial form then the equations are form invariant. What constitutes "proper tensorial form" is a topic for this chapter and Chapter 9.

When the equations do not manifest form invariance, then that signals either a mistake or, more relevant to our study, a subjective view that arises when describing motion from a non-inertial reference frame. In Part II, we study the accelerations that result from viewing physical systems from a non-inertial reference frame, with such accelerations (planetary centrifugal and planetary Coriolis) fundamental to geophysical fluid mechanics. For this chapter and Chapter 9, we focus on coordinate invariance as a statement that the equations look the same regardless the choice of coordinates. Consequently, "physics as geometry" has a major practical implication. Namely, we can establish the validity of a physical relation in any convenient set of coordinates, and then extend that relation to all coordinates so long as we respect the basic rules of tensor analysis.

8.1.1 Tensor operations

Extending a mathematical equation to all coordinates requires the equations to respect certain tensor rules. In brief, all tensor indices are properly matched and each derivative is covariant as specified in Section 9.10. In chapter 9, we provide the details needed to understand general

coordinate invariance. In this chapter we outline the procedure. The elegance and power rendered by coordinate invariance is the key reason that tensor analysis is ubiquitous in theoretical physics.

To ensure an equation respects coordinate invariance requires us to understand certain properties of tensors and operations with tensors that produce components of new tensors. We here summarize the specific properties characterizing coordinate invariance (taken after page 153 of *Schutz*, 1985):

1. Manipulations of tensor components are called *permissible tensor operations* if they produce components of new tensors. The following are permissible operations:
   (a) Multiplication of a tensor by a scalar produces a new tensor of the same type.
   (b) Addition of components of two tensors of the same type gives components of a new tensor of the same type. In particular, only tensors of the same type can be equal.
   (c) Multiplication of components of two tensors of arbitrary type gives components of a new tensor whose type is given by the sum of the types for the individual tensors. This operation is called the *outer product* or *tensor product* and is denoted by the operator $\otimes$. For example, $\boldsymbol{A} \otimes \boldsymbol{B}$ is a second order tensor built from the outer product of two vectors, $\boldsymbol{A}$ and $\boldsymbol{B}$.
   (d) Covariant differentiation (Sections 9.10 and 9.11) increases by one the order of a tensor, with the covariant derivative operator denoted by ∇.
   (e) Contraction on a pair of indices of the components of a tensor reduces by one the order of a tensor.
   (f) A corollary of the multiplication rule is that if the inner product of two objects yields a tensor, and if one of these objects is itself a tensor then so too is the other. This result is known as the *quotient* rule.
2. If two tensors of the same type have equal components in a given coordinate system, then they have equal components in all coordinate systems. Hence, the tensors are identical. As a corollary, if a tensor is zero in one coordinate system, then it is zero in all coordinate systems.
3. If a mathematical equation consists of tensors combined only by the permissible tensor operations, and if the equation is true in one coordinate system, then it is true in any coordinate system. If the equations involve covariant derivatives, then the equations remain form invariant under changes in coordinates. For the partial differential equations of geophysical fluid mechanics, covariant differentiation is the key to coordinate invariance.

8.1.2 Comments

The remainder of this chapter, as well as Chapter 9, provide the details needed for unpacking the notions of coordinate invariance and specifying particular tensor operations. Even without penetrating these details, the reader should be able to appreciate why coordinate invariance is so central to physics.

8.2 Points, trajectories, and coordinates

Consider a point in space, $\mathscr{P}$, at a particular time, τ. If this point represents the position of a point particle that moves, then as time increases the point traces out a curve in space-time. We call that curve the *trajectory* of the particle. In general, a trajectory through space-time could be

determined by a point particle satisfying Newton's laws, as discussed in Chapter 11. Or it could be that of a fluid particle within a continuum, whose motion defines the Lagrangian reference frame (Section 18.3). Or it could trace the path of something else such as a fish, balloon, boat, or airplane. As the trajectory is a one-dimensional curve, it is specified mathematically by a single parameter (see Section 7.2.1). We choose the time measured by an observer on the trajectory for this parameter. Since we are working with Newtonian time, there is no ambiguity concerning past, present, and future. In this manner, time is monotonically increasing with the same value at all points in space.

A point in the fluid as well as the trajectory in space-time are both geometric objects that exist independently of any coordinate representation. Even so, we find the need to represent points, trajectories, vectors, and other geometric objects using coordinates. For example, coordinates are needed to make quantitative statements about fluid flow in relation to observers. What is its speed and direction relative to a chosen reference frame? What is the distance from an origin or from another particle? Tensor analysis provides a formalism that enables us to answer such quantitative questions while maintaining a clear view on the underlyng physics and geometry.

8.2.1 Time as a parameter and time as a coordinate

In special and general relativity, there is a mixing of space and time that warrants the use of four-dimensional space-time tensor analysis. In contrast, for classical mechanics forming the foundation of geophysical fluid mechanics, time is a monotonically increasing parameter that is numerically the same value throughout all of space. We thus make use of the same universal (or Newtonian) time since the fluid velocity and wave speeds are far smaller than the speed of light. Hence, for our studies we generally restrict attention to the space + time formalism of classical mechanics rather than the space-time formalism of relativity. See Section 8.5.4 for one qualification to this usage.

The time parameter, τ, specifies a point along a trajectory in space. The coordinate time, t, measures time for all positions throughout space. This distinction between the time parameter and time coordinate is pedantic given that $\tau = t$ (up to a constant offset) in a Newtonian universe. Nonetheless, it is convenient to make the distinction when measuring how fluid properties change since these changes are subject to motion of the observer. For example, changes following a trajectory, found by computing the trajectory time derivative $\partial/\partial\tau$, are generally distinct from changes found by computing the time derivative $\partial/\partial t$, in which the spatial coordinates are held fixed.

When the trajectory is defined by a fluid particle, we refer to $\partial/\partial\tau$ as the *material or Lagrangian time derivative*. This time derivative is the same as when working with Newtonian particle mechanics as in Chapter 11. In contrast, if the spatial coordinates are fixed in space, then $\partial/\partial t$ is an Eulerian time derivative. When alternative spatial coordinates are used, some of which can move (see Section 8.2.2), then $\partial/\partial t$ can be a mixture of Lagrangian and Eulerian or perhaps neither. We return to these time derivatives in Section 18.8 when discussing fluid kinematics.

8.2.2 The importance of index placement

The position (up or down) of a tensor label has significance in general tensor analysis, whereas there is no significance for Cartesian tensors. We follow the standard terminology by labeling an arbitrary coordinate with indices upstairs in their *contravariant* position, ξ^α. It is furthermore common to express each of the coordinates in an ordered list according to

$$\xi^\alpha = (\xi^0, \xi^1, \xi^2, \xi^3), \tag{8.1}$$

with ξ^α representing a *generalized coordinate*. The α index is a tensor label; it is not an exponent or power. We use a convention whereby Greek labels run from $\alpha = 0, 1, 2, 3$ with $\alpha = 0$ the time coordinate and $\alpha = a = 1, 2, 3$ the three coordinates used to locate a point in space. The following shorthand notations are commonly used in this book

$$\xi^\alpha = (\xi^0, \xi^1, \xi^2, \xi^3) = (\xi^0, \xi^a) = (\xi^0, \boldsymbol{\xi}). \tag{8.2}$$

8.3 Example coordinate descriptions

We here offer a few examples of coordinates used for describing geophysical fluid systems. As the time coordinate remains universal in our study, the following is only concerned with the spatial coordinates, $a = 1, 2, 3$.

8.3.1 Locally orthogonal coordinates

In Chapter 10 we detail three sets of commonly used locally orthogonal coordinates: Cartesian, spherical, and cylindrical-polar. In Cartesian coordinates, (x, y, z), the position vector for a point in space is written

$$\boldsymbol{x} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + z\,\hat{\boldsymbol{z}} \qquad \text{Cartesian.} \tag{8.3}$$

For spherical coordinates, (λ, ϕ, r), the position vector is (see Figure 10.1)

$$\boldsymbol{x} = r\,\hat{\boldsymbol{r}} \qquad \text{spherical,} \tag{8.4}$$

and cylindrical-polar coordinates, (r, ϑ, z), (see Figure 10.2) we have

$$\boldsymbol{x} = r\,\hat{\boldsymbol{r}} + z\,\hat{\boldsymbol{z}} \qquad \text{cylindrical-polar.} \tag{8.5}$$

Note that in spherical coordinates, r is the distance from the origin to the point and $\hat{\boldsymbol{r}}$ points from the origin to the point. In contrast, for cylindrical-polar coordinates, r is the distance from the z-axis and $\hat{\boldsymbol{r}}$ is the horizontal vector pointing from the z-axis to the point. Each of these coordinate representations identify positions in space relative to a fixed coordinate origin.

As shown in Section 8.4, Cartesian coordinates have basis vectors that maintain a fixed direction throughout space. This feature lends simplicity to Cartesian coordinates and its corresponding Cartesian tensor analysis (Chapters 1 and 2). In contrast, the spherical basis vectors are spatially dependent. Likewise, the radial and angular basis vectors for polar cylindrical coordinates are spatially dependent, whereas the vertical direction is the same as the fixed Cartesian vertical direction. Additionally, the spherical and cylindrical coordinates do not all have the same physical dimensions. Each of these features of spherical and cylindrical coordinates places them outside the purview of Cartesian tensor analysis.

8.3.2 Isopycnal coordinates

In geophysical fluids that are stably stratified in the vertical, it is common to measure the vertical position of a fluid element by specifying its entropy, buoyancy, or potential density depending on the application. We generically write these *isentropic*, *buoyancy*, or *isopycnal* coordinates as

$$\xi^a = (x, y, b) \qquad \text{with} \qquad b = b(x, y, z, t) \qquad \text{isopycnal coordinates,} \tag{8.6}$$

where $b = b(x, y, z, t)$ is a generic symbol for entropy, buoyancy, or potential density. Entropy, buoyancy, and potential density are materially invariant for perfect fluid flow (flow absent irre-

versible processes such as mixing or heating). Hence, all fluid particle motion occurs on surfaces of constant b. Under such perfect fluid conditions, isopycnal coordinates are of great use for describing fluid mechanics of stably stratified geophysical flows.[2]

The isopycnal coordinates are generally not orthogonal since the direction normal to a buoyancy surface is not generally vertical. Hence, even if the horizontal coordinates are Cartesian, the use of b to measure the vertical precludes the use of Cartesian tensor analysis. Furthermore, we note the distinct physical dimensions of the three spatial coordinates (x, y, b), again necessitating the use of general tensor analysis. We pursue such *generalized vertical coordinate* descriptions in Part XI of this book.

8.3.3 Lagrangian or material coordinates

We can conceive of a fluid as a continuum of fluid particles that are distinguished by continuum marker coordinates or labels. The initial position for a fluid particle offers a suitable (and common) choice for these *material coordinates*. The fluid dynamical equations of motion (i.e., Newton's Law of motion) can be formulated using material coordinates so long as the material coordinate maintains a 1-to-1 invertible relation to points in space. This kinematical framework is termed *Lagrangian* or *material*. The resulting dynamical equations share much in common with Newtonian particle mechanics, though with the added feature of contact forces acting between the fluid elements. We formally describe Lagrangian coordinates in Section 18.4 and encounter Lagrangian descriptions throughout this book. Transformations between material coordinates and spatial coordinates is facilitated by the methods of general tensor analysis.

8.3.4 Tracer coordinates

Consider a triplet of linearly independent tracer concentrations, $C^a = C^a(x, y, z, t)$, that spans $\mathbb{R}^3$. Hence, at any point in space there is a unique intersection of three tracer isosurfaces, so that we can uniquely determine a point in space by specifying the value for the three tracer concentrations. Correspondingly, we can use tracer concentrations as the spatial coordinates

$$\xi^a = (C^1, C^2, C^3). \tag{8.7}$$

In some cases there are only two linearly independent tracers, in which case the two may be used in combination with a third spatial coordinate such as depth or pressure. Furthermore, the case of one tracer coordinate formally reduces to the isopycnal coordinate system from Section 8.3.2.[3]

8.4 The velocity vector and basis vectors

Consider two points in space that sit along a particular trajectory separated by an infinitesimal time increment, $\mathrm{d}\tau$. The velocity vector for this trajectory is defined by

$$\vec{v}(\tau) = \lim_{\Delta\tau \to 0} \frac{\mathscr{P}(\tau + \Delta\tau/2) - \mathscr{P}(\tau - \Delta\tau/2)}{\Delta\tau} = \frac{\mathrm{d}\mathscr{P}(\tau)}{\mathrm{d}\tau}. \tag{8.8}$$

The velocity is a vector pointing in the direction determined by the difference between two points on a trajectory, in the limit as the time separation between the points vanishes. Consequently,

[2] We can make use of the isopycnal coordinate system to determine the vertical position so long as there is a one-to-one invertible relation between z and b at each horizontal point and at each time instance.

[3] See *Nurser et al.* (2022) for a description of fluid flow in the space defined by arbitrary continuous properties such as tracers.

the velocity points in a direction tangent to the trajectory. Notably, the above definition for the velocity makes no use of coordinates. Rather, the velocity vector is determined by the geometry of the trajectory and the specification of the trajectory's time parameter. Hence, velocity is fundamentally an arrow with a length and direction and as such, the velocity is a geometric object with this fact emphasized by exposing the arrow.

8.4.1 Coordinate representation

We now establish an arbitrary set of spatial coordinates, ξ^a, to represent points in space. These coordinates are used to measure the spatial position of the trajectory according to

$$\mathscr{P}(\tau) = \mathscr{P}[\xi^a(\tau)], \tag{8.9}$$

where $\xi^a(\tau)$ is the coordinate position on the trajectory at time τ. This coordinate representation for the trajectory induces a coordinate representation for the velocity through use of the chain rule

$$\vec{v}(\tau) = \frac{\mathrm{d}\mathscr{P}(\tau)}{\mathrm{d}\tau} = \frac{\mathrm{d}\xi^a}{\mathrm{d}\tau}\,\frac{\partial\mathscr{P}}{\partial\xi^a} \equiv v^a\,\vec{e}_a. \tag{8.10}$$

The expansion coefficients

$$v^a = \frac{\mathrm{d}\xi^a}{\mathrm{d}\tau} \tag{8.11}$$

provide a representation for the velocity vector, $\vec{v}(\tau)$, within the coordinate system, ξ^a.

8.4.2 Basis vectors

As seen by equation (8.10), for each number, v^a, there is a corresponding basis vector, $\vec{e}_a$, whose value at the point $\mathscr{P}$ is given by

$$\vec{e}_a(\mathscr{P}) = \frac{\partial\mathscr{P}}{\partial\xi^a}. \tag{8.12}$$

The basis vectors are generally a function of space and time, with Cartesian coordinates a notable exception whereby they are space-time constants.

8.4.3 Vectors living on a tangent space

Generalization allowed when we dispense with the coordinate origin

The definition of velocity as a vector tangent to the trajectory is a general property of all vectors living on a manifold. Namely, a vector at a point on a manifold lives within the *tangent space* to the manifold, with a distinct tangent space defined at each point of the manifold. So although we started by considering vectors to connect two points, as afforded by Euclidean space using Cartesian coordinates, we really do not need two points nor do we need an origin to define a vector. Instead, we simply consider a vector at a point on a manifold to be an object defined at that point within the tangent space at the point. In this manner we can dispense with an origin when defining vectors, but in so doing we must be careful when comparing vectors living on a curved manifold. Namely, the comparison of two vectors (e.g., their sums or integrals) can only occur when they live in the same tangent space. So before comparing two vectors, they must be brought to the same tangent space so they can be compared. Herein lies the fundamental reason for extending the partial derivative operator to a covariant derivative when acting on vectors and higher order tensors.

As noted at the start of this chapter, we do not generally make use of the "vectors as differential operators", and its generalization to higher order tensors. The reason is that we are ultimately

concerned with the motion of fluids on a rotating sphere. Even so, the more general approach can be of great use in circumstances, and so the interested reader is encouraged to pursue the study.

A comment on the mapping between vectors and partial differential operators

Mathematically abstracting the identity (8.12) allows us to identify the basis vector as the partial derivative

$$\vec{e}_a = \frac{\partial}{\partial \xi^a}. \tag{8.13}$$

This identification of basis vectors as partial derivative operators is the key to defining a vector without the need to specify an origin. However, some care should be exercised when using this notation for physics since dropping $\mathscr{P}$ changes the physical dimensions of the basis vectors relative to the definition (8.12). For example, in Cartesian coordinates, the basis vectors $\vec{e}_a(\mathscr{P}) = \partial_a \mathscr{P}$ are dimensionless; e.g., the basis vectors are the unit vectors $\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}}$. In contrast, the alternative basis vectors, $\vec{e}_a = \partial_a$, have dimension of inverse length. For dimensional consistency with the treatment in Cartesian tensors, we consider the basis vectors to be the partial derivative operator acting on a point on the manifold as in equation (8.12), rather than the partial derivative operators as in equation (8.13).

8.5 Notational conventions

We here introduce notational conventions that help to simplify many of the manipulations, sometimes referred to as *index gymnastics*, encountered with general tensors.

8.5.1 Placement of tensor labels

As indicated in Section 8.2.2, the placement of tensor labels has specific meaning with general tensor analysis. Therefore, it is critical to maintain proper usage to ensure *conservation of indices* across an equal sign. As a first example of this usage, notice how the basis vectors in equation (8.12) inherit a lowered tensor label. This placement follows from the partial derivative operator that carries an upper coordinate label in the denominator of the operator.

8.5.2 Covariant, contravariant, and Einstein summation

For general tensors, the Einstein summation convention assumes that labels are summed over their range when a lower *covariant* label matches an upper *contravariant* label. In this way we have an arbitrary vector in space written as

$$\vec{F} = \sum_{a=1}^{3} F^a \, \vec{e}_a = F^a \, \vec{e}_a. \tag{8.14}$$

This form of the summation convention generalizes that used for Cartesian tensors in Chapter 1. Importantely, for general tensors we form the contraction (summation) between a lower and an upper label.

The names *covariant* and *contravariant* originate from their relation to the labels placed on a coordinate basis vectors (Section 8.4.2), and thus how they change under coordinate transformations relative to how basis vectors change (Section 9.1). The covariant tensor label accords with the downstairs label placement for a coordinate basis, whereas the upstairs contravariant label is contrary to the coordinate basis (e.g., see Section 2.26 of *Schutz* (1980). A useful mneumonic is "co-low" to signal that the covariant label is downstairs ("low"). The names covariant and

contravariant are used infrequently in modern tensor analysis, which instead considers tensors as geometric objects and so is not primarily concerned with the coordinate representations of tensors. Additionally, when allowing for a metric tensor (as for a Riemannian manifold), then the metric can move indices up and down, thus further blurring the importance of covariant and contravariant.

8.5.3 The boldface notation

In Cartesian tensor analysis we have no need to distinguish $\vec{F}$ from the boldface $\boldsymbol{F}$. One means to extend this notation to general tensors is to organize the contravariant representation F^a into an ordered list (F^1, F^2, F^3) and to use the boldface notation

$$\boldsymbol{F} = (F^1, F^2, F^3). \tag{8.15}$$

Likewise, we can organize the basis vectors according to

$$\vec{\boldsymbol{e}} = (\vec{e}_1, \vec{e}_2, \vec{e}_3) \tag{8.16}$$

and the generalized coordinates as

$$\boldsymbol{\xi} = (\xi^1, \xi^2, \xi^3). \tag{8.17}$$

With this notation the velocity vector representation from equation (8.10) takes on the form

$$\vec{v} = v^a \, \vec{e}_a \tag{8.18}$$

Likewise, the position of a point in space can be represented in terms of a chosen set of coordinates according to

$$\mathscr{P} \leftrightarrow \xi^a \, \vec{e}_a. \tag{8.19}$$

Notice that the arrow symbol over the basis vector remains even when using the boldface. This usage is required since the arrow carries information about the vector nature of the object, whereas the boldface is merely a shorthand for an ordered list.

Although the above notation makes good sense, we more generally allow the boldface to be synonymous with the vector arrow notation

$$\boldsymbol{F} = \vec{F} = F^a \, \vec{e}_a. \tag{8.20}$$

Though corrupting the convention in equation (8.18), this notation is readily used in the literature and as such will be employed in this book where the meaning is clear and after our tensor brain-muscle has been exercised.

8.5.4 Space-time approach

As introduced in Section 8.2.2, we make use of a Greek label when incorporating time to the tensor indices, with $\alpha = 0$ denoting the time coordinate. Time remains universal in the Newtonian world of geophysical fluid mechanics. However, many coordinates are functions of both space and time. Therefore, when measuring time changes in one coordinate system it will differ from time changes in another. Following equation (8.2) used for coordinates, we make use of the following index notation and ordered list for contravariant components of 4-vectors

$$F^\alpha = (F^0, F^1, F^2, F^3) = (F^0, F^a) = (F^0, \boldsymbol{F}). \tag{8.21}$$

In Cartesian coordinates, the time component of the velocity 4-vector is unity

$$v^\alpha = (1, v^1, v^2, v^3) = (1, v^a) = (1, \boldsymbol{v}) \qquad \text{4-velocity in Cartesian coordinates.} \tag{8.22}$$

We make use of the 4-vector formalism in Section 9.9 when performing the transformation of partial derivatives. We also make use of the 4-vector formalism in Section 18.9 for Galilean transformation and Section 18.10 for a general transformation of the material time operator. In those particular discussions we note that the time coordinate is not a function of space and yet the space coordinates are generally a function of time, which makes the 4-vector formalism of use to transform partial derivatives.

Chapter 9

General tensor analysis

In this chapter we generalize the Cartesian algebra of Chapter 1 and Cartesian calculus of Chapter 2 to general tensors. Our focus concerns general tensor analysis needed to describe the physics of particles and continua embedded in a background Euclidean space, with this limited extension of Cartesian tensors sufficient for our purposes in geophysical fluid mechanics (see the start of Chapter 8 for more on this point). Furthermore, since time remains universal, we typically focus on space tensors. The single exception is that we consider a space-time transformation of the partial time derivative operator (Section 9.9), since the time derivative cares about the motion of space coordinates even though the time itself is universal.

Cartesian tensor analysis provides a systematic formulation of vector analysis. The Euclidean metric provided by the Kronecker tensor (i.e., the identity tensor) underlies Cartesian tensors. Here, we extend the formalism of Cartesian tensors by allowing for an arbitrary spatial metric, and in so doing move into the realm of *Riemannian differential geometry*. A more mathematically deductive approach would be to first study calculus on differential manifolds that are not endowed with a metric, which constitutes the subject matter of *differential forms* or the *exterior calculus*. Doing so is beyond our scope.

READER'S GUIDE TO THIS CHAPTER

This chapter is necessary for understanding the mathematics of generalized vertical coordinates in Chapters 59, 60, and 61, as well as general curvilinear coordinates such as those in Chapter 10. Otherwise, this chapter can be skimmed or returned to later if the need arises. Some material in this chapter is an updated version of Chapters 20 and 21 from *Griffies* (2004), along with some streamlining. Other resources include the treatment of tensors for fluid mechanics as given by *Aris* (1962) as well as the classical physics treatment by *Thorne and Blandford* (2017).

9.1 The metric tensor and coordinate transformations

In the study of fluid mechanics we find the need to measure the distance between two points in space at a particular time instance. Since we assume all points live on a smooth and orientable manifold (e.g., a sphere, an isopycnal in a stably stratified fluid), it is sufficient to consider the distance between two infinitesimally close points and use integration to measure finite distances. The measurement of distance requires a metric tensor, which is the subject of this section.

9.1.1 Cartesian coordinates in Euclidean space

Consider a Cartesian coordinate representation for the spatial position of two points, with point $\mathscr{P}$ having space coordinates $\xi^a = x^a$ and the other point $\mathscr{Q}$ an infinitesimal distance away at $x^a + \mathrm{d}x^a$. Furthermore, let

$$\mathrm{d}\boldsymbol{x} = \mathrm{d}x^a \, \vec{e}_a \tag{9.1}$$

be the infinitesimal space vector pointing from $\mathscr{P}$ to $\mathscr{Q}$. Since the space is Euclidean, the squared distance between the two points is based on the Euclidean norm; i.e., the familiar scalar or dot product (Section 1.3)

$$\mathrm{d}s^2 = \mathrm{d}\boldsymbol{x} \cdot \mathrm{d}\boldsymbol{x} = \vec{e}_a \cdot \vec{e}_b \, \mathrm{d}x^a \mathrm{d}x^b = \delta_{ab} \, \mathrm{d}x^a \mathrm{d}x^b. \tag{9.2}$$

In this expression,

$$(\mathrm{d}s)^2 \equiv \mathrm{d}s^2 \tag{9.3}$$

is the squared infinitesimal arc-length separating the two points. The Kronecker symbol, δ_{ab}, is symmetric

$$\delta_{ab} = \delta_{ba}, \tag{9.4}$$

and vanishes when $a \neq b$ and is unity when $a = b$

$$\delta_{ab} = \begin{cases} 0 & \text{if } a \neq b \\ 1 & \text{if } a = b. \end{cases} \tag{9.5}$$

The Kronecker symbol is a representation of the identity tensor.

9.1.2 The metric as a symmetric second order tensor

As defined by equation (9.2), δ_{ab} forms the Cartesian representation of the *metric tensor* for Euclidean space. The metric is a second order tensor, meaning that its coordinate representation carries two tensor labels. Contracting the metric tensor with two vectors leads to a number, namely the squared distance between the two points. Hence, the metric establishes the means to measure the distance between two points that live on a manifold.

We write this distance-measuring property of the metric tensor in a geometric manner through

$$\text{distance}(\vec{P}, \vec{Q}) = \sqrt{\mathbb{g}(\vec{P}, \vec{Q})}. \tag{9.6}$$

Here, $\mathbb{g}$ is the metric tensor with coordinate representation g_{ab} and $\vec{P}$, $\vec{Q}$ are infinitesimally close vectors with coordinate representations

$$\vec{P} = \xi^a \, \vec{e}_a \quad \text{and} \quad \vec{Q} = \vec{P} + \mathrm{d}\xi^a \, \vec{e}_a. \tag{9.7}$$

Equation (9.6) indicates that the metric tensor takes two vectors as argument and produces a scalar. Furthermore, since

$$\text{distance}(\vec{P}, \vec{Q}) = \text{distance}(\vec{Q}, \vec{P}) \geq 0, \tag{9.8}$$

the metric tensor is a symmetric and positive tensor that produces zero only when $\vec{P} = \vec{Q}$.

9.1.3 Coordinate representation of the metric tensor

Given the geometric expression (9.6) for the metric, we determine its representation in an arbitrary coordinate system by considering the squared distance between the coordinate basis vectors

$$\text{distance}(\vec{e}_a, \vec{e}_b) = \sqrt{\mathbb{g}(\vec{e}_a, \vec{e}_b)}. \tag{9.9}$$

This relation determines the coordinate components of the metric tensor

$$\mathbb{g}(\vec{e}_a, \vec{e}_b) \equiv g_{ab}. \tag{9.10}$$

Furthermore, for a manifold embedded in Euclidean space (as considered in this book) this relation is written

$$g_{ab} = \vec{e}_a \cdot \vec{e}_b = \sum_{i=1}^{3} (e_a)_i \, (e_b)_i. \tag{9.11}$$

In this manner, we see that the metric tensor components are determined by computing the Euclidean scalar product between the basis vectors. We also see that if the basis vectors are orthogonal, then the metric tensor components vanish for $a \neq b$.

9.1.4 Transforming the coordinate representation of the metric tensor

We find opportunities to represent the metric tensor in various coordinate systems. Here, we consider the transformation from Cartesian coordinates $\xi^a = x^a$ to arbitrary coordinates $\xi^{\overline{a}}$. Use of the chain rule along with some index gymnastics leads to the equivalent expression for the squared infinitesimal length between two points

$$\mathrm{d}s^2 = \delta_{ab} \, \mathrm{d}\xi^a \, \mathrm{d}\xi^b = \delta_{ab} \frac{\partial \xi^a}{\partial \xi^{\overline{a}}} \frac{\partial \xi^b}{\partial \xi^{\overline{b}}} \, \mathrm{d}\xi^{\overline{a}} \, \mathrm{d}\xi^{\overline{b}} \equiv \delta_{ab} \Lambda^a_{\ \overline{a}} \, \Lambda^b_{\ \overline{b}} \, \mathrm{d}\xi^{\overline{a}} \, \mathrm{d}\xi^{\overline{b}} \equiv g_{\overline{a}\overline{b}} \, \mathrm{d}\xi^{\overline{a}} \, \mathrm{d}\xi^{\overline{b}}, \tag{9.12}$$

where

$$g_{\overline{a}\overline{b}} = \delta_{ab} \Lambda^a_{\ \overline{a}} \, \Lambda^b_{\ \overline{b}} \tag{9.13}$$

defines the components to the metric tensor as represented by the new set of coordinates $\xi^{\overline{a}}$. We also introduced elements to the *transformation matrix*

$$\Lambda^a_{\ \overline{a}} = \frac{\partial \xi^a}{\partial \xi^{\overline{a}}}. \tag{9.14}$$

This matrix of partial derivatives has a non-zero entry when a coordinate in one representation changes while moving along the direction of a coordinate in the other representation. As for any partial derivative, the complement coordinates are held fixed when performing the derivative. Although carrying indices, the numbers $\Lambda^a_{\ \overline{a}}$ are *not* components of a tensor. Instead, they are components of a matrix used to transform tensor representations from one coordinate system to another. Organized as a matrix, we follow a convention whereby the row is denoted by a and the column by $\overline{a}$

$$\Lambda^a_{\overline{a}} = \begin{bmatrix} (\partial\xi^1/\partial\xi^{\overline{1}})_{\overline{2},\overline{3}} & (\partial\xi^1/\partial\xi^{\overline{2}})_{\overline{1},\overline{3}} & (\partial\xi^1/\partial\xi^{\overline{3}})_{\overline{1},\overline{2}} \\ (\partial\xi^2/\partial\xi^{\overline{1}})_{\overline{2},\overline{3}} & (\partial\xi^2/\partial\xi^{\overline{2}})_{\overline{1},\overline{3}} & (\partial\xi^2/\partial\xi^{\overline{3}})_{\overline{1},\overline{2}} \\ (\partial\xi^3/\partial\xi^{\overline{1}})_{\overline{2},\overline{3}} & (\partial\xi^3/\partial\xi^{\overline{2}})_{\overline{1},\overline{3}} & (\partial\xi^3/\partial\xi^{\overline{3}})_{\overline{1},\overline{2}} \end{bmatrix}. \tag{9.15}$$

Note that the lower index is displaced to the right to delineate which index refers to the column. The transformation matrix is nonsingular for one-to-one invertible coordinate transformations, in which case its determinant, called the *Jacobian of the transformation*, is nonvanishing and single signed. Finally, we sometimes find it useful to write the un-barred coordinates as an ordered list in a column, $\boldsymbol{\xi} = (\xi^1, \xi^2, \xi^3)^T$, in which case the transformation matrix takes on the abbreviated form

$$\Lambda^a_{\overline{a}} = \begin{bmatrix} (\partial\boldsymbol{\xi}/\partial\xi^{\overline{1}})_{\overline{2},\overline{3}} & (\partial\boldsymbol{\xi}/\partial\xi^{\overline{2}})_{\overline{1},\overline{3}} & (\partial\boldsymbol{\xi}/\partial\xi^{\overline{3}})_{\overline{1},\overline{2}} \end{bmatrix}. \tag{9.16}$$

Use of this expression for the transformation matrix leads to the arbitrary coordinate representation of the metric tensor

$$g_{\overline{a}\overline{b}} = \vec{e}_{\overline{a}} \cdot \vec{e}_{\overline{b}} = \begin{bmatrix} \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \\ \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \\ \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} & \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}} \end{bmatrix}. \tag{9.17}$$

9.1.5 Basis vectors

We transform the basis vectors from Cartesian into arbitrary coordinates through the transformation

$$\vec{e}_{\overline{a}} = \Lambda^{a}_{\ \overline{a}}\, \vec{e}_a. \tag{9.18}$$

Use of the transformation matrix (9.16) renders the arbitrary coordinate basis vectors

$$\vec{e}_{\overline{1}} = \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} \qquad \text{and} \qquad \vec{e}_{\overline{2}} = \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}} \qquad \text{and} \qquad \vec{e}_{\overline{3}} = \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}}, \tag{9.19}$$

which corresponds to the metric tensor written as in equation (9.17).

9.1.6 Finite distance between points

Once the metric is determined, the distance along a curve between two finitely separated points is given by integration

$$L = \int \sqrt{\mathrm{d}s^2} = \int_{\varphi_1}^{\varphi_2} \left| g_{ab} \frac{\mathrm{d}\xi^a}{\mathrm{d}\varphi} \frac{\mathrm{d}\xi^b}{\mathrm{d}\varphi} \right|^{1/2} \mathrm{d}\varphi, \tag{9.20}$$

where φ is a parameter specifying the curve (e.g., the arc length as in Section 2.4), with φ_1 and φ_2 specifying the endpoints of the curve.

9.2 One-forms

The metric tensor, $\mathfrak{g}$, is a function of two vectors, so that when the metric "eats" the two vectors the result is the scalar distance between the vectors (equation (9.6))

$$\text{distance}(\vec{A}, \vec{B}) = \sqrt{\mathfrak{g}(\vec{A}, \vec{B})}. \tag{9.21}$$

What if the metric only eats one vector? The resulting geometric object is known as a *one-form*

$$\widetilde{A} \equiv \mathfrak{g}(\vec{A},\ ), \tag{9.22}$$

with the tilde used to distinguish a one-form from a vector.

9.2.1 Coordinate representation of a one-form

We can determine the coordinate representation of a one-form by eating a basis vector

$$\widetilde{A}(\vec{e}_b) = \mathfrak{g}(\vec{A}, \vec{e}_b) = \mathfrak{g}(A^a\, \vec{e}_a, \vec{e}_b) = \mathfrak{g}(\vec{e}_a, \vec{e}_b)\, A^a = g_{ab} A^a. \tag{9.23}$$

To reach this result we pulled the coordinate representation A^a outside of the metric tensor since the tensor eats vectors rather than numbers. This equation defines the coordinate representation of the one-form $\widetilde{A}$ in terms of its *dual* vector $\vec{A}$ and the metric tensor

$$A_b = g_{ab} A^a. \tag{9.24}$$

We thus see that the metric tensor provides the means to lower an index on the representation of a vector, thus producing the representation of a one-form. We return to this important point in Section 9.2.3.

9.2.2 Basis one-forms and the bi-orthogonality relation

Just as for vectors, we find use for a basis of one-forms to specify their coordinate representation. The basis of one-forms, $\widetilde{e}^a$, are defined through the bi-orthogonality relation

$$\mathbb{g}(\widetilde{e}^a, \vec{e}_b) = \widetilde{e}^a \cdot \vec{e}_b = \delta^a_{\ b}, \tag{9.25}$$

where

$$\delta^a_{\ b} = g^{ac}\, g_{cb} \tag{9.26}$$

are components to the Kronecker tensor, taking the value of unity when $a = b$ and zero otherwise

$$\delta^a_{\ b} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{9.27}$$

Note that it is only for Cartesian coordinates that we have

$$\delta^a_{\ c} = g^{ab}\, \delta_{bc} \qquad \text{Cartesian coordinates}, \tag{9.28}$$

which follows since $g^{ab} = \delta^{ab}$ in Cartesian coordinates.

We can obtain an explicit expression for the basis one-forms in arbitrary coordinates by transforming from Cartesian coordinates through use of the inverse transformation

$$\widetilde{e}^{\overline{a}} = \Lambda^{\overline{a}}_{\ a}\, \widetilde{e}^a, \tag{9.29}$$

which renders

$$\widetilde{e}^{\overline{1}} = \hat{\boldsymbol{x}}\, \frac{\partial \xi^{\overline{1}}}{\partial x} + \hat{\boldsymbol{y}}\, \frac{\partial \xi^{\overline{1}}}{\partial y} + \hat{\boldsymbol{z}}\, \frac{\partial \xi^{\overline{1}}}{\partial z} = \nabla \xi^{\overline{1}} \tag{9.30a}$$

$$\widetilde{e}^{\overline{2}} = \hat{\boldsymbol{x}}\, \frac{\partial \xi^{\overline{2}}}{\partial x} + \hat{\boldsymbol{y}}\, \frac{\partial \xi^{\overline{2}}}{\partial y} + \hat{\boldsymbol{z}}\, \frac{\partial \xi^{\overline{2}}}{\partial z} = \nabla \xi^{\overline{2}} \tag{9.30b}$$

$$\widetilde{e}^{\overline{3}} = \hat{\boldsymbol{x}}\, \frac{\partial \xi^{\overline{3}}}{\partial x} + \hat{\boldsymbol{y}}\, \frac{\partial \xi^{\overline{3}}}{\partial y} + \hat{\boldsymbol{z}}\, \frac{\partial \xi^{\overline{3}}}{\partial z} = \nabla \xi^{\overline{3}}. \tag{9.30c}$$

In Section 9.9.3 we verify that the basis one-forms satisfy the orthogonality relation (9.25) with the basis vectors

$$\widetilde{e}^{\overline{a}} \cdot \vec{e}_{\overline{b}} = \delta^{\overline{a}}_{\ \overline{b}}. \tag{9.31}$$

9.2.3 Metric as a mapping between vectors and one-forms

We can contract the expression (9.24) with components of the inverse metric tensor, g^{ab}, to render

$$g^{ab} A_b = g^{ab}\, g_{bc} A^c = \delta^a_{\ c} A^c = A^a. \tag{9.32}$$

This identity, as well as equation (9.24), show that the metric provides a map between coordinate representations of one-forms and vectors.

To every vector $\vec{A}$ there is a corresponding one-form $\widetilde{A}$. We say that the one-forms and vectors are *dual*, with the mapping between one-forms and vectors rendered by the metric tensor. Abstractly, we say that a vector at a point on a manifold lives on the tangent space at that point, whereas a one-form lives on the cotangent space. The metric tensor attaches the tangent space to the co-tangent space. For Cartesian tensor analysis, the duality between one-forms and vectors is the duality between row vectors and column vectors. Furthermore, as for Cartesian tensors, we construct an inner product by contracting one-forms and vectors to produce a scalar. Finally, the duality relation given by equation (9.24) offers us the means to raise and lower tensor indices in a manner akin to the transpose operation in linear algebra that produces a row vector from a column vector.

9.2.4 Transformation of the coordinate representation

The transformation matrix (9.14) provides the means to convert any arbitrary coordinate representation of a tensor from one coordinate system to another. For example, consider the coordinate representation of a vector, which is realized by letting the vector eat one of the basis one-forms

$$\vec{F}(\widetilde{e}^a) = F^a. \tag{9.33}$$

Now consider another coordinate system with basis one-forms $\widetilde{e}^{\overline{a}}$, so that the vector has a representation

$$\vec{F}(\widetilde{e}^{\overline{a}}) = F^{\overline{a}}. \tag{9.34}$$

Transforming the basis one-form using the transformation matrix leads to

$$F^{\overline{a}} = \vec{F}(\widetilde{e}^{\overline{a}}) = \vec{F}(\Lambda^{\overline{a}}_{\ a}\, \widetilde{e}^a) = \Lambda^{\overline{a}}_{\ a}\, \vec{F}(\widetilde{e}^a) = \Lambda^{\overline{a}}_{\ a}\, F^a. \tag{9.35}$$

Transformation of an arbitrary one-form representation takes place with the inverse transformation matrix

$$F_{\overline{a}} = \widetilde{F}(\vec{e}_{\overline{a}}) = \widetilde{F}(\Lambda^{a}_{\ \overline{a}}\, \vec{e}_a) = \Lambda^{a}_{\ \overline{a}}\, \widetilde{F}(\vec{e}_a) = \Lambda^{a}_{\ \overline{a}}\, F_a. \tag{9.36}$$

9.2.5 Arbitrary coordinate representation of inverse metric

The inverse metric tensor has an arbitrary coordinate representation given by

$$g^{\overline{a}\overline{b}} = \widetilde{e}^{\overline{a}} \cdot \widetilde{e}^{\overline{b}} = \begin{bmatrix} \nabla\xi^{\overline{1}} \cdot \nabla\xi^{\overline{1}} & \nabla\xi^{\overline{1}} \cdot \nabla\xi^{\overline{2}} & \nabla\xi^{\overline{1}} \cdot \nabla\xi^{\overline{3}} \\ \nabla\xi^{\overline{2}} \cdot \nabla\xi^{\overline{1}} & \nabla\xi^{\overline{2}} \cdot \nabla\xi^{\overline{2}} & \nabla\xi^{\overline{2}} \cdot \nabla\xi^{\overline{3}} \\ \nabla\xi^{\overline{3}} \cdot \nabla\xi^{\overline{1}} & \nabla\xi^{\overline{3}} \cdot \nabla\xi^{\overline{2}} & \nabla\xi^{\overline{3}} \cdot \nabla\xi^{\overline{3}} \end{bmatrix}. \tag{9.37}$$

Proof that $g^{\overline{a}\overline{b}}\, g_{\overline{b}\overline{c}} = \delta^{\overline{a}}_{\ \overline{c}}$ requires use of the chain rule relations derived in Section 9.9.3.

9.2.6 Functions versus scalars

A scalar field carries no tensor labels and as such it does not transform under coordinate transformations. That is, a scalar is coordinate invariant and it is the simplest type of tensor field. Temperature, kinetic energy, and specific entropy are example scalar fields considered in this book. Now consider the first component of a vector field, F^1, whose value at a point, $\mathscr{P}$, and time, τ, is written $F^1(\mathscr{P},\tau)$. Now change the coordinates so that the first component to the vector field at the same $(\mathscr{P},\tau)$ is written $F^{\overline{1}}(\mathscr{P},\tau)$. Yet under a coordinate transformation we generally have $F^{\overline{1}}(\mathscr{P},\tau) \neq F^1(\mathscr{P},\tau)$, so that the individual components to a vector field, though functions of space and time, *do not* individually transform as a scalar field. Instead, they transform as components to a vector field. This very basic example illustrates the distinction between functions of space and time, which includes any component of any tensor field, from scalar fields, which are coordinate invariant.

9.3 Scalar product

In Section 1.3.2 we defined the scalar product between two Cartesian vectors. The natural generalization is given by

$$\vec{P}\cdot\vec{Q} = P^a\,Q^b\,\vec{e}_a\cdot\vec{e}_b = P^a\,Q^b\,g_{ab} = P^a\,Q_a = P_b\,Q^b, \tag{9.38}$$

where the second equality made use of the metric tensor coordinate representation given by equation (9.11). We can conceive of the scalar product in a somewhat more general manner by recalling that a one-form operates on a vector, $\widetilde{P}(\vec{Q})$. Conversely, a vector operates on a one-form, $\vec{Q}(\widetilde{P})$. Exposing components leads to

$$\widetilde{P}(\vec{Q}) = \widetilde{P}(Q^a\,\vec{e}_a) = Q^a\,\widetilde{P}(\vec{e}_a) = Q^a\,P_a, \tag{9.39}$$

which equals to

$$\vec{Q}(\widetilde{P}) = \vec{Q}(P_a\,\widetilde{e}^a) = P_a\,\vec{Q}(\widetilde{e}^a) = P_a\,Q^a. \tag{9.40}$$

The scalar product is invariant to coordinate changes, as seen through

$$\vec{Q}(\widetilde{P}) = \vec{Q}(P_a\,\widetilde{e}^a) = P_a\,Q^a = \vec{Q}(P_{\overline{a}}\,\widetilde{e}^{\overline{a}}) = P_{\overline{a}}\,Q^{\overline{a}}. \tag{9.41}$$

The invariance is also revealed by working just with the coordinate representations and introducing the transformation matrix elements

$$P_a\,Q^a = (\Lambda^{\overline{a}}{}_a\,P_{\overline{a}})\,(\Lambda^a{}_{\overline{b}}\,Q^{\overline{b}}) = \Lambda^{\overline{a}}{}_a\,\Lambda^a{}_{\overline{b}}\,P_{\overline{a}}\,Q^{\overline{b}} = \delta^{\overline{a}}{}_{\overline{b}}\,P_{\overline{a}}\,Q^{\overline{b}} = P_{\overline{a}}\,Q^{\overline{a}}. \tag{9.42}$$

9.4 Worked example: oblique coordinates

We pause in our development to work through some of the formalism for *oblique coordinates* for the x-z plane as specified by the basis vectors

$$\vec{e}_{\overline{1}} = \vec{e}_1\cos\varphi + \vec{e}_3\sin\varphi = \hat{\boldsymbol{x}}\cos\varphi + \hat{\boldsymbol{z}}\sin\varphi \qquad \text{and} \qquad \vec{e}_{\overline{3}} = \vec{e}_3 = \hat{\boldsymbol{z}}. \tag{9.43}$$

The oblique coordinate basis vectors, $\vec{e}_{\overline{a}}$, are orthogonal when the angle $\varphi = 0,\pi$; otherwise they are non-orthogonal. Also note that if $\varphi = \pi/2, 3\pi/2$ then $\vec{e}_{\overline{1}} = \pm\vec{e}_{\overline{3}}$, in which case the vectors no longer form a basis for the x-z plane. So in the following we assume $\varphi \in (-\pi/2,\pi/2)$. These coordinates are oriented so that they correspond to the generalized vertical coordinate basis

FIGURE 9.1: Oblique basis vectors for the x-z plane where $\vec{e}_{\bar{1}} = \vec{e}_1 \cos\varphi + \vec{e}_3 \sin\varphi$ and $\vec{e}_{\bar{3}} = \vec{e}_3$, with $\vec{e}_1 = \hat{\boldsymbol{x}}$ and $\vec{e}_3 = \hat{\boldsymbol{z}}$. These coordinate basis vectors are related to those used for generalized vertical coordinates shown in the left panel of Figure 59.2.

vectors depicted in Figure 59.2. Finally, for the purposes of this section we ignore the 2 direction and just work within the x-z plane. Hence, tensor indices carry values 1 and 3 with 2 ignored.

9.4.1 Turning the crank

We here exhibit the results of turning the crank for the oblique coordinates.

Transformation matrix and its inverse

We can construct the transformation matrix through $\vec{e}_{\bar{a}} = \Lambda^a_{\ \bar{a}}\, \vec{e}_a$, and use of the coordinate basis definition (9.43)

$$\vec{e}_{\bar{1}} = \Lambda^1_{\ \bar{1}}\, \vec{e}_1 + \Lambda^3_{\ \bar{1}}\, \vec{e}_3 \Longrightarrow \Lambda^1_{\ \bar{1}} = \cos\varphi, \quad \Lambda^3_{\ \bar{1}} = \sin\varphi \tag{9.44a}$$

$$\vec{e}_{\bar{3}} = \Lambda^1_{\ \bar{3}}\, \vec{e}_1 + \Lambda^3_{\ \bar{3}}\, \vec{e}_3 \Longrightarrow \Lambda^1_{\ \bar{3}} = 0, \quad \Lambda^3_{\ \bar{3}} = 1, \tag{9.44b}$$

so that the transformation matrix is

$$\Lambda^a_{\ \bar{a}} = \begin{bmatrix} \Lambda^1_{\ \bar{1}} & \Lambda^1_{\ \bar{3}} \\ \Lambda^3_{\ \bar{1}} & \Lambda^3_{\ \bar{3}} \end{bmatrix} = \begin{bmatrix} \cos\varphi & 0 \\ \sin\varphi & 1 \end{bmatrix}, \tag{9.45}$$

and a matrix inversion yields the inverse transformation matrix

$$\Lambda^{\bar{a}}_{\ a} = \begin{bmatrix} \Lambda^{\bar{1}}_{\ 1} & \Lambda^{\bar{1}}_{\ 3} \\ \Lambda^{\bar{3}}_{\ 1} & \Lambda^{\bar{3}}_{\ 3} \end{bmatrix} = \frac{1}{\cos\varphi} \begin{bmatrix} 1 & 0 \\ -\sin\varphi & \cos\varphi \end{bmatrix}. \tag{9.46}$$

Basis one-forms

The basis one-forms using oblique coordinates are determined by

$$\tilde{e}^{\bar{a}} = \Lambda^{\bar{a}}_{\ a}\, \tilde{e}^a = \Lambda^{\bar{a}}_{\ 1}\, \tilde{e}^1 + \Lambda^{\bar{a}}_{\ 3}\, \tilde{e}^3 \tag{9.47}$$

with $\tilde{e}^1 = \hat{\boldsymbol{x}}$ and $\tilde{e}^3 = \hat{\boldsymbol{z}}$ for Cartesian coordinates. Making use of the inverse transformation matrix (9.46) leads to

$$\tilde{e}^{\bar{1}} = \Lambda^{\bar{1}}_{\ 1}\, \tilde{e}^1 + \Lambda^{\bar{1}}_{\ 3}\, \tilde{e}^3 = \frac{\hat{\boldsymbol{x}}}{\cos\varphi} \tag{9.48a}$$

$$\tilde{e}^{\bar{3}} = \Lambda^{\bar{3}}_{\ 1}\, \tilde{e}^1 + \Lambda^{\bar{3}}_{\ 3}\, \tilde{e}^3 = -\hat{\boldsymbol{x}} \tan\varphi + \hat{\boldsymbol{z}}. \tag{9.48b}$$

We can readily verify the bi-orthogonality relation (9.25) whereby

$$\vec{e}_{\overline{a}} \cdot \tilde{e}^{\overline{b}} = \delta^{\overline{b}}_{\overline{a}}. \tag{9.49}$$

Representing a vector

The inverse transformation matrix (9.46) can be used to relate the Cartesian coordinate representation of an arbitrary vector, $\vec{P} = P^a \, \vec{e}_a$, to the oblique coordinate representation, $\vec{P} = P^{\overline{a}} \, \vec{e}_{\overline{a}}$. Doing so leads to the contravariant components written using oblique coordinates

$$P^{\overline{a}} = \Lambda^{\overline{a}}_{\ a} \, P^a = \Lambda^{\overline{a}}_{\ 1} \, P^1 + \Lambda^{\overline{a}}_{\ 3} \, P^3 \quad \Longrightarrow P^{\overline{1}} = \frac{1}{\cos\varphi} \, P^1 \ \text{ and } \ P^{\overline{3}} = -\tan\varphi \, P^1 + P^3. \tag{9.50}$$

Likewise, the covariant representation can be found by using the transformation matrix (9.45) to render

$$P_{\overline{a}} = \Lambda^{a}_{\ \overline{a}} \, P_a = \Lambda^{1}_{\ \overline{a}} \, P_1 + \Lambda^{3}_{\ \overline{a}} \, P_3 \quad \Longrightarrow P_{\overline{1}} = P_1 \cos\varphi + P_3 \sin\varphi \ \text{ and } \ P_{\overline{3}} = P_3, \tag{9.51}$$

where $P^a = P_a$ for the Cartesian coordinate representation.

Representing the metric tensor

The covariant representation of the metric tensor is given by

$$g_{\overline{a}\,\overline{b}} = \delta_{ab} \, \Lambda^{a}_{\ \overline{a}} \, \Lambda^{b}_{\ \overline{b}} = \begin{bmatrix} g_{\overline{11}} & g_{\overline{13}} \\ g_{\overline{31}} & g_{\overline{33}} \end{bmatrix} = \begin{bmatrix} 1 & \sin\varphi \\ \sin\varphi & 1 \end{bmatrix}, \tag{9.52}$$

and its inverse is

$$g^{\overline{a}\,\overline{b}} = \delta^{ab} \, \Lambda^{\overline{a}}_{\ a} \, \Lambda^{\overline{b}}_{\ b} = \begin{bmatrix} g^{\overline{11}} & g^{\overline{13}} \\ g^{\overline{31}} & g^{\overline{33}} \end{bmatrix} = \frac{1}{(\cos\varphi)^2} \begin{bmatrix} 1 & -\sin\varphi \\ -\sin\varphi & 1 \end{bmatrix}. \tag{9.53}$$

Squared magnitude

The squared magnitude of a vector is given by

$$\begin{aligned}
\vec{P} \cdot \vec{P} &= g_{\overline{a}\overline{b}} \, P^{\overline{a}} \, P^{\overline{b}} && (9.54a)\\
&= P_{\overline{b}} \, P^{\overline{b}} && (9.54b)\\
&= (P_1 \cos\varphi + P_3 \sin\varphi) \, \frac{1}{\cos\varphi} \, P^1 + P_3 \, (P^3 - \tan\varphi \, P^1) && (9.54c)\\
&= P_1 \, P^1 + P_3 \, P^3 && (9.54d)\\
&= \delta_{ab} \, P^a \, P^b. && (9.54e)
\end{aligned}$$

9.4.2 Comments

Oblique coordinate offer a pedagogical step towards the more complex case of generalized vertical coordinates studied in Chapter 59. Indeed, much of the tensor algebra needed for generalized vertical coordinates is concisely summarized in the above steps using oblique coordinates.

9.5 The volume element and Jacobian of transformation

Recall from Section 1.5.2 that we derived an expression for the volume of an infinitesimal region of Euclidean space, $\mathbb{R}^3$, using Cartesian coordinates

$$\mathrm{d}V = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z\,(\hat{\boldsymbol{x}} \times \hat{\boldsymbol{y}}) \cdot \hat{\boldsymbol{z}} = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z. \tag{9.55}$$

This volume element is used for integrating over a region of $\mathbb{R}^3$ when using Cartesian coordinates. Furthermore, its material fluid expression measures the volume of a fluid element. We now generalize this result to arbitrary coordinates.

9.5.1 Jacobian of transformation

From multi-variate calculus, the relation between $\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3$ and $\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}}$ for two sets of coordinates is given by

$$\begin{aligned}
\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3 &= \frac{\partial \boldsymbol{\xi}}{\partial \overline{\boldsymbol{\xi}}}\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}} && (9.56a)\\
&= \frac{\partial(\xi^1,\xi^2,\xi^3)}{\partial(\xi^{\overline{1}},\xi^{\overline{2}},\xi^{\overline{3}})}\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}} && (9.56b)\\
&= \left[\frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{1}}} \times \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{2}}}\right] \cdot \frac{\partial \boldsymbol{\xi}}{\partial \xi^{\overline{3}}}\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}} && (9.56c)\\
&= \det(\Lambda^a{}_{\overline{a}})\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}}, && (9.56d)
\end{aligned}$$

where $\det(\Lambda^a{}_{\overline{a}})$ is the determinant of the transformation matrix, also known as the *Jacobian of transformation*. The transformation is well defined so long as the Jacobian does not vanish. We maintain labels on the transformation matrix inside the determinant symbol to help indicate the sense for the tranformation. This notation also helps maintain proper conservation of tensor indices.

9.5.2 Relating the Jacobian to the determinant of the metric

Recall the expression (9.12) for the transformation of the metric

$$g_{\overline{a}\overline{b}} = \Lambda^a{}_{\overline{a}}\Lambda^b{}_{\overline{b}}\,g_{ab}. \tag{9.57}$$

We can write this expression as a matrix equation

$$\overline{\mathbb{g}} = \Lambda^T\,\mathbb{g}\,\Lambda \tag{9.58}$$

where Λ^T is the transposed matrix. Taking determinants of both sides yields

$$\det(\overline{\mathbb{g}}) = \det(\Lambda^T\,\mathbb{g}\,\Lambda) = \det(\Lambda^T)\,\det(\mathbb{g})\,\det(\Lambda) = [\det(\Lambda)]^2\,\det(\mathbb{g}). \tag{9.59}$$

To reach this result we used the property of determinants that $\det(A\,B) = \det(A)\det(B)$ for any two matrices, and $\det(\Lambda^T) = \det(\Lambda)$. Consequently,

$$\det(\Lambda^a{}_{\overline{a}}) = \frac{\sqrt{\det(g_{\overline{a}\overline{b}})}}{\sqrt{\det(g_{ab})}} = \frac{\sqrt{\det(\overline{\mathbb{g}})}}{\sqrt{\det(\mathbb{g})}}. \tag{9.60}$$

We are thus led to the equivalent expressions for the volume element

$$\mathrm{d}V \equiv \sqrt{\det(\mathbb{g})}\,\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3 = \sqrt{\det(\overline{\mathbb{g}})}\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}}. \tag{9.61}$$

This relation provides us with our desired general coordinate expression for the volume element. For the special case when the unbarred coordinates are Cartesian, $g_{ab} = \delta_{ab}$ so that $\det(\mathbb{g}) = 1$ and

$$\det(\Lambda^a{}_{\overline{a}}) = \sqrt{\det(g_{\overline{a}\overline{b}})} \qquad \text{unbarred coordinates are Cartesian.} \tag{9.62}$$

This is a rather useful expression for our purposes, since we can always use Cartesian as the unbarred coordinates given that geophysical fluids move in a background Euclidean space.

9.6 The permutation symbol and the determinant

As discussed in Section 1.4.1, the Cartesian components of the Levi-Civita tensor are given by the permutation symbol, ϵ_{abc}. To help determine the general coordinate representation of the Levi-Civita tensor, we here develop some identities satisfied by the determinant of the transformation matrix.

9.6.1 Connecting the permutation symbol to the determinant

Consider a two-dimensional space with a transformation matrix $\Lambda^a{}_{\overline{a}}$ between two sets of coordinates. The determinant of the transformation is given by

$$\det(\Lambda^a{}_{\overline{a}}) = \Lambda^1{}_{\overline{1}}\,\Lambda^2{}_{\overline{2}} - \Lambda^1{}_{\overline{2}}\,\Lambda^2{}_{\overline{1}}. \tag{9.63}$$

Introducing the permutation symbol ϵ_{ab} allows us to write this expression in a more tidy manner

$$\det(\Lambda^a{}_{\overline{a}}) = \epsilon_{ab}\,\Lambda^a{}_{\overline{1}}\,\Lambda^b{}_{\overline{2}} \tag{9.64}$$

with

$$\epsilon_{12} = 1 \qquad \text{and} \qquad \epsilon_{21} = -1. \tag{9.65}$$

The permutation symbol is defined to have numerically the same values whether the labels are raised or lowered: $\epsilon^{ab} = \epsilon_{ab}$.

We can generalize the above to any number of dimensions, each of which adds one more label to the permutation symbol and one more number added to the permutation string. We already encountered the three dimensional version in Section 1.4.1 when discussing the vector cross product, in which case the permutation symbol is

$$\epsilon_{123} = 1 \tag{9.66a}$$

$$\epsilon_{abc} = \begin{cases} 0 & \text{if any two labels are the same,} \\ 1 & \text{if } a,b,c \text{ is an even permutation of } 1,2,3, \\ -1 & \text{if } a,b,c \text{ is an odd permutation of } 1,2,3. \end{cases} \tag{9.66b}$$

Likewise, the determinant of the transformation matrix takes the form

$$\det(\Lambda^a{}_{\overline{a}}) = \frac{\partial \boldsymbol{\xi}}{\partial \overline{\boldsymbol{\xi}}} = \frac{\partial(\xi^1,\xi^2,\xi^3)}{\partial(\xi^{\overline{1}},\xi^{\overline{2}},\xi^{\overline{3}})} = \epsilon_{abc}\,\Lambda^a{}_{\overline{1}}\,\Lambda^b{}_{\overline{2}}\,\Lambda^c{}_{\overline{3}}. \tag{9.67}$$

9.6.2 Further identities satisfied by the determinant

The following identity in two dimensions can be readily verified through enumeration

$$\epsilon_{ab}\,\Lambda^a{}_{\bar{a}}\,\Lambda^b{}_{\bar{b}} = \epsilon_{\bar{a}\bar{b}}\,\det(\Lambda^a{}_{\bar{a}}), \tag{9.68}$$

which follows directly from the definition of the determinant and can be explicity verified so long as we assume the permutation symbol $\epsilon_{\bar{a}\bar{b}}$ is numerically identical to ϵ_{ab}. Now contract both sides of this relation with $\epsilon^{\bar{a}\bar{b}}$ to isolate the determinant

$$\frac{1}{2}\,\epsilon^{\bar{a}\bar{b}}\,\epsilon_{ab}\,\Lambda^a{}_{\bar{a}}\,\Lambda^b{}_{\bar{b}} = \det(\Lambda^a{}_{\bar{a}}), \tag{9.69}$$

where we used

$$\epsilon^{\bar{a}\bar{b}}\,\epsilon_{\bar{a}\bar{b}} = \epsilon^{\overline{12}}\,\epsilon_{\overline{12}} + \epsilon^{\overline{21}}\,\epsilon_{\overline{21}} = 2. \tag{9.70}$$

The three dimensional version takes the form

$$\epsilon_{abc}\,\Lambda^a{}_{\bar{a}}\,\Lambda^b{}_{\bar{b}}\,\Lambda^c{}_{\bar{c}} = \epsilon_{\bar{a}\bar{b}\bar{c}}\,\det(\Lambda^a{}_{\bar{a}}), \tag{9.71}$$

so that

$$\frac{1}{3!}\,\epsilon^{\bar{a}\bar{b}\bar{c}}\,\epsilon_{abc}\,\Lambda^a{}_{\bar{a}}\,\Lambda^b{}_{\bar{b}}\,\Lambda^c{}_{\bar{c}} = \det(\Lambda^a{}_{\bar{a}}). \tag{9.72}$$

9.7 The Levi-Civita tensor and the volume element

The metric tensor introduced in Section 9.1 provides a means to measure distance between two points. The Levi-Civita tensor allows us to compute volumes (or areas for two dimensional manifolds). We make particular use of this tensor to compute the volume element used for integration. This section generalizes the Cartesian coordinate discussion provided in Section 1.5.3.

9.7.1 General coordinate representation of the Levi-Civita tensor

The relation (9.68) indicates that the permutation symbol, ϵ_{ab}, *does not* transform as the components to a second order covariant tensor, unless the determinant of the transformation is unity. The same can be said for the permutation symbol, ϵ_{abc}, with equation (9.71) indicating that it does not transform as the components to a third order covariant tensor, unless the determinant of the transformation is unity. Unit determinants occur for special transformations, such as rotations (i.e., Cartesian to Cartesian coordinate transformation as in Chapter 1) and the identity transformation. Indeed, we have already noted that the permutation symbol has the same representation regardless the coordinate choice. As we now show, the permutation symbol is the Cartesian coordinate representation of the Levi-Civita tensor.

The above relations for the determinant motivate us to introduce the general coordinate form of the *Levi-Civita tensor*

$$\varepsilon_{abc} \equiv \sqrt{\det(\mathbb{g})}\,\epsilon_{abc}. \tag{9.73}$$

We highlight the distinct symbols in this definition, with ε the Levi-Civita tensor and ϵ the

permutation symbol. By construction, the components to the Levi-Civita tensor transform as

$$\Lambda^a{}_{\overline{a}}\,\Lambda^b{}_{\overline{b}}\,\Lambda^c{}_{\overline{c}}\,\varepsilon_{abc} = \Lambda^a{}_{\overline{a}}\,\Lambda^b{}_{\overline{b}}\,\Lambda^c{}_{\overline{c}}\,\sqrt{\det(\mathbb{g})}\,\epsilon_{abc} \tag{9.74a}$$
$$= \sqrt{\det(\mathbb{g})}\,\epsilon_{\overline{a}\overline{b}\overline{c}}\,\det(\Lambda^a{}_{\overline{a}}) \tag{9.74b}$$
$$= \sqrt{\det(\overline{\mathbb{g}})}\,\epsilon_{\overline{a}\overline{b}\overline{c}} \tag{9.74c}$$
$$= \varepsilon_{\overline{a}\overline{b}\overline{c}}, \tag{9.74d}$$

where equations (9.60) and (9.68) were used. Therefore, ε_{abc} transforms as components to a third order covariant tensor. Likewise,

$$\varepsilon^{abc} = \frac{\epsilon^{abc}}{\sqrt{\det(\mathbb{g})}} \tag{9.75}$$

transforms as the components to a third order contravariant tensor. These transformation rules allow us to identify ε as a tensor rather than just a combination of numbers.

9.7.2 The volume element

As a third order tensor, the Levi-Civita tensor takes three vectors as its argument. In particular, for three infinitesimal vectors we have

$$\varepsilon(\vec{e}_1\,\mathrm{d}\xi^1, \vec{e}_2\,\mathrm{d}\xi^2, \vec{e}_3\,\mathrm{d}\xi^3) = \mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3\,\varepsilon(\vec{e}_1, \vec{e}_2, \vec{e}_3) \tag{9.76a}$$
$$= \mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3\,\varepsilon_{123} \tag{9.76b}$$
$$= \mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3\,\sqrt{\det(\mathbb{g})}\,\epsilon_{123} \tag{9.76c}$$
$$= \mathrm{d}V, \tag{9.76d}$$

where we used equation (9.61) for the final step. This result means that geometrically, the Levi-Civita tensor measures the volume defined by three vectors

$$\varepsilon(\vec{A}, \vec{B}, \vec{C}) = \mathrm{volume}(\vec{A}, \vec{B}, \vec{C}). \tag{9.77}$$

This interpretation accords with the Cartesian coordinate discussion of the Levi-Civita tensor in Section 1.5.3.

9.8 Vector cross product

The vector cross product of two Cartesian basis vectors yields the third, so that

$$\hat{\boldsymbol{x}} \times \hat{\boldsymbol{y}} = \hat{\boldsymbol{z}} \qquad \text{and cyclic permutations.} \tag{9.78}$$

The coordinate invariant generalization of this relation is given by

$$\vec{e}_a \times \vec{e}_b \equiv \varepsilon_{abc}\,\widetilde{e}^c. \tag{9.79}$$

As defined, the vector cross product of two vectors leads to a one-form. We are thus led to the general coordinate expression for the vector cross product of two arbitrary vectors

$$\vec{P} \times \vec{Q} = P^a\,Q^b\,\vec{e}_a \times \vec{e}_b \tag{9.80a}$$
$$= P^a\,Q^b\,\varepsilon_{abc}\,\widetilde{e}^c. \tag{9.80b}$$

9.9 Coordinate transformation of partial derivatives

Throughout this book, the background space is Euclidean and time is universal. We are thus concerned with space tensors rather than the space-time tensors of special and general relativity. Nonetheless, our description of points in space generally makes use of curved surfaces that are time dependent. Curved surfaces motivate the use of general tensors. Time dependence motivates a space-time formulation (Section 8.5.4) for the purpose of transforming the partial time derivative operator. In this section we establish some properties of the space-time transformation matrix and then exhibit the transformation of space and time partial time derivatives. We have further use of a space-time formulation in Sections 18.9 and 18.10, also for considering the transformation of partial derivatives.

9.9.1 The space-time transformation matrix

As discussed in Section 9.1.4, transformations between coordinate representations are enabled by the transformation matrix built from partial derivatives of the coordinate transformations. The transformation matrix with a universal Newtonian time plus spatial coordinates (that are functions of space and time) takes on the form

$$\Lambda^{\alpha}{}_{\overline{\alpha}} = \frac{\partial \xi^{\alpha}}{\partial \xi^{\overline{\alpha}}} = \begin{bmatrix} \frac{\partial \xi^0}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^0}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^0}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^0}{\partial \xi^{\overline{3}}} \\ \frac{\partial \xi^1}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{3}}} \\ \frac{\partial \xi^2}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{3}}} \\ \frac{\partial \xi^3}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{3}}} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ \frac{\partial \xi^1}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^1}{\partial \xi^{\overline{3}}} \\ \frac{\partial \xi^2}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^2}{\partial \xi^{\overline{3}}} \\ \frac{\partial \xi^3}{\partial \xi^{\overline{0}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{1}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{2}}} & \frac{\partial \xi^3}{\partial \xi^{\overline{3}}} \end{bmatrix}. \tag{9.81}$$

The final equality made use of our assumption that $\xi^{\overline{0}} = \xi^0$ since the time coordinate remains universal. Hence, when computing $\partial \xi^0 / \partial \xi^{\overline{a}}$ we keep $\xi^{\overline{0}}$ fixed so that the derivative vanishes as in the specific case of

$$\left[\frac{\partial \xi^0}{\partial \xi^{\overline{1}}}\right]_{\xi^{\overline{0}},\xi^{\overline{2}},\xi^{\overline{3}}} = \left[\frac{\partial \xi^0}{\partial \xi^{\overline{1}}}\right]_{\xi^{0},\xi^{\overline{2}},\xi^{\overline{3}}} = 0. \tag{9.82}$$

Zero elements in the first row of the transformation matrix (9.81) reveals that time is not a function of space

$$\frac{\partial \xi^0}{\partial \xi^{\overline{a}}} = 0, \tag{9.83}$$

which is expected since we are assuming universal *Newtonian time* in which time is independent of space. In contrast, nonzero elements in the first column indicate that our description of space is generally a function of time

$$\frac{\partial \xi^a}{\partial \xi^{\overline{0}}} \neq 0. \tag{9.84}$$

We see the same overall structure in the inverse space-time transformation matrix

$$\Lambda^{\overline{\alpha}}{}_{\alpha} = \frac{\partial \xi^{\overline{\alpha}}}{\partial \xi^{\alpha}} = \begin{bmatrix} \frac{\partial \xi^{\overline{0}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{0}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{0}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{0}}}{\partial \xi^{3}} \\ \frac{\partial \xi^{\overline{1}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{3}} \\ \frac{\partial \xi^{\overline{2}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{3}} \\ \frac{\partial \xi^{\overline{3}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{3}} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ \frac{\partial \xi^{\overline{1}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{1}}}{\partial \xi^{3}} \\ \frac{\partial \xi^{\overline{2}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{2}}}{\partial \xi^{3}} \\ \frac{\partial \xi^{\overline{3}}}{\partial \xi^{0}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{1}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{2}} & \frac{\partial \xi^{\overline{3}}}{\partial \xi^{3}} \end{bmatrix}. \tag{9.85}$$

9.9.2 Determinant of the transformation matrix

The determinant of the space-time transformation and its inverse remains identical to the determinant of their purely space portions

$$\det(\Lambda^{\alpha}{}_{\overline{\alpha}}) = \det(\Lambda^{a}{}_{\overline{a}}) \qquad \text{and} \qquad \det(\Lambda^{\overline{\alpha}}{}_{\alpha}) = \det(\Lambda^{\overline{a}}{}_{a}), \tag{9.86}$$

which follows since the first row in both transformations has only a single non-zero value, $\Lambda^{0}{}_{\overline{0}} = 1$ and $\Lambda^{\overline{0}}{}_{0} = 1$. Hence, the relations developed in Sections 9.5 and 9.6 for the volume element and Jacobian of transformation remain unchanged when adding the universal time coordinate.

9.9.3 Multiplying the transformation matrix and its inverse

We here verify that the transformation matrix (9.81) indeed has its inverse given by (9.85). For this purpose we must prove that

$$\delta^{\alpha}_{\beta} = \Lambda^{\alpha}{}_{\overline{\beta}}\,\Lambda^{\overline{\beta}}{}_{\beta} \qquad \text{and} \qquad \delta^{\overline{\alpha}}_{\overline{\beta}} = \Lambda^{\overline{\alpha}}{}_{\beta}\,\Lambda^{\beta}{}_{\overline{\beta}}, \tag{9.87}$$

where δ^{α}_{β} and $\delta^{\overline{\alpha}}_{\overline{\beta}}$ are components to the identity tensor. The proof relies on writing the space-time coordinate transformation as a composite function

$$\xi^{\overline{\alpha}} = \xi^{\overline{\alpha}}(\xi^{\alpha}) = \xi^{\overline{\alpha}}[\xi^{\alpha}(\xi^{\overline{\beta}})]. \tag{9.88}$$

Taking partial derivatives and using the chain rule renders

$$\delta^{\overline{\alpha}}_{\overline{\beta}} = \frac{\partial \xi^{\overline{\alpha}}}{\partial \xi^{\overline{\beta}}} = \frac{\partial \xi^{\overline{\alpha}}}{\partial \xi^{\alpha}}\frac{\partial \xi^{\alpha}}{\partial \xi^{\overline{\beta}}} = \Lambda^{\overline{\alpha}}{}_{\alpha}\,\Lambda^{\alpha}{}_{\overline{\beta}} \qquad \text{and} \qquad \delta^{\alpha}_{\beta} = \frac{\partial \xi^{\alpha}}{\partial \xi^{\beta}} = \frac{\partial \xi^{\alpha}}{\partial \xi^{\overline{\alpha}}}\frac{\partial \xi^{\overline{\alpha}}}{\partial \xi^{\beta}} = \Lambda^{\alpha}{}_{\overline{\alpha}}\,\Lambda^{\overline{\alpha}}{}_{\beta}. \tag{9.89}$$

Furthermore, the space subcomponents decouple from time, which can be seen by considering a few representative cases

$$1 = \delta^{0}_{0} = \Lambda^{0}{}_{\overline{\alpha}}\,\Lambda^{\overline{\alpha}}{}_{0} = \Lambda^{0}{}_{\overline{0}}\,\Lambda^{\overline{0}}{}_{0} \tag{9.90a}$$

$$1 = \delta^{1}_{1} = \Lambda^{1}{}_{\overline{\alpha}}\,\Lambda^{\overline{\alpha}}{}_{1} = \Lambda^{1}{}_{\overline{a}}\,\Lambda^{\overline{a}}{}_{1} \tag{9.90b}$$

$$0 = \delta^{0}_{1} = \Lambda^{0}{}_{\overline{\alpha}}\,\Lambda^{\overline{\alpha}}{}_{1} = \Lambda^{0}{}_{\overline{0}}\,\Lambda^{\overline{0}}{}_{1} \tag{9.90c}$$

$$0 = \delta^{1}_{2} = \Lambda^{1}{}_{\overline{\alpha}}\,\Lambda^{\overline{\alpha}}{}_{2} = \Lambda^{1}{}_{\overline{a}}\,\Lambda^{\overline{a}}{}_{2}. \tag{9.90d}$$

Consequently, the spatial components satisfy

$$\delta^{a}_{b} = \Lambda^{a}{}_{\overline{b}}\,\Lambda^{\overline{b}}{}_{b} \qquad \text{and} \qquad \delta^{\overline{a}}_{\overline{b}} = \Lambda^{\overline{a}}{}_{b}\,\Lambda^{b}{}_{\overline{b}}, \tag{9.91}$$

which allows for a splitting of the spatial components from the time component.

9.9.4 Transformation of space and time partial derivatives

Application of the chain rule leads to the transformation of the partial derivative operator

$$\partial_{\overline{\alpha}} = \frac{\partial}{\partial \xi^{\overline{\alpha}}} = \frac{\partial \xi^{\alpha}}{\partial \xi^{\overline{\alpha}}} \frac{\partial}{\partial \xi^{\alpha}} = \Lambda^{\alpha}_{\overline{\alpha}} \, \partial_{\alpha}. \tag{9.92}$$

Extracting the time and space components from the transformation matrix (9.81) yields

$$\partial_{\overline{0}} = \Lambda^{\alpha}_{\overline{0}} \, \partial_{\alpha} = \partial_0 + \Lambda^{a}_{\overline{0}} \, \partial_a \tag{9.93a}$$

$$\partial_{\overline{a}} = \Lambda^{\alpha}_{\overline{a}} \, \partial_{\alpha} = \Lambda^{a}_{\overline{a}} \, \partial_a. \tag{9.93b}$$

Notably, the time derivative operator in one coordinate system transforms into both space and time derivative operators in the new coordinate system. We expect this result since time derivative in one coordinate system is computed with its spatial coordinates held fixed, but these coordinates are generally moving with respect to the other coordinate system. In contrast, the spatial components to the partial derivative operator transform among just the other spatial components; there is no mixing with the time derivative operator. This property of the spatial derivative operator follows from the use of universal Newtonian time. It allows us to focus on space tensors in the following sections.

9.10 Covariant derivative of a scalar

We now return to a focus on space tensor analysis by considering the contraction of spatial components to the partial derivative operator with the basis of one-forms. This contraction renders the geometric expression of the gradient operator acting on a scalar

$$\text{grad}(\psi) = \nabla \psi = \widetilde{e}^{a} \, \partial_a \psi = \widetilde{e}^{\overline{a}} \, \partial_{\overline{a}} \psi. \tag{9.94}$$

From this expression we define the *covariant derivative operator*

$$\nabla = \widetilde{e}^{a} \, \partial_a \tag{9.95}$$

so that we refer to equation (9.94) as either the gradient acting on a scalar or the covariant derivative acting on a scalar.

9.11 Covariant derivative of a vector

The covariant derivative operator can act on a vector, in which case we consider $\nabla \vec{F}$. To perform calculations requires us to unpack the manifestly covariant expression $\nabla \vec{F}$ by introducing a coordinate representation

$$\nabla \vec{F} = (\widetilde{e}^{b} \, \partial_b) \, (F^{a} \, \vec{e}_a). \tag{9.96}$$

9.11.1 Derivative of a vector and Christoffel symbols

The chain rule leads to the expression for the partial derivative operator acting on a vector field

$$\begin{aligned}
\partial_b \vec{F} &= \partial_b(\vec{e}_a\, F^a) && \text{coordinate representation of the vector } \vec{F} && (9.97a)\\
&= (\partial_b\, F^a)\, \vec{e}_a + F^a\, \partial_b\, \vec{e}_a && \text{chain rule} && (9.97b)\\
&= (\partial_b\, F^a)\, \vec{e}_a + F^a\, \Gamma^c_{ba}\, \vec{e}_c && \text{define Christoffel symbols} && (9.97c)\\
&= (\partial_b\, F^a + F^c\, \Gamma^a_{bc})\, \vec{e}_a && \text{reorganize} && (9.97d)\\
&\equiv (\nabla_b F^a)\, \vec{e}_a && \text{define covariant derivative acting on vector component.} && (9.97e)
\end{aligned}$$

In the third equality we introduced the *Christoffel symbols*

$$\partial_b\, \vec{e}_a \equiv \Gamma^c_{ba}\, \vec{e}_c. \tag{9.98}$$

The Christoffel symbols carry information about the partial derivatives of the basis vectors. They vanish in Cartesian coordinates yet are generally nonzero. In the final equality we introduced components to the covariant derivative acting on the vector components

$$\nabla_b F^a \equiv \partial_b\, F^a + \Gamma^a_{bc}\, F^c. \tag{9.99}$$

Contracting $\partial_b \vec{F}$ with the basis one-form $\tilde{e}^b$ leads to the coordinate invariant expression for the covariant derivative of a vector field

$$\nabla \vec{F} = \tilde{e}^b\, (\partial_b\, \vec{F}) = (\tilde{e}^b\, \nabla_b\, F^a)\, \vec{e}_a. \tag{9.100}$$

9.11.2 An alternative derivation

A heuristic explanation of these ideas follows by applying the elementary calculus notions to a vector field $\vec{F}$ as represented by arbitrary coordinates ξ^a, in which case

$$\partial_b \vec{F} = \lim_{\Delta \to 0} \frac{\vec{F}(\vec{P} + \Delta\, \vec{e}_b) - \vec{F}(\vec{P})}{\Delta}, \tag{9.101}$$

where $\vec{P} = \vec{e}_a\, \xi^a$ is the position vector for an arbitrary point and $\vec{e}_b$ specifies the direction for computing the partial derivative. The basis vectors $\vec{e}_a$ are spatially independent for Cartesian coordinates, so that the derivative of a vector is computed merely by taking the derivative of each Cartesian component

$$\partial_b \vec{F} = (\partial_b F^a)\, \vec{e}_a \qquad \text{Cartesian coordinates.} \tag{9.102}$$

For general coordinates, however, both the vector components and the basis vectors are spatially dependent, in which case

$$\begin{aligned}
\vec{F}(\vec{P} + \Delta\, \vec{e}_b) - \vec{F}(\vec{P}) &= [F^a + \Delta\, \partial_b F^a]\, [\vec{e}_a + \Delta\, \partial_b\, \vec{e}_a] - F^a\, \vec{e}_a && (9.103a)\\
&= \Delta\, \partial_b (F^a\, \vec{e}_a) + \mathcal{O}(\Delta^2). && (9.103b)
\end{aligned}$$

This is the same result as found in the first step of the chain rule used in equation (9.97a). Following through that derivation then leads to the same coordinate expression for the covariant derivative acting on a vector field.

9.11.3 Christoffel symbols as the metric connection

Recall from elementary calculus that the derivative of a function is computed by comparing the function at two points in space, dividing by the distance between those points, and taking the limit as the points get infinitesimally close. This operation is well defined for scalar fields on arbitrary manifolds. However, it is problematic for vectors since the vectors live on distinct tangent spaces and so cannot be directly compared (see Section 8.4 for more on tangent spaces). For example, how do we compare two vectors at distinct points on a sphere? To do so we must provide a method to move one vector to the position of the other before comparing. As seen through the above discussion of covariant derivative of a vector, the Christoffel symbols provide the means to move vectors. Namely, they connect the two vectors by carrying information about how the basis vectors change in space. It is for this reason that some refer to the Christoffel symbols as the *metric connection*.

There is a distinct coordinate dependence of Christoffel symbols. For example, the Christoffel symbols all vanish in Euclidean space when using Cartesian coordinates whereas they are nonzero with other coordinates. As discussed in Section 8.1, a tensor that vanishes in one coordinate system remains zero for all coordinate systems. We thus conclude that the Christoffel symbols are *not* components to a tensor. Rather, they carry information regarding the partial derivatives of the coordinate basis vectors and as such they are fundamentally tied to a chosen coordinate system.

9.11.4 Transformation of the Christoffel symbols

We noted above that the Christoffel symbols do not transform as components to a tensor. We here derive just how the Christoffel symbols transform under coordinate transformations. For that purpose, note that the covariant derivative of a vector defines a tensor, so that its components must transform according to

$$\nabla_{\bar{b}} F^{\bar{a}} = \Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ a} \, \nabla_b F^a. \tag{9.104}$$

We expand the left hand side according to

$$\begin{aligned}
\nabla_{\bar{b}} F^{\bar{a}} &= \partial_{\bar{b}} \, F^{\bar{a}} + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, F^{\bar{c}} && (9.105a)\\
&= \partial_{\bar{b}} \, (\Lambda^{\bar{a}}_{\ a} \, F^a) + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, \Lambda^{\bar{c}}_{\ a} \, F^a && (9.105b)\\
&= (\partial_{\bar{b}} \, \Lambda^{\bar{a}}_{\ a} + \Lambda^{\bar{a}}_{\ a} \, \partial_{\bar{b}} + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, \Lambda^{\bar{c}}_{\ a}) \, F^a && (9.105c)\\
&= (\partial_{\bar{b}} \, \Lambda^{\bar{a}}_{\ a} + \Lambda^{\bar{a}}_{\ a} \, \Lambda^{b}_{\ \bar{b}} \, \partial_b + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, \Lambda^{\bar{c}}_{\ a}) \, F^a && (9.105d)
\end{aligned}$$

The expanded right hand side of equation (9.104) is given by

$$\Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ a} \, \nabla_b F^a = \Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ a} \, (\partial_b F^a + \Gamma^{a}_{bc} \, F^c). \tag{9.106}$$

Notice how the $\Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ a} \, \partial_b F^a$ term cancels from equation (9.105d), thus rendering

$$\partial_{\bar{b}} \, \Lambda^{\bar{a}}_{\ a} \, F^a + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, \Lambda^{\bar{c}}_{\ a} \, F^a = \Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ a} \, \Gamma^{a}_{bc} \, F^c \tag{9.107}$$

Relabeling the tensor indices on the right hand side term and rearranging leads to

$$(\partial_{\bar{b}} \, \Lambda^{\bar{a}}_{\ a} + \Gamma^{\bar{a}}_{\bar{b}\bar{c}} \, \Lambda^{\bar{c}}_{\ a} - \Lambda^{b}_{\ \bar{b}} \Lambda^{\bar{a}}_{\ d} \, \Gamma^{d}_{ba}) \, F^a = 0. \tag{9.108}$$

This equality holds for all vectors, so that we have the identity satisfied by the Christoffel symbols and the transformation matrix

$$\partial_{\overline{b}}\,\Lambda^{\overline{a}}{}_{a} + \Gamma^{\overline{a}}_{\overline{b}\overline{c}}\,\Lambda^{\overline{c}}{}_{a} = \Lambda^{b}{}_{\overline{b}}\,\Lambda^{\overline{a}}{}_{d}\,\Gamma^{d}_{ba}. \tag{9.109}$$

Finally, we can contract with $\Lambda^{a}{}_{\overline{d}}$ to render

$$\Gamma^{\overline{a}}_{\overline{b}\overline{d}} = \Lambda^{a}{}_{\overline{d}}\,\Lambda^{b}{}_{\overline{b}}\,\Lambda^{\overline{a}}{}_{d}\,\Gamma^{d}_{ba} - \Lambda^{a}{}_{\overline{d}}\,\partial_{\overline{b}}\,\Lambda^{\overline{a}}{}_{a}. \tag{9.110}$$

The presence of a nonzero term, $\Lambda^{a}{}_{\overline{d}}\,\partial_{\overline{b}}\,\Lambda^{\overline{a}}{}_{a}$, means that $\Gamma^{\overline{a}}_{\overline{b}\overline{d}}$ does not transform as components to a tensor.

9.12 Covariant derivative of a one-form

The product of a one-form and a vector is a scalar. As seen in Section 9.10, the covariant derivative of a scalar field is given by the gradient operator

$$\nabla(\widetilde{E}\cdot\vec{F}) = \widetilde{e}^{b}\,\partial_b\,(E_a\,F^a). \tag{9.111}$$

Expanding the partial derivative yields

$$\begin{aligned}
\partial_b(E_a\,F^a) &= F^a\,\partial_b E_a + E_a\,\partial_b F^a && (9.112a)\\
&= F^a\,\partial_b E_a + E_a\,(\nabla_b F^a - \Gamma^a_{bc}F^c) && (9.112b)\\
&= F^a(\partial_b E_a - \Gamma^c_{ba}E_c) + E_a\,\nabla_b F^a && (9.112c)\\
&\equiv F^a\,\nabla_b E_a + E_a\,\nabla_b F^a. && (9.112d)
\end{aligned}$$

The last equality defines the covariant derivative when acting on the components to a one form

$$\nabla_b E_a = \partial_b E_a - \Gamma^c_{ba}E_c, \tag{9.113}$$

which leads to the coordinate invariant expression for the covariant derivative of a one-form

$$\nabla\widetilde{E} = (\widetilde{e}^{b}\,\partial_b)\,\widetilde{E} = (\widetilde{e}^{b}\,\nabla_b E_a)\,\widetilde{e}^{a}. \tag{9.114}$$

9.13 Covariant derivative of the metric tensor

When written in Cartesian coordinates, the covariant derivative of components to the metric tensor for Euclidean space vanishes,

$$\nabla g_{ab} = \nabla\delta_{ab} = 0, \tag{9.115}$$

because the Cartesian representation of the metric is the unit tensor, δ_{ab}, in which case all Christoffel symbols vanish. Previous results establish the tensorial nature of the covariant derivative. Hence, $\nabla g_{ab} = 0$ is a valid result for *all* coordinates. This result is often called the *metricity* condition. It represents a self-consistency condition required for the manifolds considered in this book.

9.14 Christoffel symbols in terms of the metric tensor

We can develop an expression for the covariant derivative when acting on the components to a second order tensor. When applied to the metric tensor, its vanishing covariant derivative (equation (9.115)) then leads to the identity

$$0 = \nabla_c\, g_{ab} = \partial_c\, g_{ab} - \Gamma^d_{ca}\, g_{db} - \Gamma^d_{cb}\, g_{ad}. \tag{9.116}$$

We can solve this equation for the Christoffel symbols

$$\Gamma^c_{ab} = \frac{1}{2}\, g^{cd}\,(\partial_b\, g_{da} + \partial_a\, g_{db} - \partial_d\, g_{ab}). \tag{9.117}$$

This expression exhibits the symmetry property of the lower two indices on the Christoffel symbols

$$\Gamma^c_{ab} = \Gamma^c_{ba}. \tag{9.118}$$

9.15 Covariant divergence of a vector

The covariant divergence of the components to a vector results in a scalar

$$\nabla_a F^a = \partial_a F^a + \Gamma^a_{ab} F^b. \tag{9.119}$$

We now bring this expression into a form more convenient for practical calculations.

9.15.1 Contraction of the Christoffel symbols

Expression (9.117) for the Christoffel symbols yields the contraction

$$\Gamma^a_{ab} = \frac{1}{2}\, g^{ad}(\partial_b\, g_{da} + \partial_a\, g_{db} - \partial_d\, g_{ab}) = \frac{1}{2}\, g^{ad}\, \partial_b\, g_{ad} \tag{9.120}$$

where symmetry of the metric tensor and its inverse was used.

9.15.2 Exponential of the determinant

For the matrix representation of a symmetric positive definite tensor, such as the metric tensor, we can write

$$\det(A) = e^{\ln\det(A)} \qquad \text{identity} \tag{9.121a}$$

$$= e^{\ln(\Pi_i \Lambda_i)} \qquad \text{determinant related to product of eigenvalues} \tag{9.121b}$$

$$= e^{\Sigma_i \ln \Lambda_i} \qquad \text{identity} \tag{9.121c}$$

$$= e^{\mathrm{Tr}(\ln A)} \qquad \text{sum of eigenvalues related to trace of matrix.} \tag{9.121d}$$

Each of these identities is trivial to verify using a set of coordinates in which the matrix is diagonal. For any symmetric and positive definite matrix, such a set of coordinates always exists, in which case

$$\partial_c \ln\det(A) = \partial_c[\mathrm{Tr}(\ln A)] = \mathrm{Tr}(\partial_c \ln A) = \mathrm{Tr}(A^{-1}\partial_c A). \tag{9.122}$$

With A now set equal to the metric tensor $\mathfrak{g}$ with components g_{ab}, this result yields

$$\partial_c \ln\det(\mathfrak{g}) = g^{ab}\, \partial_c\, g_{ab} \tag{9.123}$$

which in turn yields for the contracted Christoffel symbol

$$\Gamma^a_{ac} = \partial_c \ln \sqrt{\det(\mathbb{g})}. \tag{9.124}$$

This result brings the covariant divergence of a vector to the form

$$\nabla_a F^a = \partial_a F^a + F^a \, \partial_a \ln \sqrt{\det(\mathbb{g})} = \frac{1}{\sqrt{\det(\mathbb{g})}} \, \partial_a \, [\sqrt{\det(\mathbb{g})} \, F^a]. \tag{9.125}$$

This is a very convenient result since it only requires partial derivatives in the chosen coordinate system, with all of the coordinate dependent properties summarized by $\sqrt{\det(\mathbb{g})}$.

9.16 Covariant Laplacian of a scalar

Making use of equation (9.125) with

$$F^a = g^{ab} \, \partial_b \psi \tag{9.126}$$

leads to the covariant Laplacian of a scalar field

$$\nabla_a \, (g^{ab} \, \partial_b \, \psi) = \frac{1}{\sqrt{\det(\mathbb{g})}} \, \partial_a \, [\sqrt{\det(\mathbb{g})} \, g^{ab} \, \partial_b \psi]. \tag{9.127}$$

This expression is fundamental to the evolution of scalar fields under the impacts from diffusion (Chapter 64).

9.17 Covariant curl of a vector

The Levi-Civita tensor

$$\varepsilon_{abc} = \sqrt{\det(\mathbb{g})} \, \epsilon_{abc} \tag{9.128}$$

from Section 9.7 is useful for generalizing the curl operation from Cartesian coordinates in Euclidean space to arbitrary coordinates on a curved manifold embedded in Euclidean space. Consequently, we define the curl according to the coordinate invariant expression

$$\mathrm{curl}(\vec{F}) = \vec{e}_a \, \varepsilon^{abc} \, (\nabla_b F_c) = \widetilde{e}^a \, \varepsilon_{abc} \, (\nabla^b F^c). \tag{9.129}$$

This expression simplifies by making use of equation (9.113) for the covariant derivative $\nabla_b \, F_c = \partial_b F_c - \Gamma^a_{cb} \, F_a$. Conveniently, the contraction $\varepsilon^{abc} \, \Gamma^a_{cb}$ vanishes identically since $\varepsilon^{abc} = -\varepsilon^{acb}$ whereas $\Gamma^a_{cb} = \Gamma^a_{bc}$. Hence, we are left with a general expression for the covariant curl that involves just the partial derivatives

$$\mathrm{curl}(\vec{F}) = \vec{e}_a \, \varepsilon^{abc} \, (\partial_b F_c) = \vec{e}_a \, \varepsilon^{abc} \, [\partial_b (g_{cd} F^d)]. \tag{9.130}$$

The second equality made use of the identity $F_c = g_{cd} F^d$.

9.18 Gauss's divergence theorem

The integral theorems from Cartesian vector analysis transform in a straightforward manner to arbitrary coordinates in arbitrary smooth and oriented spaces. An easy way to prove the theorems is to invoke the ideas of general coordinate invariance from Section 8.1, in which the integral theorems are written in a tensorially proper manner with partial derivatives changed to covariant

derivatives. The divergence theorem offers a particularly simple example. For this purpose, we make use of the volume element (9.61)

$$\mathrm{d}V = \sqrt{\det(\mathbb{g})}\,\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3, \tag{9.131}$$

multiplied by the covariant divergence (9.125). Hence, the volume integral of the divergence is given by

$$\int_{\mathcal{R}} (\nabla_a F^a)\,\mathrm{d}V = \int_{\mathcal{R}} \partial_a[\sqrt{\det(\mathbb{g})}\,F^a]\,\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3 = \oint_{\partial\mathcal{R}} F^a\,\hat{n}_a\,\mathrm{d}\mathcal{S}. \tag{9.132}$$

In this equation, $\hat{\boldsymbol{n}}$ is the outward normal one-form for the boundary, $\partial\mathcal{R}$, with $\mathrm{d}\mathcal{S}$ the invariant area element on the boundary, and $\hat{n}_a$ the covariant components of the outward normal.

9.19 Stokes' curl theorem

The Cartesian form of Stokes' Theorem from Section 2.6 is generalized in a manner similar to the divergence theorem

$$\oint_{\partial\mathcal{S}} \vec{F}\cdot\mathrm{d}\vec{x} = \int_{\mathcal{S}} \mathrm{curl}(\vec{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{9.133}$$

where $\mathrm{d}\vec{x}$ is the vector line element along the path and $\partial\mathcal{S}$ is the closed path defining the boundary to a simply connected two-dimensional surface $\mathcal{S}$. For the circulation on the left hand side we have

$$\vec{F}\cdot\mathrm{d}\vec{x} = F^a\,\vec{e}_a\cdot\vec{e}_b\,\mathrm{d}x^b = F_b\,\mathrm{d}x^b = F_{\bar{b}}\,\mathrm{d}\xi^{\bar{b}}. \tag{9.134}$$

For the curl on the right hand side we have

$$\mathrm{curl}(\vec{F})\cdot\hat{\boldsymbol{n}} = \varepsilon^{abc}\,(\partial_b F_c)\,\vec{e}_a\cdot\hat{\boldsymbol{n}} = \varepsilon^{abc}\,(\partial_b F_c)\,\hat{n}_a = \varepsilon^{\bar{a}\bar{b}\bar{c}}\,(\partial_{\bar{b}} F_{\bar{c}})\,\hat{n}_{\bar{a}}, \tag{9.135}$$

thus leading to the expression of Stokes' theorem in arbitrary coordinates

$$\oint_{\partial\mathcal{S}} F_{\bar{b}}\,\mathrm{d}\xi^{\bar{b}} = \int_{\mathcal{S}} \varepsilon^{\bar{a}\bar{b}\bar{c}}\,(\partial_{\bar{b}} F_{\bar{c}})\,\hat{n}_{\bar{a}}\,\mathrm{d}\mathcal{S}. \tag{9.136}$$

Chapter 10

Orthogonal coordinates

READER'S GUIDE TO THIS CHAPTER

In this chapter we provide a compendium of mathematical results for Cartesian, spherical, and cylindrical-polar coordinates. In so doing, we offer examples of the general tensor analysis machinery from Chapter 9, at least that arising from the use of curvilinear orthogonal coordinates. These coordinates are commonly used in geophysical fluid studies. They are time independent and locally orthogonal, and as such they are simpler than the non-orthogonal generalized vertical coordinates studied in Part XI of this book.

10.1 Cartesian coordinates

Whenever developing a general tensor relation it is useful to check its validity by considering Cartesian coordinates, in which case we can make use of familiar rules from vector calculus. We here summarize some results from our discussion of Cartesian tensors in Chapters 1 and 2.

10.1.1 The basics

We start by expressing the trajectory of a point through space in the following equivalent forms

$$\mathscr{P}(\tau) = \vec{e}_1\, x(\tau) + \vec{e}_2\, y(\tau) + \vec{e}_3\, z(\tau) \tag{10.1a}$$
$$= \hat{\boldsymbol{x}}\, x(\tau) + \hat{\boldsymbol{y}}\, y(\tau) + \hat{\boldsymbol{z}}\, z(\tau) \tag{10.1b}$$
$$= \vec{x}(\tau) \tag{10.1c}$$
$$= \boldsymbol{x}(\tau), \tag{10.1d}$$

with the basis vectors written

$$\vec{e}_1 = \hat{\boldsymbol{x}} \qquad \text{and} \qquad \vec{e}_2 = \hat{\boldsymbol{y}} \qquad \text{and} \qquad \vec{e}_3 = \hat{\boldsymbol{z}}. \tag{10.2}$$

The boldface notation is used for the position vector in the final equality of equation (10.1d), with the boldface commonly used throughout this book. Notably, the orthogonal unit vectors for Cartesian coordinates are normalized so that

$$\vec{e}_1 \cdot \vec{e}_1 = \vec{e}_2 \cdot \vec{e}_2 = \vec{e}_3 \cdot \vec{e}_3 = 1. \tag{10.3}$$

Furthermore, the basis vectors are identical to the basis one-forms

$$\vec{e}_1 = \widetilde{e}^1 = \hat{\boldsymbol{x}} \qquad \text{and} \qquad \vec{e}_2 = \widetilde{e}^2 = \hat{\boldsymbol{y}} \qquad \text{and} \qquad \vec{e}_3 = \widetilde{e}^3 = \hat{\boldsymbol{z}}, \tag{10.4}$$

in which we see there is no importance placed on whether a tensor index is up or down. Since the Cartesian basis vectors are independent of both space and time, we compute the coordinate representation of the velocity vector through taking the time derivative as

$$\vec{v}(\tau) = \boldsymbol{v}(\tau) = \frac{\mathrm{d}\mathscr{P}}{\mathrm{d}\tau} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\tau}, \tag{10.5}$$

which takes on the expanded expressions

$$\vec{v}(\tau) = \vec{e}_1\, \frac{\mathrm{d}x(\tau)}{\mathrm{d}\tau} + \vec{e}_2\, \frac{\mathrm{d}y(\tau)}{\mathrm{d}\tau} + \vec{e}_3\, \frac{\mathrm{d}z(\tau)}{\mathrm{d}\tau} \tag{10.6a}$$
$$= \hat{\boldsymbol{x}}\, v^1(\tau) + \hat{\boldsymbol{y}}\, v^2(\tau) + \hat{\boldsymbol{z}}\, v^3(\tau). \tag{10.6b}$$
$$= \hat{\boldsymbol{x}}\, u(\tau) + \hat{\boldsymbol{y}}\, v(\tau) + \hat{\boldsymbol{z}}\, w(\tau), \tag{10.6c}$$

where (u, v, w) is the notation commonly used in this book for the three velocity components.

10.1.2 Summary

In Cartesian coordinates, mathematical operators and integral theorems take their familiar form from vector calculus. We here list the key ones in forms that are encountered throughout this

book.

$$\boldsymbol{x} = (x^1, x^2, x^3) = (x, y, z) \qquad \text{Cartesian coordinates} \tag{10.7}$$

$$\boldsymbol{F} = \hat{\boldsymbol{x}} F^1 + \hat{\boldsymbol{y}} F^2 + \hat{\boldsymbol{z}} F^3 = \hat{\boldsymbol{x}} F_1 + \hat{\boldsymbol{y}} F_2 + \hat{\boldsymbol{z}} F_3 \qquad \text{covariant} = \text{contravariant} \tag{10.8}$$

$$\frac{\partial}{\partial x^a} = \partial_a \ \text{ or } \ (\partial_x, \partial_y, \partial_z) \qquad \text{partial derivative operator} \tag{10.9}$$

$$\nabla = \hat{\boldsymbol{x}}\, \partial_x + \hat{\boldsymbol{y}}\, \partial_y + \hat{\boldsymbol{z}}\, \partial_z \qquad \text{gradient} = \text{covariant derivative} \tag{10.10}$$

$$\nabla_z = \hat{\boldsymbol{x}}\, \partial_x + \hat{\boldsymbol{y}}\, \partial_y \qquad \text{horizontal gradient operator} \tag{10.11}$$

$$\nabla \cdot \boldsymbol{F} = \partial_x F_x + \partial_y F_y + \partial_z F_z \qquad \text{divergence of a vector} \tag{10.12}$$

$$\nabla_z \cdot \boldsymbol{F} = \partial_x F_x + \partial_y F_y \qquad \text{horizontal divergence of a vector} \tag{10.13}$$

$$(\nabla \times \boldsymbol{F})_a = \epsilon_{abc}\, \partial_b F_c \qquad \text{components to the curl} \tag{10.14}$$

$$\nabla \cdot \nabla \psi = \nabla^2 \psi = (\partial_{xx} + \partial_{yy} + \partial_{zz})\, \psi \qquad \text{Laplacian of a scalar} \tag{10.15}$$

$$\int_{\mathcal{R}} \nabla \cdot \boldsymbol{F}\, \mathrm{d}V = \oint_{\partial \mathcal{R}} \boldsymbol{F} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{Gauss's divergence theorem} \tag{10.16}$$

$$\oint_{\partial \mathcal{S}} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} (\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \qquad \text{Stokes' curl theorem.} \tag{10.17}$$

10.2 Spherical coordinates

We now consider spherical coordinates defined by Figure 10.1 and related to Cartesian coordinates through the transformation

$$x = r \cos\phi\, \cos\lambda \tag{10.18a}$$

$$y = r \cos\phi\, \sin\lambda \tag{10.18b}$$

$$z = r \sin\phi. \tag{10.18c}$$

The radial coordinate

$$r = |\boldsymbol{x}| = \sqrt{\boldsymbol{x} \cdot \boldsymbol{x}} = \sqrt{x^2 + y^2 + z^2} \tag{10.19}$$

measures the distance from the center of the sphere to the position of the point. The spherical angle coordinates

$$0 \le \lambda \le 2\pi \qquad \text{longitude} \tag{10.20}$$

$$-\pi/2 \le \phi \le \pi/2 \qquad \text{latitude} \tag{10.21}$$

specify the longitude, measuring the radians of the position east of the prime meridian, and latitude, measuring the radians north ($\phi > 0$) or south ($\phi < 0$) from the equator. To streamline notation in the following, we introduce the unbarred and barred labels for the Cartesian and spherical coordinates, respectively

$$(x, y, z) = (\xi^1, \xi^2, \xi^3) \equiv \xi^a \qquad \text{and} \qquad (\lambda, \phi, r) = (\xi^{\bar{1}}, \xi^{\bar{2}}, \xi^{\bar{3}}) \equiv \xi^{\bar{a}}. \tag{10.22}$$

10.2.1 Cartesian and spherical transformation

Following the general discussion in Section 9.1.4, we consider the infinitesimal distance along one of the Cartesian coordinate axes, $\mathrm{d}\xi^a$. The chain rule allows us to relate this distance to those

FIGURE 10.1: Geometry and notation for motion around a rotating sphere. For geophysical applications, the sphere rotates counter-clockwise when looking down from the north polar axis and it has an angular speed Ω. The planetary Cartesian triad of orthonormal basis vectors, $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$ points along the orthogonal axes and rotates with the sphere. The planetary spherical triad (also rotating with the sphere) of orthonormal basis vectors, $(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{r}})$, makes use of the longitudinal unit vector $\hat{\boldsymbol{\lambda}}$, which points in the longitudinal direction (positive eastward), the latitudinal unit vector $\hat{\boldsymbol{\phi}}$, which points in the latitudinal direction (positive northward) and the radial unit vector $\hat{\boldsymbol{r}}$, which point in the radial direction (positive away from the center).

along the axes of the spherical coordinate system

$$\mathrm{d}\xi^a = \frac{\partial \xi^a}{\partial \xi^{\overline{a}}}\,\mathrm{d}\xi^{\overline{a}} = \Lambda^a_{\ \overline{a}}\,\mathrm{d}\xi^{\overline{a}}. \tag{10.23}$$

The partial derivatives $\partial\xi^a/\partial\xi^{\overline{a}}$ form components to the transformation matrix that transforms between coordinate representations. For the coordinate transformation (10.18a)-(10.18c), the transformation matrix is given by

$$\Lambda^a_{\ \overline{a}} = \begin{bmatrix} \partial\xi^1/\partial\xi^{\overline{1}} & \partial\xi^1/\partial\xi^{\overline{2}} & \partial\xi^1/\partial\xi^{\overline{3}} \\ \partial\xi^2/\partial\xi^{\overline{1}} & \partial\xi^2/\partial\xi^{\overline{2}} & \partial\xi^2/\partial\xi^{\overline{3}} \\ \partial\xi^3/\partial\xi^{\overline{1}} & \partial\xi^3/\partial\xi^{\overline{2}} & \partial\xi^3/\partial\xi^{\overline{3}} \end{bmatrix} = \begin{bmatrix} -r\cos\phi\sin\lambda & -r\sin\phi\,\cos\lambda & \cos\phi\cos\lambda \\ r\cos\phi\cos\lambda & -r\sin\phi\,\sin\lambda & \cos\phi\sin\lambda \\ 0 & r\cos\phi & \sin\phi \end{bmatrix}. \tag{10.24}$$

The determinant of the transformation (Jacobian) is given by

$$\det(\Lambda^a_{\ \overline{a}}) = r^2\cos\phi. \tag{10.25}$$

The Jacobian vanishes at the north and south poles ($\phi = \pm\pi/2$), where the transformation is singular. Methods familiar from linear algebra render the inverse transformation matrix

$$\Lambda^{\overline{a}}_{\ a} = \frac{1}{r^2\cos\phi}\begin{bmatrix} -r\sin\lambda & r\cos\lambda & 0 \\ -r\cos\phi\,\sin\phi\,\cos\lambda & -r\cos\phi\sin\phi\sin\lambda & r\cos^2\phi \\ r^2\cos^2\phi\cos\lambda & r^2\,\cos^2\phi\sin\lambda & r^2\cos\phi\sin\phi \end{bmatrix}. \tag{10.26}$$

10.2.2 Basis vectors

The spherical coordinate basis vectors, $\vec{e}_{\overline{a}}$, are related to the Cartesian coordinate basis vectors, $\vec{e}_a$, through the transformation

$$\vec{e}_{\overline{a}} = \Lambda^a_{\overline{a}}\, \vec{e}_a. \tag{10.27}$$

The transformation matrix (10.24) leads to

$$\vec{e}_\lambda = r\cos\phi\,(-\hat{\boldsymbol{x}}\sin\lambda + \hat{\boldsymbol{y}}\cos\lambda) \tag{10.28a}$$
$$\vec{e}_\phi = r(-\hat{\boldsymbol{x}}\sin\phi\,\cos\lambda - \hat{\boldsymbol{y}}\sin\phi\,\sin\lambda + \hat{\boldsymbol{z}}\cos\phi) \tag{10.28b}$$
$$\vec{e}_r = \hat{\boldsymbol{x}}\cos\phi\,\cos\lambda + \hat{\boldsymbol{y}}\cos\phi\,\sin\lambda + \hat{\boldsymbol{z}}\sin\phi. \tag{10.28c}$$

We can introduce the orthonormal unit vectors $(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{r}})$ through

$$\vec{e}_\lambda = r\cos\phi\,\hat{\boldsymbol{\lambda}} \qquad \text{and} \qquad \vec{e}_\phi = r\,\hat{\boldsymbol{\phi}} \qquad \text{and} \qquad \vec{e}_r = \hat{\boldsymbol{r}}, \tag{10.29}$$

so that

$$\hat{\boldsymbol{\lambda}} = -\hat{\boldsymbol{x}}\sin\lambda + \hat{\boldsymbol{y}}\cos\lambda \tag{10.30a}$$
$$\hat{\boldsymbol{\phi}} = -\hat{\boldsymbol{x}}\cos\lambda\,\sin\phi - \hat{\boldsymbol{y}}\sin\lambda\,\sin\phi + \hat{\boldsymbol{z}}\cos\phi \tag{10.30b}$$
$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}}\,\cos\lambda\,\cos\phi + \hat{\boldsymbol{y}}\sin\lambda\,\cos\phi + \hat{\boldsymbol{z}}\sin\phi \tag{10.30c}$$

along with the inverse relations

$$\hat{\boldsymbol{x}} = -\hat{\boldsymbol{\lambda}}\sin\lambda - \hat{\boldsymbol{\phi}}\cos\lambda\sin\phi + \hat{\boldsymbol{r}}\,\cos\lambda\,\cos\phi \tag{10.31a}$$
$$\hat{\boldsymbol{y}} = \hat{\boldsymbol{\lambda}}\cos\lambda - \hat{\boldsymbol{\phi}}\,\sin\lambda\,\sin\phi + \hat{\boldsymbol{r}}\sin\lambda\,\cos\phi \tag{10.31b}$$
$$\hat{\boldsymbol{z}} = \hat{\boldsymbol{\phi}}\,\cos\phi + \hat{\boldsymbol{r}}\,\sin\phi. \tag{10.31c}$$

10.2.3 Basis one-forms

Since spherical coordinates are locally orthogonal, we can readily derive the one-form basis through inverting the vector basis

$$\widetilde{e}^\lambda = (r\cos\phi)^{-1}\,\hat{\boldsymbol{\lambda}} \qquad \text{and} \qquad \widetilde{e}^\phi = r^{-1}\hat{\boldsymbol{\phi}} \qquad \text{and} \qquad \widetilde{e}^r = \hat{\boldsymbol{r}}, \tag{10.32}$$

which satisfy the bi-orthogonality relation with the basis vectors (Section 9.2.2)

$$\widetilde{e}^{\overline{b}} \cdot \vec{e}_{\overline{a}} = \delta^{\overline{b}}_{\overline{a}}. \tag{10.33}$$

10.2.4 Position and velocity

In spherical coordinates, the position of a point is fully specified by the radial position

$$\mathscr{P}(\tau) = r\,\vec{e}_r = r\,\hat{\boldsymbol{r}}. \tag{10.34}$$

However, the velocity requires all three spherical coordinates since the radial basis vector is a function of the angular positions, which are functions of time. Use of the chain rule renders

$$\vec{v}(\tau) = \boldsymbol{v} \tag{10.35a}$$
$$= \frac{\mathrm{d}\mathcal{P}}{\mathrm{d}\tau} \tag{10.35b}$$
$$= \vec{e}_r \frac{\mathrm{d}r}{\mathrm{d}\tau} + r \frac{\mathrm{d}\vec{e}_r}{\mathrm{d}\tau} \tag{10.35c}$$
$$= \vec{e}_r \frac{\mathrm{d}r}{\mathrm{d}\tau} + r \frac{\partial \vec{e}_r}{\partial \lambda} \frac{\mathrm{d}\lambda}{\mathrm{d}\tau} + r \frac{\partial \vec{e}_r}{\partial \phi} \frac{\mathrm{d}\phi}{\mathrm{d}\tau} \tag{10.35d}$$
$$\equiv \vec{e}_r \frac{\mathrm{d}r}{\mathrm{d}\tau} + \vec{e}_\lambda \frac{\mathrm{d}\lambda}{\mathrm{d}\tau} + \vec{e}_\phi \frac{\mathrm{d}\phi}{\mathrm{d}\tau} \tag{10.35e}$$
$$= \vec{e}_r\, v^r + \vec{e}_\lambda\, v^\lambda + \vec{e}_\phi\, v^\phi. \tag{10.35f}$$

To reach this result we made use of the identities satisfied by the spherical basis vectors

$$\vec{e}_\lambda = r \frac{\partial \vec{e}_r}{\partial \lambda} \qquad \text{and} \qquad \vec{e}_\phi = r \frac{\partial \vec{e}_r}{\partial \phi}, \tag{10.36}$$

which can be readily verified by equations (10.28a)-(10.28c).

10.2.5 Metric tensor

Since spherical coordinates are orthogonal, the metric tensor is diagonal and it is given by

$$g_{\overline{a}\overline{b}} = \vec{e}_{\overline{a}} \cdot \vec{e}_{\overline{b}} = \begin{bmatrix} (r\cos\phi)^2 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{10.37}$$

along with the inverse metric tensor

$$g^{\overline{a}\overline{b}} = \widetilde{e}^{\overline{a}} \cdot \widetilde{e}^{\overline{b}} = \begin{bmatrix} (r\cos\phi)^{-2} & 0 & 0 \\ 0 & r^{-2} & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{10.38}$$

Volume element and Levi-Civita tensor

The square root of the determinant of the metric tensor written in spherical coordinates (from equation (10.37)) is given by

$$\sqrt{\det(\overline{\mathcal{G}})} = r^2 \cos\phi \tag{10.39}$$

so that the volume element is

$$\mathrm{d}V = r^2 \cos\phi\, \mathrm{d}r\, \mathrm{d}\lambda\, \mathrm{d}\phi. \tag{10.40}$$

The covariant Levi-Civita tensor has the spherical representation

$$\varepsilon_{\overline{a}\overline{b}\overline{c}} = (r^2 \cos\phi)\, \epsilon_{\overline{a}\overline{b}\overline{c}}, \tag{10.41}$$

where $\epsilon_{\overline{a}\overline{b}\overline{c}}$ are components to the permutation symbol (i.e., the Cartesian components to the Levi-Civita tensor) from Section 1.4.1.

Vector cross product of basis vectors

As a check on the formalism for cross products, let us verify the relation (9.79) for the vector cross product of two basis vectors using spherical coordinates

$$\vec{e}_{\overline{a}} \times \vec{e}_{\overline{b}} = \varepsilon_{\overline{a}\overline{b}\overline{c}}\, \widetilde{e}^{\overline{c}} \Longrightarrow \vec{e}_{\overline{a}} \times \vec{e}_{\overline{b}} = (r^2 \cos\phi)\epsilon_{\overline{a}\overline{b}\overline{c}}\, \widetilde{e}^{\overline{c}}. \tag{10.42}$$

Making use of the spherical coordinate basis vectors and one-forms renders

$$\vec{e}_r \times \vec{e}_\lambda = (r\cos\phi)\,(\hat{\boldsymbol{r}} \times \hat{\boldsymbol{\lambda}}) = (r\cos\phi)\,\hat{\boldsymbol{\phi}} = (r^2\cos\phi)\,\widetilde{e}^{\phi} = \varepsilon_{r\lambda\phi}\,\widetilde{e}^{\phi} \tag{10.43a}$$

$$\vec{e}_\lambda \times \vec{e}_\phi = (r^2\cos\phi)\,(\hat{\boldsymbol{\lambda}} \times \hat{\boldsymbol{\phi}}) = (r^2\cos\phi)\,\hat{\boldsymbol{r}} = (r^2\cos\phi)\,\widetilde{e}^{r} = \varepsilon_{\lambda\phi r}\,\widetilde{e}^{r} \tag{10.43b}$$

$$\vec{e}_\phi \times \vec{e}_r = r\,(\hat{\boldsymbol{\phi}} \times \hat{\boldsymbol{r}}) = r\,\hat{\boldsymbol{\lambda}} = (r^2\cos\phi)\,\widetilde{e}^{\lambda} = \varepsilon_{\phi r\lambda}\,\widetilde{e}^{\lambda}. \tag{10.43c}$$

To reach these results we made use of the cross products for the spherical coordinate unit vectors

$$\hat{\boldsymbol{r}} \times \hat{\boldsymbol{\lambda}} = \hat{\boldsymbol{\phi}} \qquad \text{and} \qquad \hat{\boldsymbol{\lambda}} \times \hat{\boldsymbol{\phi}} = \hat{\boldsymbol{r}} \qquad \text{and} \qquad \hat{\boldsymbol{\phi}} \times \hat{\boldsymbol{r}} = \hat{\boldsymbol{\lambda}}. \tag{10.44}$$

10.2.6 Components of a vector field

A vector field $\vec{F}$ has Cartesian components, F^a, related to spherical components, $F^{\overline{a}}$, via the transformation matrix, $F^{\overline{a}} = \Lambda^{\overline{a}}_{\ a}\, F^a$. This transformation leads to

$$F^{\overline{1}} = (r\cos\phi)^{-1}\,[-F^x \sin\lambda + F^y \cos\lambda] \tag{10.45a}$$

$$F^{\overline{2}} = r^{-1}\,[-F^x \sin\phi\cos\lambda - F^y \sin\phi\sin\lambda + F^z\cos\phi] \tag{10.45b}$$

$$F^{\overline{3}} = F^x \cos\phi\cos\lambda + F^y\cos\phi\sin\lambda + F^z\sin\phi. \tag{10.45c}$$

Making use of the spherical unit vector (10.30a)-(10.30c) leads to the more tidy relations

$$(r\cos\phi)\,F^{\overline{1}} = \hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F} \tag{10.46a}$$

$$r\,F^{\overline{2}} = \hat{\boldsymbol{\phi}}\cdot\boldsymbol{F} \tag{10.46b}$$

$$F^{\overline{3}} = \hat{\boldsymbol{r}}\cdot\boldsymbol{F}, \tag{10.46c}$$

where $\boldsymbol{F}$ is the Cartesian representation.

10.2.7 Differential operators

In spherical coordinates the gradient operator $\nabla = \widetilde{e}^a \partial_a$ takes on the form

$$\nabla = \hat{\boldsymbol{\lambda}}\,(r\,\cos\phi)^{-1}\,\partial_\lambda + \hat{\boldsymbol{\phi}}\,r^{-1}\,\partial_\phi + \hat{\boldsymbol{r}}\,\partial_r \tag{10.47}$$

and the covariant divergence of a vector field is given by

$$\nabla_{\overline{a}} F^{\overline{a}} = (r^2\cos\phi)^{-1}\partial_{\overline{a}}[r^2\cos\phi\, F^{\overline{a}}] \tag{10.48a}$$

$$= (r^2\cos\phi)^{-1}\left(\partial_\lambda[r^2\cos\phi\, F^{\overline{1}}] + \partial_\phi[r^2\cos\phi\, F^{\overline{2}}] + \partial_r[r^2\cos\phi\, F^{\overline{3}}]\right) \tag{10.48b}$$

$$= \frac{1}{r\cos\phi}\,\frac{\partial(\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F})}{\partial\lambda} + \frac{1}{r\cos\phi}\,\frac{\partial\,(\hat{\boldsymbol{\phi}}\cdot\boldsymbol{F}\,\cos\phi)}{\partial\phi} + \frac{1}{r^2}\,\frac{\partial\,(\hat{\boldsymbol{r}}\cdot\boldsymbol{F}\,r^2)}{\partial r}. \tag{10.48c}$$

The covariant Laplacian of a scalar, $\nabla^2\psi = \nabla\cdot\nabla\psi$, is given by

$$\nabla^2\psi = \nabla\cdot\left[\hat{\boldsymbol{\lambda}}\,(r\cos\phi)^{-1}\,\partial_\lambda\psi + \hat{\boldsymbol{\phi}}\,r^{-1}\,\partial_\phi\psi + \hat{\boldsymbol{r}}\,\partial_r\psi\right] \tag{10.49a}$$

$$= \frac{1}{(r\cos\phi)^2}\,\frac{\partial^2\psi}{\partial\lambda^2} + \frac{1}{r^2\cos\phi}\,\frac{\partial}{\partial\phi}\left[\cos\phi\,\frac{\partial\psi}{\partial\phi}\right] + \frac{1}{r^2}\,\frac{\partial}{\partial r}\left[r^2\,\frac{\partial\psi}{\partial r}\right]. \tag{10.49b}$$

The covariant curl (Section 9.17) takes the form

$$(\mathrm{curl}\vec{F})^{\overline{1}} = (r^2\cos\phi)^{-1}\,[\partial_\phi\,F^{\overline{3}} - \partial_r\,(r^2\,F^{\overline{2}})] \tag{10.50a}$$

$$(\mathrm{curl}\vec{F})^{\overline{2}} = (r^2\cos\phi)^{-1}\,[\partial_r\,(r^2\cos^2\phi\,F^{\overline{1}}) - \partial_\lambda\,F^{\overline{3}}] \tag{10.50b}$$

$$(\mathrm{curl}\vec{F})^{\overline{3}} = (r^2\cos\phi)^{-1}\,[\partial_\lambda\,(r^2\,F^{\overline{2}}) - \partial_\phi\,(r^2\cos^2\phi\,F^{\overline{1}})], \tag{10.50c}$$

which can be written in the more conventional form (e.g., equation (2.33) of *Vallis* (2017))

$$r\cos\phi\,(\mathrm{curl}\vec{F})^{\overline{1}} = \frac{1}{r}\left[\frac{\partial(\hat{\boldsymbol{r}}\cdot\boldsymbol{F})}{\partial\phi} - \frac{\partial(r\,\hat{\boldsymbol{\phi}}\cdot\boldsymbol{F})}{\partial r}\right] \tag{10.51a}$$

$$r\,(\mathrm{curl}\vec{F})^{\overline{2}} = \frac{1}{r}\left[\frac{\partial(r\,\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F})}{\partial r} - \frac{1}{\cos\phi}\,\frac{\partial(\hat{\boldsymbol{r}}\cdot\boldsymbol{F})}{\partial\lambda}\right] \tag{10.51b}$$

$$(\mathrm{curl}\vec{F})^{\overline{3}} = \frac{1}{r\cos\phi}\left[\frac{\partial(\hat{\boldsymbol{\phi}}\cdot\boldsymbol{F})}{\partial\lambda} - \frac{\partial(\cos\phi\,\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F})}{\partial\phi}\right]. \tag{10.51c}$$

10.2.8 Summary

We here summarize the spherical coordinate version of some common mathematical operators.

$$(\lambda,\phi,r) = (x^{\overline{1}},x^{\overline{2}},x^{\overline{3}}) \qquad \text{spherical coordinates} \tag{10.52}$$

$$(r\cos\phi)\,F^{\overline{1}} = \hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F} \qquad r\,F^{\overline{2}} = \hat{\boldsymbol{\phi}}\cdot\boldsymbol{F} \qquad F^{\overline{3}} = \hat{\boldsymbol{r}}\cdot\boldsymbol{F} \qquad \text{vector components} \tag{10.53}$$

$$\nabla = \hat{\boldsymbol{\lambda}}\,(r\,\cos\phi)^{-1}\,\partial_\lambda + \hat{\boldsymbol{\phi}}\,r^{-1}\,\partial_\phi + \hat{\boldsymbol{r}}\,\partial_r \qquad \text{gradient operator} \tag{10.54}$$

$$\nabla_{\overline{a}}F^{\overline{a}} = \frac{1}{r\cos\phi}\,\frac{\partial(\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{F})}{\partial\lambda} + \frac{1}{r\cos\phi}\,\frac{\partial\,(\hat{\boldsymbol{\phi}}\cdot\boldsymbol{F}\,\cos\phi)}{\partial\phi} + \frac{1}{r^2}\,\frac{\partial\,(\hat{\boldsymbol{r}}\cdot\boldsymbol{F}\,r^2)}{\partial r} \qquad \text{divergence of vector} \tag{10.55}$$

$$\nabla^2\psi = \frac{1}{(r\cos\phi)^2}\,\frac{\partial^2\psi}{\partial\lambda^2} + \frac{1}{r^2\cos\phi}\,\frac{\partial}{\partial\phi}\left[\cos\phi\,\frac{\partial\psi}{\partial\phi}\right] + \frac{1}{r^2}\,\frac{\partial}{\partial r}\left[r^2\,\frac{\partial\psi}{\partial r}\right] \qquad \text{Laplacian of scalar} \tag{10.56}$$

$$(\nabla\times\boldsymbol{F})_{\overline{a}} = \varepsilon_{\overline{a}\overline{b}\overline{c}}\partial_{\overline{b}}F^{\overline{c}} \qquad \text{see equations (10.51a) – (10.51c)} \qquad \text{curl of vector.} \tag{10.57}$$

10.3 Cylindrical-polar coordinates

Many physical systems exhibit circular symmetry in two-dimensions or cylindrical symmetry in three-dimensions. The primary example encountered in this book is the laboratory motion of liquid in a rotating circular tank. In the following, we emulate the discussion presented for the spherical coordinates in Section 10.2, here focusing on cylindrical-polar coordinates as shown in Figure 10.2. Our task here is somewhat simpler than for the spherical coordinates since the vertical/axial position, z, remains unchanged from its Cartesian value. In a slight corruption of notation, we use the symbol r for the radial distance from the vertical axis in cylindrical-polar coordinates (Figure 10.2), which is distinct from the radial distance, r, used to measure the distance from the origin in spherical coordinates (Figure 10.1).

The coordinate transformation between Cartesian coordinates and cylindrical-polar coordi-

FIGURE 10.2: This schematic illustrates the geometry and notation for cylindrical-polar coordinates. The Cartesian triad of orthonormal basis vectors, $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$ points along the orthogonal axes. The cylindrical-polar triad of orthonormal basis vectors, $(\hat{\boldsymbol{r}}, \hat{\boldsymbol{\vartheta}}, \hat{\boldsymbol{z}})$, makes use of the radial unit vector $\hat{\boldsymbol{r}}$, which points outward from the vertical axis, the angular unit vector $\hat{\boldsymbol{\vartheta}}$, which points in the counter-clockwise direction around the circle, and the vertical unit vector $\hat{\boldsymbol{z}}$. Note that the radial unit vector used for cylindrical-polar coordinates is distinct from that radial vector used in spherical coordinates shown in Figure 10.1.

nates is given by

$$x = r\cos\vartheta \equiv \xi^{\bar{1}}\cos\xi^{\bar{2}} \tag{10.58a}$$

$$y = r\sin\vartheta \equiv \xi^{\bar{1}}\sin\xi^{\bar{2}} \tag{10.58b}$$

$$z = \xi^{\bar{3}}. \tag{10.58c}$$

The radial coordinate for cylindrical-polar coordinates

$$r = \sqrt{x^2 + y^2} \tag{10.59}$$

measures the distance from the vertical z-axis, and the angular coordinate $0 \leq \vartheta \leq 2\pi$ measures the angle counter-clockwise from the positive x-axis. We introduce the unbarred and barred labels for the Cartesian and cylindrical polar coordinates

$$(x, y, z) = (\xi^1, \xi^2, \xi^3) \equiv \xi^a \qquad \text{and} \qquad (r, \vartheta, z) = (\xi^{\bar{1}}, \xi^{\bar{2}}, \xi^{\bar{3}}) \equiv \xi^{\bar{a}}. \tag{10.60}$$

Although the vertical position z remains the same in both coordinates, and it is orthogonal to the other coordinates, we find it useful to introduce a distinct symbols, ξ^3 and $\xi^{\bar{3}}$, to specify what other coordinates are held fixed when performing derivative operations.

10.3.1 Cartesian and cylindrical-polar transformation

The coordinate transformation (10.58a)-(10.58c) leads to the transformation matrix

$$\Lambda^{a}_{\overline{a}} = \begin{bmatrix} \partial\xi^1/\partial\xi^{\overline{1}} & \partial\xi^1/\partial\xi^{\overline{2}} & \partial\xi^1/\partial\xi^{\overline{3}} \\ \partial\xi^2/\partial\xi^{\overline{1}} & \partial\xi^2/\partial\xi^{\overline{2}} & \partial\xi^2/\partial\xi^{\overline{3}} \\ \partial\xi^3/\partial\xi^{\overline{1}} & \partial\xi^3/\partial\xi^{\overline{2}} & \partial\xi^3/\partial\xi^{\overline{3}} \end{bmatrix} = \begin{bmatrix} \cos\vartheta & -r\sin\vartheta & 0 \\ \sin\vartheta & r\cos\vartheta & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{10.61}$$

and the inverse transformation is given by

$$\Lambda^{\overline{a}}_{a} = \frac{1}{r}\begin{bmatrix} r\cos\vartheta & r\sin\vartheta & 0 \\ -\sin\vartheta & \cos\vartheta & 0 \\ 0 & 0 & r \end{bmatrix}. \tag{10.62}$$

The determinant of the transformation (Jacobian) is given by

$$\det(\Lambda^{a}_{\overline{a}}) = r, \tag{10.63}$$

which vanishes along the vertical axis, which is where the transformation is singular.

10.3.2 Basis vectors

The cylindrical-polar coordinate basis vectors, $\vec{e}_{\overline{a}}$, are related to the Cartesian coordinate basis vectors, $\vec{e}_a$, through the transformation $\vec{e}_{\overline{a}} = \Lambda^{a}_{\overline{a}}\,\vec{e}_a$. The transformation matrix (10.61) leads to

$$\vec{e}_r = \hat{\boldsymbol{x}}\cos\vartheta + \hat{\boldsymbol{y}}\sin\vartheta \tag{10.64a}$$
$$\vec{e}_\vartheta = r\left(-\hat{\boldsymbol{x}}\sin\vartheta + \hat{\boldsymbol{y}}\cos\vartheta\right) \tag{10.64b}$$
$$\vec{e}_{\overline{z}} = \hat{\boldsymbol{z}}. \tag{10.64c}$$

We sometimes make use of the following orthonormal unit vectors $(\hat{\boldsymbol{r}}, \hat{\boldsymbol{\vartheta}}, \hat{\boldsymbol{z}})$

$$\vec{e}_r = \hat{\boldsymbol{r}} \qquad \text{and} \qquad \vec{e}_\vartheta = r\,\hat{\boldsymbol{\vartheta}} \qquad \text{and} \qquad \vec{e}_{\overline{z}} = \hat{\boldsymbol{z}} \tag{10.65}$$

along with the inverse relations

$$\hat{\boldsymbol{x}} = \hat{\boldsymbol{r}}\cos\vartheta - \hat{\boldsymbol{\vartheta}}\sin\vartheta \tag{10.66a}$$
$$\hat{\boldsymbol{y}} = \hat{\boldsymbol{r}}\sin\vartheta + \hat{\boldsymbol{\vartheta}}\cos\vartheta \tag{10.66b}$$
$$\hat{\boldsymbol{z}} = \hat{\boldsymbol{z}}. \tag{10.66c}$$

10.3.3 Basis one-forms

Since cylindrical-polar coordinates are orthogonal, we can readily derive the one-form basis through inverting the vector basis

$$\widetilde{e}^r = \hat{\boldsymbol{r}} \qquad \text{and} \qquad \widetilde{e}^\vartheta = r^{-1}\hat{\boldsymbol{\vartheta}} \qquad \text{and} \qquad \widetilde{e}^{\overline{z}} = \hat{\boldsymbol{z}}, \tag{10.67}$$

which satisfy the orthogonality relation (Section 9.2.2)

$$\widetilde{e}^{\overline{b}} \cdot \vec{e}_{\overline{a}} = \delta^{\overline{b}}_{\overline{a}}. \tag{10.68}$$

10.3.4 Position and velocity

In cylindrical-polar coordinates, the position of a point is specified by the radial position plus the vertical position

$$\mathscr{P}(\tau) = r\,\vec{e}_r + z\,\vec{e}_{\overline{z}}. \tag{10.69}$$

The velocity requires all three coordinates since the radial basis vector is a function of the angular positions, which are in turn functions of time. Use of the chain rule renders

$$\begin{aligned}
\vec{v}(\tau) &= \frac{\mathrm{d}\mathscr{P}}{\mathrm{d}\tau} && (10.70a)\\
&= \vec{e}_r\,\frac{\mathrm{d}r}{\mathrm{d}\tau} + r\,\frac{\mathrm{d}\vec{e}_r}{\mathrm{d}\tau} + \vec{e}_{\overline{z}}\,\frac{\mathrm{d}z}{\mathrm{d}\tau} && (10.70b)\\
&= \vec{e}_r\,\frac{\mathrm{d}r}{\mathrm{d}\tau} + r\,\frac{\partial\vec{e}_r}{\partial\vartheta}\,\frac{\mathrm{d}\vartheta}{\mathrm{d}\tau} + \vec{e}_{\overline{z}}\,\frac{\mathrm{d}z}{\mathrm{d}\tau} && (10.70c)\\
&= \vec{e}_r\,\frac{\mathrm{d}r}{\mathrm{d}\tau} + \vec{e}_\vartheta\,\frac{\mathrm{d}\vartheta}{\mathrm{d}\tau} + \vec{e}_{\overline{z}}\,\frac{\mathrm{d}z}{\mathrm{d}\tau} && (10.70d)\\
&= \vec{e}_r\,v^r + \vec{e}_\vartheta\,v^\vartheta + \vec{e}_{\overline{z}}\,v^{\overline{z}}. && (10.70e)
\end{aligned}$$

To reach this result we made use of the identity

$$\vec{e}_\vartheta = r\,\frac{\partial\vec{e}_r}{\partial\vartheta} = r\,\hat{\boldsymbol{\vartheta}}. \tag{10.71}$$

10.3.5 Metric tensor

Cylindrical-polar coordinates are orthogonal with the metric tensor and its inverse represented by the diagonal matrices

$$g_{\overline{a}\overline{b}} = \vec{e}_{\overline{a}}\cdot\vec{e}_{\overline{b}} = \begin{bmatrix} 1 & 0 & 0\\ 0 & r^2 & 0\\ 0 & 0 & 1\end{bmatrix} \qquad \text{and} \qquad g^{\overline{a}\overline{b}} = \widetilde{e}^{\overline{a}}\cdot\widetilde{e}^{\overline{b}} = \begin{bmatrix} 1 & 0 & 0\\ 0 & r^{-2} & 0\\ 0 & 0 & 1\end{bmatrix}. \tag{10.72}$$

10.3.6 Volume element and Levi-Civita tensor

The square root of the determinant of the metric tensor written in cylindrical-polar coordinates (from equation (10.72)) is given by

$$\sqrt{\det(\overline{\mathcal{G}})} = r \tag{10.73}$$

so that the volume element is

$$\mathrm{d}V = r\,\mathrm{d}r\,\mathrm{d}\vartheta\,\mathrm{d}z. \tag{10.74}$$

The covariant Levi-Civita tensor has the cylindrical-polar representation

$$\varepsilon_{\overline{a}\overline{b}\overline{c}} = r\,\epsilon_{\overline{a}\overline{b}\overline{c}}. \tag{10.75}$$

10.3.7 Vector cross product of basis vectors

As a check on the formalism for vector cross products, let us verify the relation (9.79) for the cross product of two basis vectors using cylindrical-polar coordinates

$$\vec{e}_{\overline{a}}\times\vec{e}_{\overline{b}} = \varepsilon_{\overline{a}\overline{b}\overline{c}}\,\widetilde{e}^{\overline{c}} \Longrightarrow \vec{e}_{\overline{a}}\times\vec{e}_{\overline{b}} = r\,\epsilon_{\overline{a}\overline{b}\overline{c}}\,\widetilde{e}^{\overline{c}}. \tag{10.76}$$

Making use of the cylindrical-polar coordinate basis vectors and one-forms renders

$$\vec{e}_r \times \vec{e}_\vartheta = r\,(\hat{\boldsymbol{r}} \times \hat{\boldsymbol{\vartheta}}) = r\,\widetilde{e}^{\overline{z}} = \varepsilon_{r\vartheta\overline{z}}\,\widetilde{e}^{\overline{z}} \tag{10.77a}$$

$$\vec{e}_\vartheta \times \vec{e}_{\overline{z}} = r\,(\hat{\boldsymbol{\vartheta}} \times \hat{\boldsymbol{z}}) = r\,\hat{\boldsymbol{r}} = r\,\widetilde{e}^{r} = \varepsilon_{\vartheta\overline{z}r}\,\widetilde{e}^{r} \tag{10.77b}$$

$$\vec{e}_{\overline{z}} \times \vec{e}_r = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}} = \hat{\boldsymbol{\vartheta}} = r\,\widetilde{e}^{\vartheta} = \varepsilon_{\overline{z}r\vartheta}\,\widetilde{e}^{\vartheta}. \tag{10.77c}$$

To reach these results we made use of the cross products for the unit vectors

$$\hat{\boldsymbol{r}} \times \hat{\boldsymbol{\vartheta}} = \hat{\boldsymbol{z}} \qquad \text{and} \qquad \hat{\boldsymbol{\vartheta}} \times \hat{\boldsymbol{z}} = \hat{\boldsymbol{r}} \qquad \text{and} \qquad \hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}} = \hat{\boldsymbol{\vartheta}}. \tag{10.78}$$

10.3.8 Components of a vector field

A vector field $\vec{F}$ has Cartesian components, F^a, related to cylindrical-polar components, $F^{\overline{a}}$, via the transformation matrix, $F^{\overline{a}} = \Lambda^{\overline{a}}_{\ a}\,F^a$. This transformation leads to

$$F^{\overline{1}} = F^x \cos\vartheta + F^y \sin\vartheta \tag{10.79a}$$

$$F^{\overline{2}} = r^{-1}\left[-F^x \sin\vartheta + F^y \cos\vartheta\right] \tag{10.79b}$$

$$F^{\overline{3}} = F^z. \tag{10.79c}$$

Introducing the cylindrical-polar unit vectors (10.65) leads to the more tidy expressions

$$F^{\overline{1}} = \hat{\boldsymbol{r}} \cdot \boldsymbol{F} \tag{10.80a}$$

$$r\,F^{\overline{2}} = \hat{\boldsymbol{\vartheta}} \cdot \boldsymbol{F} \tag{10.80b}$$

$$F^{\overline{3}} = \hat{\boldsymbol{z}} \cdot \boldsymbol{F}, \tag{10.80c}$$

where $\boldsymbol{F}$ is the Cartesian representation.

10.3.9 Differential operators

In cylindrical-polar coordinates, the gradient operator $\nabla = \widetilde{e}^a \partial_a$ takes on the form

$$\nabla = \hat{\boldsymbol{r}}\,\frac{\partial}{\partial r} + \frac{\hat{\boldsymbol{\vartheta}}}{r}\,\frac{\partial}{\partial \vartheta} + \hat{\boldsymbol{z}}\,\frac{\partial}{\partial z} \tag{10.81}$$

and the covariant divergence of a vector field is given by

$$\nabla_{\overline{a}} F^{\overline{a}} = r^{-1}\,\partial_{\overline{a}}\,(r\,F^{\overline{a}}) \tag{10.82a}$$

$$= r^{-1}\left(\partial_r[r\,F^{\overline{1}}] + \partial_\vartheta[r\,F^{\overline{2}}] + \partial_{\overline{z}}[r\,F^{\overline{3}}]\right) \tag{10.82b}$$

$$= \frac{1}{r}\,\frac{\partial(r\,\hat{\boldsymbol{r}} \cdot \boldsymbol{F})}{\partial r} + \frac{1}{r}\,\frac{\partial\,(\hat{\boldsymbol{\vartheta}} \cdot \boldsymbol{F})}{\partial \vartheta} + \frac{\partial(\hat{\boldsymbol{z}} \cdot \boldsymbol{F})}{\partial z}. \tag{10.82c}$$

The covariant Laplacian of a scalar, $\nabla^2\psi = \nabla \cdot \nabla\psi$, is given by

$$\nabla^2\psi = \nabla \cdot \left[\hat{\boldsymbol{r}}\,\frac{\partial\psi}{\partial r} + \frac{\hat{\boldsymbol{\vartheta}}}{r}\,\frac{\partial\psi}{\partial \vartheta} + \hat{\boldsymbol{z}}\,\frac{\partial\psi}{\partial z}\right] \tag{10.83a}$$

$$= \frac{1}{r}\,\frac{\partial}{\partial r}\left[r\,\frac{\partial\psi}{\partial r}\right] + \frac{1}{r^2}\,\frac{\partial^2\psi}{\partial \vartheta^2} + \frac{\partial^2\psi}{\partial z^2}. \tag{10.83b}$$

The covariant curl (Section 9.17) takes the form

$$(\mathrm{curl}\vec{F})^{\overline{1}} = r^{-1}\,[\partial_\vartheta\, F^{\overline{3}} - \partial_{\overline{z}}\,(r^2\, F^{\overline{2}})] \tag{10.84a}$$

$$(\mathrm{curl}\vec{F})^{\overline{2}} = r^{-1}\,[\partial_{\overline{z}}\, F^{\overline{1}} - \partial_r\, F^{\overline{3}}] \tag{10.84b}$$

$$(\mathrm{curl}\vec{F})^{\overline{3}} = r^{-1}\,[\partial_r\,(r^2\, F^{\overline{2}}) - \partial_\vartheta\, F^{\overline{1}})], \tag{10.84c}$$

which can be written more conventionally as

$$(\mathrm{curl}\vec{F})^{\overline{1}} = \frac{1}{r}\,\frac{\partial(\hat{\boldsymbol{z}}\cdot\boldsymbol{F})}{\partial\vartheta} - \frac{\partial(\hat{\boldsymbol{\vartheta}}\cdot\boldsymbol{F})}{\partial z} \tag{10.85a}$$

$$r\,(\mathrm{curl}\vec{F})^{\overline{2}} = \frac{\partial(\hat{\boldsymbol{r}}\cdot\boldsymbol{F})}{\partial z} - \frac{\partial(\hat{\boldsymbol{z}}\cdot\boldsymbol{F})}{\partial r} \tag{10.85b}$$

$$(\mathrm{curl}\vec{F})^{\overline{3}} = \frac{1}{r}\,\frac{\partial(r\,\hat{\boldsymbol{\vartheta}}\cdot\boldsymbol{F})}{\partial r} - \frac{1}{r}\,\frac{\partial(\hat{\boldsymbol{r}}\cdot\boldsymbol{F})}{\partial\vartheta}. \tag{10.85c}$$

10.3.10 Summary

We here summarize the cylindrical coordinate version of some common mathematical operators.

$$(r,\vartheta,z) = (x^{\overline{1}}, x^{\overline{2}}, x^{\overline{3}}) \qquad \text{cylindrical coordinates} \tag{10.86}$$

$$F^{\overline{1}} = \hat{\boldsymbol{r}}\cdot\boldsymbol{F} \qquad r\,F^{\overline{2}} = \hat{\boldsymbol{\vartheta}}\cdot\boldsymbol{F} \qquad F^{\overline{3}} = \hat{\boldsymbol{z}}\cdot\boldsymbol{F} \qquad \text{vector components} \tag{10.87}$$

$$\nabla = \hat{\boldsymbol{r}}\,\frac{\partial}{\partial r} + \frac{\hat{\boldsymbol{\vartheta}}}{r}\,\frac{\partial}{\partial\vartheta} + \hat{\boldsymbol{z}}\,\frac{\partial}{\partial z} \qquad \text{gradient} \tag{10.88}$$

$$\nabla_{\overline{a}}F^{\overline{a}} = \frac{1}{r}\,\frac{\partial(r\,\hat{\boldsymbol{r}}\cdot\boldsymbol{F})}{\partial r} + \frac{1}{r}\frac{\partial\,(\hat{\boldsymbol{\vartheta}}\cdot\boldsymbol{F})}{\partial\vartheta} + \frac{\partial(\hat{\boldsymbol{z}}\cdot\boldsymbol{F})}{\partial z}. \qquad \text{divergence} \tag{10.89}$$

$$\nabla^2\psi = \frac{1}{r}\,\frac{\partial}{\partial r}\left[r\,\frac{\partial\psi}{\partial r}\right] + \frac{1}{r^2}\,\frac{\partial^2\psi}{\partial\vartheta^2} + \frac{\partial^2\psi}{\partial z^2} \qquad \text{Laplacian of scalar} \tag{10.90}$$

$$(\nabla\times\boldsymbol{F})_{\overline{a}} = \varepsilon_{\overline{a}\overline{b}\overline{c}}\partial_{\overline{b}}F^{\overline{c}} \qquad \text{see equations (10.84a)} - \text{(10.84c)}. \qquad \text{curl of a vector} \tag{10.91}$$

10.4 General orthogonal coordinates

We can generalize the spherical and cylindrical-polar coordinates by considering a nonsingular and orthogonal set of coordinates defined such that the metric tensor takes on the diagonal form

$$g_{\overline{a}\overline{b}} = \vec{e}_{\overline{a}}\cdot\vec{e}_{\overline{b}} = \begin{bmatrix} h_{\overline{1}} & 0 & 0 \\ 0 & h_{\overline{2}} & 0 \\ 0 & 0 & h_{\overline{3}} \end{bmatrix}, \tag{10.92}$$

where $h_{\overline{a}} > 0$ are "stretching" functions. The corresponding volume element is expressed as

$$\mathrm{d}V = h_{\overline{1}}\,h_{\overline{2}}\,h_{\overline{3}}\,\mathrm{d}\xi^{\overline{1}}\,\mathrm{d}\xi^{\overline{2}}\,\mathrm{d}\xi^{\overline{3}}. \tag{10.93}$$

These *generalized orthogonal curvilinear coordinates* have a corresponding orthogonal set of basis vectors

$$\vec{e}_{\overline{a}} = h_{\overline{a}}\,\hat{\mathbf{e}}_{(\overline{a})} \qquad \text{no implied sum.} \tag{10.94}$$

The objects $\hat{\mathbf{e}}_{(\overline{a})}$ are the dimensionless unit directions. The corresponding one-form basis is given by

$$\widetilde{e}^{\overline{a}} = (h_{\overline{a}})^{-1}\,\hat{\mathbf{e}}_{(\overline{a})}. \tag{10.95}$$

The index on the unit directions is enclosed in parentheses to advertise that it is not tensorial; i.e., the unit directions do not transform as tensors. Rather, the functions $h_{\overline{a}}$ carry the tensorial properties of the basis vectors $\vec{e}_{\overline{a}}$. Results for the trajectory and velocity are straightforward generalizations of the spherical results in Section 10.2 and cylindrical-polar results from Section 10.3. A detailed presentation of generalized orthogonal coordinates is found in Section 21.11 of *Griffies* (2004), with these coordinates commonly used for ocean and atmospheric models.

10.5 Comments on gradient operators

A feature common to non-Cartesian coordinates concerns the presence of spatially dependent factors in front of certain components of the gradient operators. Indeed, recall the gradient for the three coordinates discussed in this chapter:

$$\nabla = \hat{\boldsymbol{x}} \frac{\partial}{\partial x} + \hat{\boldsymbol{y}} \frac{\partial}{\partial y} + \hat{\boldsymbol{z}} \frac{\partial}{\partial z} \qquad \text{Cartesian} \tag{10.96a}$$

$$\nabla = \frac{\hat{\boldsymbol{\lambda}}}{r \cos\phi} \frac{\partial}{\partial \lambda} + \frac{\hat{\boldsymbol{\phi}}}{r} \frac{\partial}{\partial \phi} + \hat{\boldsymbol{r}} \frac{\partial}{\partial r} \qquad \text{spherical} \tag{10.96b}$$

$$\nabla = \hat{\boldsymbol{r}} \frac{\partial}{\partial r} + \frac{\hat{\boldsymbol{\vartheta}}}{r} \frac{\partial}{\partial \vartheta} + \hat{\boldsymbol{z}} \frac{\partial}{\partial z} \qquad \text{cylindrical-polar,} \tag{10.96c}$$

where we recall that r for the spherical coordinates measures the distance from the origin, whereas r for cylindrical-polar coordinates measures the distance from the vertical axis. Observe the r^{-1} dependence for the angular components of the gradient for both spherical and cylindrical-polar coordinates. This dependence arises since as r increases, the surfaces of constant r become flatter.

To help understand the meaning of the r^{-1} factor, consider two points with the same r but distinct angular coordinates. As r increases, so too does the distance between the two points, even though their angular positions remain unchanged. This property is why the outer portion of a pizza pie is bigger than the inner portion. Correspondingly, when measuring the derivative of a function in the angular direction, that derivative must be weighted by r^{-1} to account for the difference in the arc-distance (more precisely the geodesic distance) between the two points. The same idea explains the $\cos\phi$ factor on the longitudinal derivative in spherical coordinates. Each of these notions are are encapsulated in the spatial dependence of the basis vectors for non-Cartesian coordinates. Even so, it can be useful to have a more prosaic or everyday expression to help build intuition.

A practical implication of the r and $r\cos\phi$ factors appearing in the gradient operators arises when performing a vertical integral of the fluid mechanical equations. Such integrals are often used to study reduced order versions of the full three-dimensional equations. But to be used in practice, such integrals must be done either with Cartesian coordinates or for those cases where it is acceptable to set the r^{-1} factor to a constant, such as occurs for the shallow fluid approximation discussed in Section 28.1.2. Indeed, the vertically integrated equations are of most practical use only when making a shallow fluid approximation. If this point seems obscure now, it will be clarified when studying the depth integrated mechanical energy in Section 28.1.6, the depth integrated momentum equation in Section 29.4, the depth integrated angular momentum equation in Section 29.5, and the depth integrated vorticity equations in Sections 45.4, 45.6, and 45.7.

Part II

Classical mechanics

Planetary rotation and gravitation are two defining features of geophysical fluid mechanics. Furthermore, geophysical fluids exhibit motions whose speed is small relative to that of the rotating planet. We thus say that geophysical fluids are in near rigid-body motion, making it convenient to use a rotating (non-inertial) terrestrial reference frame to describe the fluid motion. Rotating and gravitating motion around a planet introduce new physical ideas beyond the more familiar non-rotating system. Rather than introduce rotating physics within the context of fluid mechanics, we first focus on the point particle system to establish a foundation for rotating physics. In the process, we also review facets of classical particle mechanics that are useful in the continuum mechanics of a moving fluid. Additionally, we examine systems of particles and then take their continuum limit, thus introducing notions relevant to the continuum mechanics of fluids. There is a payoff for studying these chapters on classical mechanics even for the experienced physicist. Namely, topics familiar from previous studies are presented from the viewpoint of what later proves central to the study of geophysical fluid mechanics. In particular, we encounter Newtonian mechanics, Lagrangian mechanics, Hamilton's principle, trajectories, linear momentum, angular momentum, body forces, accelerations due to the rotating reference frame (planetary Coriolis and planetary centrifugal), space-time symmetries and conservation laws, center of mass coordinates, harmonic oscillators, pendula, planetary Cartesian coordinates, and planetary spherical coordinates.

We start by reviewing foundational elements of Newtonian particle mechanics in Chapter 11, considering a single point particle, a system of particles, and paricles coupled by linear oscillators. We here also introduce some basic kinematic properties of non-inertial reference frames. Thereafter, in Chapters 13 and 14 we focus on the geophysically relevant case of a classical point particle moving around a rotating and gravitating sphere as described from the rotating terrestrial reference frame. In Chapter 12 we study Lagrangian mechanics, which formulates classical mechanics in a manner that complements Newtonian mechanics. We then follow with a suite of case studies in Chapter 15, thus exemplifying the power of the method. Lagrangian mechanics focuses on energy rather than forces, and its Euler-Lagrange differential equations (derived from Hamilton's stationary action principle) are equivalent to Newton's equations of motion. Although leading to the same end point, the energy approach of Lagrange, coupled to the variational approach of Hamilton's principle, provide a powerful means to formulate otherwise intractable problems in classical physics. It also offers the natural mathematical foundation for connecting symmetries to conservation laws via Noether's theorem. Finally, it forms the starting point for a field theoretic perspective on fluid mechanics, whereby the Euler-Lagrange field equations are derived from Hamilton's principle rather than Newton's laws.

Chapter 11

Newtonian mechanics

Classical physics is concerned with describing the motion of matter, with Newtonian classical mechanics based on using Newton's laws to deduce the cause of motion. Classical matter is organized into three categories: (i) massive point particles; (ii) extended and continuous rigid media (rigid bodies); (iii) extended and continuous non-rigid media (e.g., elastic solids, fluids). A point particle has zero dimensions and so it occupies a single point in space. Rigid bodies occupy a finite region of space and are comprised of a continuum of matter particles that maintain fixed relative positions, thus constraining the media to maintain constant mass and volume. Particles in an extended non-rigid continuous media can move relative to one another, so that the media maintains constant mass though with a generally changing volume.[1] In this chapter we focus on mechanics of point particles as a venue to introduce rudimentary features of classical mechanics.

A mechanical description of motion is decomposed into *kinematics* and *dynamics*, with kinematics concerned with the nature of motion and dynamics concerned with the causes of motion. More specifically, kinematics is concerned with the position, velocity, and acceleration, whereas dynamics, through Newton's laws, provide the means to determine how motion is altered in the presence of forces. The mechanics of Newton are summarized by three laws of motion:

- FIRST LAW: In an inertial reference frame, every massive body remains at rest or in uniform motion unless acted on by a net force. This law is sometimes referred to as the *law of inertia*.

- SECOND LAW: In an inertial reference frame, application of a net force to a body alters its linear momentum.

- THIRD LAW: To each action there is an equal and oppositely directed reaction.

The first and second laws offer definitions for an inertial reference frame and for a force. The third law provides a statement about how forces act, thus providing physical substance to the first and second laws.[2] The third law holds for central forces, such as arise in Newtonian gravity and electrostatics. However, it does not hold for all forces, such as the Lorentz force acting on a moving charged particle.

The decomposition of matter into point particles, rigid bodies, and continuous media, directly corresponds to the kinematic decomposition of motion into translations, rotations, and dilations.[3] Namely, point particles move by translations through space, with this space-time motion referred

[1] We typically abbreviate "extended non-rigid continuous media" as "continuous media". There is little room for confusion with rigid bodies since in this book we provide only tangential attention to the dynamics of rigid bodies.

[2] For more on this perspective of Newton's laws, see Chapter 1 of *Symon* (1971) or Chapter 2 of *Marion and Thornton* (1988).

[3] This decomposition is referred to as the *Cauchy-Stokes decomposition* and is studied in Section 19.4.6.

to as a *trajectory*. The motion of a rigid body consists of its center of mass translations plus rotations of the body relative to the center of mass. Finally, the motion of a continuous media consists of the translations and rotations of a rigid body, plus changes in the relative positions of the particles that can lead to changes in the volume of the media, with such motions referred to as *dilatations*.

CHAPTER GUIDE

In this chapter we study the rudiments of Newtonian particle mechanics for a single massive point particle and for a system of such particles. Along the way, we expose core concepts such as space, time, mass, force, and rotation. Notably, within the bounds of classical physics, we must remain satisfied with common experience definitions for many of the foundational concepts that are not deduced from more fundamental principles.

Every classical mechanics textbook has some form of the material presented in this chapter. The books from *Goldstein* (1980) and *Fetter and Walecka* (2003) are targeted at the entering physics graduate student, whereas *French* (1971), *Symon* (1971), *Marion and Thornton* (1988), and *Taylor* (2005) are targeted at second or third year undergraduates. This chapter is required for understanding the mechanics of a particle moving around a rotating sphere in Chapters 13 and 14. It also serves as a baseline for the complementary approach taken by the *Lagrangian mechanics* studied in Chapters 12 and 15. We make use of Cartesian tensors for ease of presentation.

11.1 Newtonian mechanics of a point particle

In this section we study the Newtonian mechanics of a single point particle of constant mass, with the point particle occupying a single point in space and so having zero extent.

11.1.1 Position, velocity, and acceleration

The Cartesian position, $\boldsymbol{x}$, of a point particle at a Newtonian time instance, t, is written

$$\boldsymbol{x} = \boldsymbol{X}(t) = X^1(t)\,\hat{\boldsymbol{x}} + X^2(t)\,\hat{\boldsymbol{y}} + X^3(t)\,\hat{\boldsymbol{z}} = x(t)\,\hat{\boldsymbol{x}} + y(t)\,\hat{\boldsymbol{y}} + z(t)\,\hat{\boldsymbol{z}}. \tag{11.1}$$

The spatial position is measured relative to an arbitrary origin, with the vector, $\boldsymbol{X}$, pointing from the origin to the position of the particle. Universal *Newtonian time*, t, is a monotonically increasing parameter that allows for the unambiguous distinction between past, present, and future. That is, time parameterizes the particle's position in Euclidean space, with $\boldsymbol{X}(t)$ providing the mathematical representation for the *trajectory* in space as determined over a finite span of time.

The time derivative of the position defines the *velocity*, and the time derivative of the velocity is the *acceleration*

$$\boldsymbol{V}(t) = \frac{\mathrm{d}\boldsymbol{X}(t)}{\mathrm{d}t} = \dot{\boldsymbol{X}}(t) \quad \text{and} \quad \boldsymbol{A}(t) = \frac{\mathrm{d}\boldsymbol{A}(t)}{\mathrm{d}t} = \dot{\boldsymbol{V}}(t) = \ddot{\boldsymbol{X}}(t), \tag{11.2}$$

where we introduced the commonly used dot notation for the time derivative. By definition, the velocity is instantaneously tangent to the trajectory, and the acceleration is instantaneously tangent to the velocity. For Newtonian mechanics we generally have no use for higher tiime derivatives since Newton's law connects the acceleration to the net force.

11.1.2 Linear momentum and Newton's second law

The *linear momentum* of the particle equals to the mass of the particle, m, times its velocity

$$\boldsymbol{P} = m\,\dot{\boldsymbol{X}} = m\,\boldsymbol{V}. \tag{11.3}$$

The linear momentum changes when it experiences a net force. The vector sum of all forces (whether conservative or non-conservative) is written $\boldsymbol{F}$, and Newton's second law of motion states that there exists *inertial reference frames* where motion of the particle is described by the differential equation

$$\frac{\mathrm{d}\boldsymbol{P}}{\mathrm{d}t} = \boldsymbol{F}. \tag{11.4}$$

If the particle mass is fixed, then this equation becomes a second order differential equation for the particle position as a function of time

$$\boldsymbol{A} = \frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = \frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2} = \boldsymbol{F}/m. \tag{11.5}$$

Many conclusions in mechanics are expressed in terms of conservation laws (Chapter 14), which provide relations or conditions whereby mechanical properties of a physical system remain time

invariant (i.e., time independent). Newton's second law provides our first conservation law since, in the absence of a net force, the linear momentum remains unchanged: $\mathrm{d}\boldsymbol{P}/\mathrm{d}t = 0$. Depending on the nature of the forces, this conservation law might hold for one, two, or all three of the vector components to the linear momentum. Note that for a constant mass particle, a time independent linear momentum means that the velocity remains constant, which is a statement of Newton's first law.

11.1.3 Galilean relativity and inertial reference frames

If the forces acting on the particle are not directly dependent on the particle velocity, then the inertial frame equation of motion (11.5) is unchanged if shifting the velocity by a constant. Such velocity-independent forces (such as Newton's gravitational force) are commonly found in the conservative (non-dissipative) motion of charge-free particles. This arbitrariness in the velocity reflects a *symmetry* respected by the equation of motion, where symmetry refers to an operation that can be performed on the system without changing any physics. This particular symmetry is known in various contexts as *Galilean invariance*, *Galilean relativity*, or *Newtonian relativity.* This property holds for all inertial reference frames in non-relativistic mechanics. It is thus notable that there is no *absolute reference frame*, since we cannot mechanically distinguish any of the inertial reference frames that differ by an arbitrary constant velocity.

These considerations indicate that there is no classical experiment that can distinguish between two arbitrary inertial reference frames, so long as the experiments are described by Newton's equation of motion (11.5) and the force is independent of the velocity. The operational reason we cannot make a distinction is that the equation of motion is indistinguishable in the two inertial frames. As a corollary, two inertial reference frames can at most be moving relative to one another by a constant velocity. Otherwise, at least one of the reference frames is accelerating, which in turn means that this accelerating reference frame is not an inertial frame.

This discussion offers a relatively simple example of the mathematical transformation theory introduced in Part I of this book. Mathematically, the Galilean transformation is written

$$\bar{t} = t \qquad \text{and} \qquad \overline{\boldsymbol{X}} = \boldsymbol{X} + \boldsymbol{U}t, \tag{11.6}$$

where the barred position vector is measured in the moving reference frame. Time remains unchanged since we make use of Newtonian universal time. In contrast, the position of the particle in the new frame equals to that in the original reference frame plus a contribution from the constant velocity, $\boldsymbol{U}$. We may sometimes refer to the barred reference frame as a *Galilean boosted* frame. The particle velocity in the moving (boosted) reference frame is given by

$$\overline{\boldsymbol{V}} = \frac{\mathrm{d}\overline{\boldsymbol{X}}}{\mathrm{d}\bar{t}} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} + \frac{\mathrm{d}\left(\boldsymbol{U}t\right)}{\mathrm{d}t} = \boldsymbol{V} + \boldsymbol{U}, \tag{11.7}$$

where we set $\mathrm{d}\boldsymbol{U}/\mathrm{d}t = 0$ since $\boldsymbol{U}$ has a fixed magnitude and direction (as per our assumption that it is a constant vector). As expected, the velocity is shifted by the constant reference frame velocity $\boldsymbol{U}$, whereas the acceleration in the two reference frames is identical

$$\overline{\boldsymbol{A}} = \frac{\mathrm{d}^2\overline{\boldsymbol{X}}}{\mathrm{d}\bar{t}^2} = \frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = \boldsymbol{A}. \tag{11.8}$$

11.1.4 Mechanical work and kinetic energy

When a force is applied to a particle as it moves along its trajectory, the force does *mechanical work* on the particle. This force affects the motion, with the work performed by the force computed

by the line integral along the trajectory

$$W = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x}, \tag{11.9}$$

where

$$\boldsymbol{x}_1 = \boldsymbol{X}(t = t_1) \quad \text{and} \quad \boldsymbol{x}_2 = \boldsymbol{X}(t = t_2) \tag{11.10}$$

are the spatial coordinates of the endpoints for the trajectory at times t_1 and t_2, and $\mathrm{d}\boldsymbol{x}$ is the differential vector increment along the trajectory. Since the particle is moving along its dynamical trajectory, we can write

$$\mathrm{d}\boldsymbol{x} = \boldsymbol{V}\,\mathrm{d}t \tag{11.11}$$

and make use of Newton's equation of motion (11.5) to reach

$$W = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = \int_{t_1}^{t_2} m\,\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} \cdot \boldsymbol{V}\,\mathrm{d}t = \frac{m}{2}\int_{t_1}^{t_2} \frac{\mathrm{d}(\boldsymbol{V}\cdot\boldsymbol{V})}{\mathrm{d}t}\,\mathrm{d}t = K(t_2) - K(t_1), \tag{11.12}$$

where we defined the kinetic energy of the particle

$$K = \frac{m}{2}\,\boldsymbol{V}\cdot\boldsymbol{V}. \tag{11.13}$$

We conclude that the work done on the particle over a time interval is equal to its change in kinetic energy. The result (11.12) is called the *work-energy theorem*.

11.1.5 Mechanical energy conservation

Consider the work done on a particle as it moves between two points in space. Now compute the work done on the particle as it moves along another path between the same initial and final positions. If the work done on the particle is independent of the path taken between the points, then the force is said to be *conservative*.

Conservation of mechanical energy

Recalling our discussion of exact differentials in Section 2.8, we know that a conservative force can be written as the gradient of a *force potential*

$$\boldsymbol{F}^{\text{cons}} = -\nabla P, \tag{11.14}$$

where P is called the *potential* or the *potential energy*. Inserting the potential into the work equation (11.12) leads to an expression of *mechanical energy* conservation

$$W = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{F}^{\text{cons}} \cdot \mathrm{d}\boldsymbol{x} = \Delta K = -\Delta P \Longrightarrow K(t_2) + P(t_2) = K(t_1) + P(t_1). \tag{11.15}$$

That is, the sum of the kinetic energy plus potential energy remains constant for a particle moving in a conservative force field. The conservation of kinetic plus potential energy within a conservative force field offers our third conservation law: the conservation of *mechanical energy*.

As a result of mechanical energy conservation (11.15), we see that if a particle takes a closed trajectory within a conservative force field, then there is zero integrated work applied to the particle

$$W = \oint_{\mathcal{C}} \boldsymbol{F}^{\text{cons}} \cdot \mathrm{d}\boldsymbol{x} = 0, \tag{11.16}$$

where $\mathcal{C}$ is an arbitrary closed trajectory. Another way to see that $W = 0$ for a closed trajectory is to write

$$W = \oint_{\mathcal{C}} \boldsymbol{F}^{\text{cons}} \cdot \mathrm{d}\boldsymbol{x} = \oint_{\mathcal{C}} m \frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} \cdot \boldsymbol{V}\, \mathrm{d}t = \frac{m}{2} \oint_{\mathcal{C}} \mathrm{d}(\boldsymbol{V} \cdot \boldsymbol{V}) = 0, \tag{11.17}$$

with the zero resulting since $\mathrm{d}(\boldsymbol{V} \cdot \boldsymbol{V})$ is an exact differential (see Section 2.8 for exact differentials).

Conservative force from the effective gravity field

The earth's gravitational field as well as the planetary centrifugal acceleration (due to motion on a rotating planet) both give rise to conservative forces. We discuss these ideas in Section 13.10.4, where we see that the combined gravitational and planetary centrifugal accelerations are encapsulated by the gradient of the geopotential, Φ. In this case, the effective gravitational force acting on a point particle of mass, m, is given by

$$\boldsymbol{F}^{\text{geo}} = -m\, \nabla \Phi. \tag{11.18}$$

Consequently, the work done on the particle by the effective gravitational field is

$$W = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{F}^{\text{geo}} \cdot \mathrm{d}\boldsymbol{x} = -m \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \nabla \Phi \cdot \mathrm{d}\boldsymbol{x} = -m\, [\Phi(\boldsymbol{x}_2) - \Phi(\boldsymbol{x}_1)]. \tag{11.19}$$

The effective gravitational force field does positive work on the particle if $\Phi(\boldsymbol{x}_1) > \Phi(\boldsymbol{x}_2)$. That is, work is applied to the particle as it moves from a high geopotential at $\boldsymbol{x}_1$ to a lower geopotential at $\boldsymbol{x}_2$, in which case the work-energy theorem (11.12) means that the kinetic energy increases. Conversely, if $\Phi(\boldsymbol{x}_1) < \Phi(\boldsymbol{x}_2)$, then gravity does negative work on the particle. In this case the potential energy of the particle increases as it moves to a higher geopotential, while, through the work-energy theorem, the kinetic energy of the particle decreases.

11.1.6 Friction as a non-conservative force

Friction is the canonical non-conservative force that typically depends on the velocity field. For example, a common form of the frictional force is given by *Rayleigh drag*

$$\boldsymbol{F}^{\text{Rayleigh}} = -\gamma\, m\, \boldsymbol{V}, \tag{11.20}$$

where $\gamma > 0$ is a constant with dimensions of inverse time. Newton's equation of motion with Rayleigh drag (and no other forces) takes the form

$$\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = -\gamma\, \boldsymbol{V}. \tag{11.21}$$

Notably, Rayleigh drag is not Galilean invariant since it is dependent on the velocity. We can understand this lack of Galilean invariance by noting that the friction force identifies the state of rest ($\boldsymbol{V} = 0$) as a special reference frame.

The solution to the first order ordinary differential equation (11.21) is the exponential decay

$$\boldsymbol{V}(t) = \boldsymbol{V}(0)\, e^{-\gamma\, t}, \tag{11.22}$$

with $\boldsymbol{V}(0)$ the velocity at time $t = 0$. We thus see that Rayleigh drag exponentially drives the velocity towards zero. Correspondingly, Rayleigh drag dissipates the kinetic energy according to

twice the exponential decay

$$\frac{\mathrm{d}K}{\mathrm{d}t} = m\,\boldsymbol{V}\cdot\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = -2\,\gamma\,K \Longrightarrow K(t) = K(0)\,e^{-2\,\gamma\,t}, \tag{11.23}$$

where $K(0) = \boldsymbol{V}(0)\cdot\boldsymbol{V}(0)/2$.

11.2 Kinematics of rigid-body rotations

The motion of a point particle is described by its trajectory, $\boldsymbol{X}(t)$, which provides the particle location in Euclidean space as time progresses. At each time instance the trajectory's velocity, $\mathrm{d}\boldsymbol{X}/\mathrm{d}t$, can be decomposed into radial motion towards or away from an arbitrary fixed origin, plus rotation about an instantaneously defined axis through the origin.[4] In this section we focus on the rotational motion, so that the particle moves on a trajectory that is a fixed distance from the origin, $\mathrm{d}|\boldsymbol{X}|/\mathrm{d}t = 0$. We make use of results encountered when studying rigid body motion, with those results available here since $|\boldsymbol{X}|$ is fixed. We thus refer to the motion as *rigid-body rotational* motion. Besides offering insights into the nature of motion, the rigid-body rotations have direct application to therigid-body rotating reference frame used by terrestrial observers. We pick up on that application in Section 11.4.

11.2.1 Angular velocity vector

A particle that moves on a trajectory, $\boldsymbol{X}(t)$, that is a fixed distance from an origin (as per points in a rigid body), can only exhibit rotational motion around an axis that extends through the origin. In general, the rotational axis has an evolving orientation in space. Yet at any time instance, the particle motion is specified by the axis around which rotation occurs, as well as the angular rate of rotation. Bringing the rotation rate and the axis orientation together leads to the notion of the *angular velocity* vector (dimensions of radians per time)

$$\boldsymbol{\Omega} = |\boldsymbol{\Omega}|\,\hat{\boldsymbol{\Omega}}, \tag{11.24}$$

where $\hat{\boldsymbol{\Omega}}$ is the unit vector specifying the direction of the rotational axis, and $|\boldsymbol{\Omega}|$ is the angular speed of the rotation. We choose the direction of the rotational axis according to the right hand rule. Although an arbitrary choice (i.e., we could just as well work with the left hand rule), the right hand rule establishes a convention from which we pursue the mechanical description. Figure 11.1 provides an example of rotational motion of a particle around an axis passing through a fixed origin.

11.2.2 Velocity of rigid-body rotation

Since the particle moves along a trajectory that has a fixed distance from the origin, its velocity is given by

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = |\boldsymbol{X}|\,\frac{\mathrm{d}\hat{\boldsymbol{X}}}{\mathrm{d}t}, \tag{11.25}$$

[4] See Section 4-6 of *Goldstein* (1980) for a general discussion of rotational kinematics, whose origin dates to the work of Euler.

FIGURE 11.1: Kinematics of the rotational motion of a particle moving a fixed distance from an origin, whereby the motion at each instance can be represented as a rotation around an instanteneously determined axis that passes through an origin. Rotational motion is characterized by the angular velocity, $\boldsymbol{\Omega}$, that is oriented according to the right hand rule, so that rotation is counter-clockwise relative to $\hat{\boldsymbol{\Omega}}$. The velocity corresponding to this rotational motion is $\boldsymbol{V} = \boldsymbol{\Omega} \times \boldsymbol{X}$, which is perpendicular to both the particle position, $\boldsymbol{X}$, and the angular velocity, $\boldsymbol{\Omega}$. The angle, ϕ, is the angle relative to plane perpendicular to the rotation axis that passes through the origin. This choice for angle is motivated from the geophysical latitude as per Figure 10.1. In contrast, it is conventional in the mechanics literature to use the co-latitude, $\pi/2 - \phi$, which is the angle relative to the rotational axis. This figure anticipates our study of motion viewed from the rotating terrestrial reference frame in Chapter 13 (see also Figure 10.1 for the geometry of a rotating sphere).

where $\mathrm{d}\hat{\boldsymbol{X}}/\mathrm{d}t$ is the time derivative of the unit vector that points from the origin to the particle. Following from Figure 11.1, we see that the unit vector evolves under rotations according to

$$\frac{\mathrm{d}\hat{\boldsymbol{X}}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \hat{\boldsymbol{X}}, \tag{11.26}$$

with this time derivative perpendicular to both $\boldsymbol{\Omega}$ and $\hat{\boldsymbol{X}}$. We are thus led to the rigid-body velocity vector

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \boldsymbol{V} = \boldsymbol{\Omega} \times \boldsymbol{X}, \tag{11.27}$$

with this velocity perpendicular to both the position vector and the rotational axis

$$\boldsymbol{V} \cdot \boldsymbol{\Omega} = 0 \quad \text{and} \quad \boldsymbol{V} \cdot \boldsymbol{X} = 0, \tag{11.28}$$

with this orientation reflected in Figure 11.1. We are also led to the corresponding linear momentum

$$\boldsymbol{P} = m\,\boldsymbol{V} = m\,\boldsymbol{\Omega} \times \boldsymbol{X}. \tag{11.29}$$

Evidently, motion that is further away from the rotational axis has a larger velocity magnitude (speed) for a given angular velocity, and thus a large linear momentum. This property accords with our experience on a merry-go-round, in which there is a higher speed at the outer rim of the merry-go-round relative to points near the center.

11.2.3 Rigid-body rotation of an arbitrary vector

The results from Section 11.2.2, in particular the key result in equation (11.27), hold for any vector undergoing rigid-body rotation with a fixed origin. This result appears many times in this book, thus motivating us to here discuss it a bit further from slightly complementary perspectives. Indeed, we offer yet another derivation in Section 11.4.2 when studying rotating reference frames.

Note that although we consider the position vector, $\boldsymbol{X}(t)$, derivations in this subsection are general, so that the results hold for an arbitrary vector of fixed magnitude that rotates about a fixed origin.

Proof that $\boldsymbol{X} \cdot \mathrm{d}\boldsymbol{X}/\mathrm{d}t = 0$ for rigid-body rotations

The rigid-body rotation of a vector does not change the vector's magnitude, so that

$$|\boldsymbol{X}(t)| = |\boldsymbol{X}(t + \delta t)|, \tag{11.30}$$

where δt is a small time increment during which the vector experiences a rigid-body rotation. The condition (11.30) can be written in the equivalent form

$$\frac{\mathrm{d}(\boldsymbol{X} \cdot \boldsymbol{X})}{\mathrm{d}t} = 0, \tag{11.31}$$

which then leads to the constraint

$$\boldsymbol{X} \cdot \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = 0. \tag{11.32}$$

Evidently, the time derivative of a vector undergoing a rigid-body rotation about a fixed origin is itself perpendicular to the vector.

Geometric derivation of $\mathrm{d}\boldsymbol{X}/\mathrm{d}t = \boldsymbol{\Omega} \times \boldsymbol{X}$ for rigid-body rotations

In Figure 11.2 we consider the vector at two time instances, $\boldsymbol{X}(t+\delta t)$ and $\boldsymbol{X}(t)$, with the change in the vector generated by an infinitesimal rotation around the axis defined by the angular velocity vector, $\boldsymbol{\Omega}$. Evidently, Figure 11.2 reveals that the infinitesimal difference, $\boldsymbol{X}(t+\delta t)-\boldsymbol{X}(t)$, equals to the vector cross product of the angular velocity with the vector

$$\boldsymbol{X}(t + \delta t) - \boldsymbol{X}(t) = \delta t\, \boldsymbol{\Omega} \times \boldsymbol{X}(t). \tag{11.33}$$

Dividing by δt leads to

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \boldsymbol{X}. \tag{11.34}$$

This time derivative satisfies the constraint (11.32) since $\boldsymbol{X} \cdot (\boldsymbol{\Omega} \times \boldsymbol{X}) = 0$, meaning that the magnitude of the vector indeed remains fixed. It is via equation (11.34) that we say $\boldsymbol{\Omega}$ generates rotations of $\boldsymbol{X}$.

Analytical derivation of $\mathrm{d}\boldsymbol{X}/\mathrm{d}t = \boldsymbol{\Omega} \times \boldsymbol{X}$ for rigid-body rotations

Let the direction of the angular velocity, $\boldsymbol{\Omega}$, be vertical, and let $\boldsymbol{X}$ be confined to the horizontal plane. In a time increment, δt, the vector is rotated by an angle

$$\delta\vartheta = |\boldsymbol{\Omega}|\, \delta t. \tag{11.35}$$

In the limit of small $\delta\vartheta$, the difference vector, $\boldsymbol{X}(t + \delta t) - \boldsymbol{X}(t)$, is perpendicular to $\boldsymbol{X}(t)$ and is of magnitude equal to the arc length

$$\delta s = |\boldsymbol{X}(t)|\, \delta\vartheta = |\boldsymbol{X}(t)|\, |\boldsymbol{\Omega}|\, \delta t. \tag{11.36}$$

FIGURE 11.2: The change in a vector under a pure rotation leaves its origin fixed and the vector magnitude unchanged, $|\boldsymbol{X}(t)| = |\boldsymbol{X}(t+\delta t)|$. Only the vector direction changes by the angle $\delta\vartheta = \Omega\,\delta t$. Infinitesimal changes generated by the angular velocity $\boldsymbol{\Omega}$ lead to the vector differences $\boldsymbol{X}(t+\delta t) - \boldsymbol{X}(t) = \delta t\,\boldsymbol{\Omega}\times\boldsymbol{X}(t)$. Evidently, $\boldsymbol{\Omega}$ generates the rotation of vectors around its axis.

Observe that the vector $\boldsymbol{\Omega}\times\boldsymbol{X}(t)$ points in the same direction as $\boldsymbol{X}(t+\delta t) - \boldsymbol{X}(t)$ and is of length $|\boldsymbol{X}(t)|\,|\boldsymbol{\Omega}|$. We conclude that

$$\boldsymbol{X}(t+\delta t) - \boldsymbol{X}(t) = \boldsymbol{\Omega}\times\boldsymbol{X}(t)\,\delta t. \tag{11.37}$$

Dividing through by δt and taking the limit $\delta t \to 0$ gives

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \boldsymbol{\Omega}\times\boldsymbol{X}. \tag{11.38}$$

The proof for the case in which $\boldsymbol{\Omega}$ has a component along $\boldsymbol{X}$ is a straightforward generalization. The rotation of the trajectory is still confined to a plane, but only the component of $\boldsymbol{\Omega}$ normal to $\boldsymbol{X}$ generates rotation.

11.2.4 Angular momentum of rigid-body rotations

The *angular momentum* is the moment of the linear momentum

$$\boldsymbol{L} = \boldsymbol{X}\times\boldsymbol{P}. \tag{11.39}$$

Newton's second law (11.4) leads to the time derivative

$$\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{X}\times\boldsymbol{F}, \tag{11.40}$$

where $\dot{\boldsymbol{X}}\times\boldsymbol{P} = \dot{\boldsymbol{X}}\times m\,\dot{\boldsymbol{X}} = 0$. The cross product, $\boldsymbol{X}\times\boldsymbol{F}$, is the *torque* acting on the system relative to the chosen origin, with torques having dimensions of a force times a length. Equation (11.40) leads to our second conservation law: a particle has a constant angular momentum when experiencing zero torques, with this statement dependent on the choice of origin for the angular momentum and the corresponding torques.[5]

Inserting the rigid-body velocity (11.27) into the angular momentum (11.39) renders

$$\boldsymbol{L} = \boldsymbol{X}\times\boldsymbol{P} = m\,\boldsymbol{X}\times(\boldsymbol{\Omega}\times\boldsymbol{X}) = m\left[\boldsymbol{\Omega}\,|\boldsymbol{X}|^2 - \boldsymbol{X}\,(\boldsymbol{\Omega}\cdot\boldsymbol{X})\right] \equiv \mathbb{M}\cdot\boldsymbol{\Omega}. \tag{11.41a}$$

[5] We emphasize that angular momentum, torque, and angular velocity, are each defined relative to a chosen origin and chosen axis. For geophysical motion, the natural origin is the center of the planet, with angular momentum and torques computed relative to the polar rotation axis. We return to these ideas in Section 14.6.

In the final equality we introduced the moment of inertia (a symmetric rank two tensor) for a point particle, with components given by

$$\mathbb{M}_{ij} = m\,(\boldsymbol{X}\cdot\boldsymbol{X}\,\delta_{ij} - X_i\,X_j). \tag{11.42}$$

The moment of inertia tensor measures the inertia appropriate for determining angular momentum relative to a rotational axis. We encounter the moment of inertia tensor for a continuous fluid in Section 38.9.4 when studying the angular momentum of a region of fluid (see equation (38.76)).

The utility and relevance of angular momentum stems from its conservation for systems exhibiting rotational symmetry about special points or special directions. For example, motion on a smooth sphere exhibits rotational symmetry with respect to the center of the sphere. Consequently, all components of angular momentum for a particle are constant in the absence of externally applied torques. For motion around a smooth rotating sphere, the rotational axis breaks the three dimensional isotropy so that we only have a single angular momentum conservation; namely, the *axial angular momentum*. We study the connection between symmetry and conservation laws in Chapter 14, with particular focus on axial angular momentum in Section 14.6.

11.2.5 Kinetic energy of rigid-body rotations

If the particle is undergoing rigid-body rotational motion so that $\boldsymbol{V} = \boldsymbol{\Omega}\times\boldsymbol{X}$ (equation (11.27)), then the kinetic energy of the particle is given by

$$\begin{aligned}
(2/m)\,K &= V_i\,V_i && (11.43a)\\
&= \epsilon_{ijk}\,\Omega_j\,X_k\,\epsilon_{ist}\,\Omega_s\,X_t && (11.43b)\\
&= \epsilon_{ijk}\,\epsilon_{ist}\,\Omega_j\,X_k\,\Omega_s\,X_t && (11.43c)\\
&= (\delta_{js}\,\delta_{kt} - \delta_{jt}\,\delta_{ks})\,\Omega_j\,X_k\,\Omega_s\,X_t && (11.43d)\\
&= (\boldsymbol{X}\cdot\boldsymbol{X})\,(\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}) - (\boldsymbol{X}\cdot\boldsymbol{\Omega})^2. && (11.43e)
\end{aligned}$$

Introducing the moment of inertia tensor (11.42) renders the kinetic energy

$$K = (1/2)\,\boldsymbol{\Omega}\cdot\mathbb{M}\cdot\boldsymbol{\Omega} = (1/2)\,\Omega_i\,\mathbb{M}_{ij}\,\Omega_j. \tag{11.44}$$

11.3 Accelerated and non-rotating reference frames

Inertial reference frames have a special status in Newtonian mechanics since it is in these reference frames that Newton's second law holds as per equations (11.4) or (11.5). Inertial reference frames are not accelerating, and as such they are related by the Galilean transformations considered in Section 11.1.3. Inertial reference frames are an idealization only approximately met in practice. For motion taking place within many terrestrial laboratories, the earth or *laboratory reference frame* provides a good approximation to an inertial reference frame. However, when the size of the physical system increases, and/or the length scale of the motion increases, then we must account for the earth's rotation. This is the situation holding for most of the geophysical fluid motions of concern in this book.

In this section we initiate our study of non-inertial reference frames by working in a frame that is accelerating along a straight line without turning (i.e. no rotation), such as when observing motion from an train accelerating on a straight track. We follow this study in Section 11.4 by examining motion from a rotating reference frame that has a fixed origin, thus allowing us to make use of the rigid-body rotating mechanics from Section 11.2.

11.3.1 Reference frame induced accelerations and forces

Let $\mathcal{R}$ be an inertial reference frame so that Newton's law of motion takes on the familiar form (11.5)

$$m\,\dot{\boldsymbol{V}} = \boldsymbol{F}, \tag{11.45}$$

where $\boldsymbol{F}$ is the net force vector, with such forces arising from force fields (e.g., gravity or electromagnetic) or from contact forces that arise from interactions between bodies. Now consider another reference frame, $\mathcal{R}^*$, that moves with velocity $\boldsymbol{V}^{\text{frame}}$ relative to $\mathcal{R}$, and let $\boldsymbol{V}^*$ be the velocity of a particle measured relative to the $\mathcal{R}^*$. Accordingly, the velocity of a particle is decomposed into two terms

$$\boldsymbol{V} = \boldsymbol{V}^{\text{frame}} + \boldsymbol{V}^*. \tag{11.46}$$

Making use of this relation in Newton's law (11.45), and rearranging, leads to

$$m\,\dot{\boldsymbol{V}}^* = m\,(\dot{\boldsymbol{V}} - \dot{\boldsymbol{V}}^{\text{frame}}) = \boldsymbol{F} - m\,\dot{\boldsymbol{V}}^{\text{frame}}. \tag{11.47}$$

If $\dot{\boldsymbol{V}}^{\text{frame}}$ vanishes, then Newton's law (11.47) remains form invariant and we refer to $\mathcal{R}^*$ as another inertial reference frame that is realized via a Galilean transformation from the original (see Section 11.1.3 for Galilean transformations between two inertial reference frames). For the more general case with a non-vanishing $\dot{\boldsymbol{V}}^{\text{frame}}$, we encounter an extra force in equation (11.47) when working in a non-inertial reference frame

$$\boldsymbol{F}^{\text{frame}} = -m\,\boldsymbol{A}^{\text{frame}} \equiv -m\,\dot{\boldsymbol{V}}^{\text{frame}}. \tag{11.48}$$

That is, by choosing to write equation (11.47) in the form of Newton's law, but from the perspective of the non-inertial reference frame, we must include a force that arises solely due to acceleration of the reference frame

$$m\,\dot{\boldsymbol{V}}^* = \boldsymbol{F} + \boldsymbol{F}^{\text{frame}}. \tag{11.49}$$

To appreciate the minus sign in equation (11.48), consider the backward force felt on the driver when accelerating forward in a car.

Equation (11.48) is somewhat overloaded. Namely, when the non-inertial reference frame is rotating, then the coordinate basis vectors are time dependent, and that time dependence must be considered when transforming vectors. As a result, we only make direct use of equation (11.48) when studying linear accelerating frames in Section 11.3.3, since in this case the basis vectors in the two reference frames are the same. The case of rotating reference frames in Section 11.4 requires a bit more work.

11.3.2 A comment on terminology

The reference frame induced force, $\boldsymbol{F}^{\text{frame}}$, from equation (11.48) is sometimes called a "fictitious force" or a "pseudo-force". We eschew that terminology since reference frame induced forces can play a dominant role in describing motion viewed from the non-inertial reference frame. So from the non-inertial reference frame perspective, there is nothing fictional about them $\boldsymbol{F}^{\text{frame}}$.

Chapter 12 of *French* (1971) refers to $\boldsymbol{F}^{\text{frame}}$ as an *inertial force* along with the corresponding *inertial acceleration*. As noted on pages 493-494 of *French* (1971), such forces that are experienced by an object due to the acceleration of a reference frame are "forces of inertia" that allow one to return Newton's law back to its familiar form found in inertial reference frames. Though ubiquitous in the literature, this terminology is prone to confusion since these so-called inertial forces arise due to non-inertial motion of the reference frame, and as such would more clearly

be referred to as "non-inertial terms" or "non-inertial forces" (see Section 9.3 of *Marion and Thornton* (1988)). We aim to avoid confusion by being somewhat pedantic in this book when discussing forces induced by a non-inertial reference frame.

11.3.3 Simple pendulum in an accelerating train

Consider a non-inertial reference frame that accelerates along a line without turning (i.e., no rotation). For example, we feel a backwards acceleration while the vehicle accelerates forward, and the converse while the vehicle slows to a stop. The opposite sense of the acceleration is accounted for by the minus sign in the expression (11.48).

As a specific example, consider a pendulum with constant mass, m, on a massless string of length L. Hang the pendulum from the top of a train car in a gravity field and assume the train has an acceleration, $\dot{\boldsymbol{V}}^{\text{frame}}$, along a straight track. When viewed from the inertial reference frame, the pendulum satisfies Newton's law in the familiar form

$$m\,\dot{\boldsymbol{V}} = \boldsymbol{F}. \tag{11.50}$$

The force, $\boldsymbol{F}$, arises from the pendulum's weight, $m\,\boldsymbol{g}$, as well as the string tension, $\boldsymbol{T}$, so that

$$m\,\dot{\boldsymbol{V}} = \boldsymbol{T} + m\,\boldsymbol{g}. \tag{11.51}$$

When viewed in the accelerating reference frame the equation of motion takes the form

$$m\,\dot{\boldsymbol{V}}^* = \boldsymbol{T} + m\,\boldsymbol{g} - m\,\dot{\boldsymbol{V}}^{\text{frame}} = \boldsymbol{T} + m\,(\boldsymbol{g} - \dot{\boldsymbol{V}}^{\text{frame}}). \tag{11.52}$$

Since the same mass, m, multipled both the gravitational force and the force due to the accelerating reference frame, we can define an effective gravity by writing

$$m\,\dot{\boldsymbol{V}}^* = \boldsymbol{T} + m\,\boldsymbol{g}^{\text{eff}} \quad \text{with} \quad \boldsymbol{g}^{\text{eff}} = \boldsymbol{g} - \dot{\boldsymbol{V}}^{\text{frame}}. \tag{11.53}$$

The effective gravity is not vertical when the reference frame accelerates. For example, if the reference frame accelerates in the $+\hat{\boldsymbol{x}}$ direction, then

$$\boldsymbol{g}^{\text{eff}} = -g\,\hat{\boldsymbol{z}} - \dot{V}^{\text{frame}}\,\hat{\boldsymbol{x}} = -g\,(\hat{\boldsymbol{z}} + \hat{\boldsymbol{x}}\,\dot{V}^{\text{frame}}/g). \tag{11.54}$$

We depict this situation in Figure 11.3.

What happens when the acceleration of the pendulum vanishes in the inertial reference frame? In this case the string tension exactly balances the weight so that from equation (11.51) we find

$$\boldsymbol{T} = -m\,\boldsymbol{g} \quad \Longleftarrow \quad \text{no acceleration in inertial frame, } \mathcal{R}. \tag{11.55}$$

Evidently, the pendulum comes to rest in the inertial frame with a string tension that exactly balances the vertical gravitational force acting on the pendulum mass. Hence, the pendulum hangs vertically.

The same question posed from the non-inertial reference frame leads to the distinct string tension

$$\boldsymbol{T} = -m\,\boldsymbol{g}^{\text{eff}} \quad \Longleftarrow \quad \text{no acceleration in non-inertial frame, } \mathcal{R}^*. \tag{11.56}$$

That is, the string tension now balances the effective gravity, so that the resting pendulum is not vertical but instead it is aligned with the effective gravity. We can readily find the angle of the resting pendulum, relative to the vertical, through the expression (11.54) for the effective gravity,

FIGURE 11.3: A pendulum oscillating from the ceiling of a train car, with the train moving with velocity $\boldsymbol{V}^{\text{frame}} = \hat{\boldsymbol{x}}\,|\boldsymbol{V}^{\text{frame}}|$. Forces acting on the pendulum arise from the string tension, $\boldsymbol{T}$, and the weight, $\boldsymbol{g}\,m = -\hat{\boldsymbol{z}}\,g\,m$. In the accelerating (non-inertial) reference frame, the additional force appears, $-\hat{\boldsymbol{x}}\,m\,|\boldsymbol{V}^{\text{frame}}|$. When viewed in the accelerating reference frame, the pendulum reaches its equilibrium ($\dot{\boldsymbol{V}}^{*} = 0$) at an angle satisfying $\tan\varphi^{\text{equil}} = |\dot{\boldsymbol{V}}^{\text{frame}}|/g$.

so that

$$\tan\varphi^{\text{equil}} = |\dot{\boldsymbol{V}}^{\text{frame}}|/g. \tag{11.57}$$

11.4 Rigid-body rotating reference frames

We now consider a rotating reference frame. For simplicity, as well as to connect to the terrestrial case, assume rotation is around a fixed axis that passes through a fixed origin, such as that depicted in Figure 11.4. In this manner, the reference frame rotates as a rigid-body, thus enabling use of the kinematics from Section 11.2.[6]

In this chapter we make use of Cartesian coordinates for both the inertial reference frame, $\mathcal{R}$, and the rigid-body rotating reference frame, $\mathcal{R}^{*}$, with orientation chosen so that the basis vectors of the rotating frame rotate counter-clockwise around the vertical axis, $\hat{\boldsymbol{z}}$. As we see in this section, a proper accounting for the basis vector rotation is critical for computing non-inertial accelerations.

11.4.1 Incorrect calculation of Coriolis acceleration

Directly plugging into the expression (11.48) leads to the force in the non-inertial reference frame

$$\begin{aligned}
\boldsymbol{F}^{\text{frame}} &= -m\,\dot{\boldsymbol{V}}^{\text{rigid}} && (11.58\text{a})\\
&= -m\,\frac{\mathrm{d}(\boldsymbol{\Omega}\times\boldsymbol{X})}{\mathrm{d}t} && (11.58\text{b})\\
&= -m\,\boldsymbol{\Omega}\times\boldsymbol{V} && (11.58\text{c})\\
&= -m\,\boldsymbol{\Omega}\times(\boldsymbol{V}^{\text{rigid}}+\boldsymbol{V}^{*}). && (11.58\text{d})
\end{aligned}$$

The first term is the correct expression for the centrifugal acceleration (see Figure 11.5), yet the second term is missing a factor of two for the Coriolis acceleration. As hinted at following

[6]Rigid-body rotating reference frame is what one generally means when studying rotating physics. However, there are more general forms of rotation, whereby that angular rotation is a function of space and time. We do not consider time dependent rotating frames in this book. However, the rigid-body frame of the earth's rotation is experienced as a latitudinally dependent rotation rate due to the sphericity of the planet.

$$\frac{\mathrm{d}\hat{\boldsymbol{x}}}{\mathrm{d}t} = +\Omega\,\hat{\boldsymbol{y}}$$
$$\frac{\mathrm{d}\hat{\boldsymbol{y}}}{\mathrm{d}t} = -\Omega\,\hat{\boldsymbol{x}}$$

FIGURE 11.4: Depicting the coordinate axes in an inertial reference frame, $(\hat{\boldsymbol{x}}^{\text{inertial}}, \hat{\boldsymbol{y}}^{\text{inertial}}, \hat{\boldsymbol{z}}^{\text{inertial}})$, and a corresponding rigid-body rotating reference frame, $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$. The origin for the two reference frames is the same, and the rotation is around the vertical axis so that $\hat{\boldsymbol{z}} = \hat{\boldsymbol{z}}^{\text{inertial}}$ and $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$. Left panel: perspective view of the inertial and rotating reference frames. Middle panel: view of the horizontal plane and the rotation of the horizontal basis vectors in the rotating reference frame. Right panel: expressing the time derivatives of the horizontal basis vectors according to the rigid-body rotation equation (11.60).

equation (11.48), the error arises since the coordinate basis vectors change as the reference frame rotates, and this time dependence must be considered when computing the acceleration seen in a non-inertial reference frame.

11.4.2 Rigid-body rotation of an arbitrary vector

We here offer yet another means to derive the key result from Section 11.2.3 concerning the time derivative of a vector undergoing rigid-body rotation around a fixed origin. For this purpose, consider a vector that is measured in the rotating reference frame and represented using Cartesian coordinates so that

$$\boldsymbol{Q} = \sum_{i*=1}^{3} Q^{i*}\,\hat{\boldsymbol{e}}_{i*} = Q^{i*}\,\hat{\boldsymbol{e}}_{i*}, \tag{11.59}$$

where the second equality made use of Einstein summation convention (Section 1.2). Also, we introduced the rotating reference frame Cartesian basis vectors, $\hat{\boldsymbol{e}}_{1*} = \hat{\boldsymbol{x}}$, $\hat{\boldsymbol{e}}_{2*} = \hat{\boldsymbol{y}}$, and $\hat{\boldsymbol{e}}_{3*} = \hat{\boldsymbol{z}}$, which are rigidly rotating with the reference frame. Following the discussion in Section 11.2.2, rigid-body rotation of the basis vectors leads to a time derivative according to equation (11.26), so that

$$\frac{\mathrm{d}\hat{\boldsymbol{e}}_{i*}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \hat{\boldsymbol{e}}_{i*}. \tag{11.60}$$

Hence, the time derivative of $\boldsymbol{Q}$, when represented in the rotating reference frame, is given by two terms,

$$\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t} = \frac{\mathrm{d}Q^{i*}}{\mathrm{d}t}\,\hat{\boldsymbol{e}}_{i*} + Q^{i*}\,(\boldsymbol{\Omega} \times \hat{\boldsymbol{e}}_{i*}) = \frac{\mathrm{d}Q^{i*}}{\mathrm{d}t}\,\hat{\boldsymbol{e}}_{i*} + \boldsymbol{\Omega} \times \boldsymbol{Q}. \tag{11.61}$$

The first expression on the right hand side is the time derivative of the vector's components as measured in the rotating reference frame, which we write as

$$\dot{\boldsymbol{Q}}^{*} \equiv \frac{\mathrm{d}Q^{i*}}{\mathrm{d}t}\,\hat{\boldsymbol{e}}_{i*}. \tag{11.62}$$

The second term in equation (11.61) arises from rigid-body rotation of the rotating reference frame's coordinate basis.

FIGURE 11.5: Depicting the kinematics of a rigid-body rotating reference frame, with rotation around a fixed vertical axis that passes through a fixed origin. The orientation is geophysically motivated as per Figure 10.1. In addition to the angular velocity, $\boldsymbol{\Omega}$, and rigid-body velocity, $\boldsymbol{V}^{\text{rigid}} = \boldsymbol{\Omega} \times \boldsymbol{X}$, both depicted in Figure 11.1, we also show the centrifugal acceleration, $\boldsymbol{A}^{\text{cent}} = -\boldsymbol{\Omega} \times \boldsymbol{V}^{\text{rigid}} = -\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \boldsymbol{X})$, that points outward away from the rotational axis.

11.4.3 Coriolis and centrifugal accelerations

We can make use of equation (11.61) for an arbitrary vector, including the particle's position vector. In this case the velocity of the particle is decompsed into

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \frac{\mathrm{d}X^{i*}}{\mathrm{d}t}\,\hat{\boldsymbol{e}}_{i*} + \boldsymbol{\Omega} \times \boldsymbol{X} = \boldsymbol{V}^* + \boldsymbol{V}^{\text{rigid}}. \tag{11.63}$$

Evidently, the velocity as measured in the inertial frame equals to the velocity measured in the non-inertial reference frame, $\boldsymbol{V}^*$, plus the rigid-body rotating velocity,

$$\boldsymbol{V}^{\text{rigid}} = \boldsymbol{\Omega} \times \boldsymbol{X}. \tag{11.64}$$

Taking the second derivative of the position vector leads to the decomposition of the acceleration measured in the inertial reference frame

$$\begin{aligned}
\frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2} &= \frac{\mathrm{d}^2X^{i*}}{\mathrm{d}t^2}\,\hat{\boldsymbol{e}}_{i*} + \frac{\mathrm{d}X^{i*}}{\mathrm{d}t}\,(\boldsymbol{\Omega} \times \hat{\boldsymbol{e}}_{i*}) + \boldsymbol{\Omega} \times \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} && \text{(11.65a)}\\
&= \boldsymbol{A}^* + \boldsymbol{\Omega} \times \boldsymbol{V}^* + \boldsymbol{\Omega} \times (\boldsymbol{V}^* + \boldsymbol{V}^{\text{rigid}}) && \text{(11.65b)}\\
&= \boldsymbol{A}^* + 2\,\boldsymbol{\Omega} \times \boldsymbol{V}^* + \boldsymbol{\Omega} \times \boldsymbol{V}^{\text{rigid}}. && \text{(11.65c)}
\end{aligned}$$

Hence, the acceleration as measured in the rigid-body rotating reference frame is given by

$$\boldsymbol{A}^* = \boldsymbol{A}\ \underbrace{-2\,\boldsymbol{\Omega} \times \boldsymbol{V}^*}_{\text{Coriolis}}\ \underbrace{-\boldsymbol{\Omega} \times \boldsymbol{V}^{\text{rigid}}}_{\text{centrifugal}}. \tag{11.66}$$

We here identified the Coriolis and centrifugal accelerations

$$\boldsymbol{A}^{\text{Coriolis}} = -2\,\boldsymbol{\Omega} \times \boldsymbol{V}^* \quad \text{and} \quad \boldsymbol{A}^{\text{centrifugal}} = -\boldsymbol{\Omega} \times \boldsymbol{V}^{\text{rigid}} = -\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \boldsymbol{X}), \tag{11.67}$$

with both of these accelerations arising from the rigid-body rotation of the non-inertial reference frame. We have much to say in this book about these accelerations, particularly as realized by the rotating earth.

11.5 Newtonian mechanics for a system of particles

We here extend the single particle mechanics from Section 11.1 to the case of N particles with mass, $m_{(i)}$, position, $\boldsymbol{X}_{(i)}(t)$, and velocity, $\boldsymbol{V}_{(i)}(t) = \mathrm{d}\boldsymbol{X}_{(i)}/\mathrm{d}t$, where i is an integer labeling the particles and we assume the particle mass remains fixed in time.[7] In the following, we find it useful to introduce the total mass of the system as well as the vector center of mass according to

$$M = \sum_{i=1}^{N} m_{(i)} \quad \text{and} \quad \boldsymbol{X} = \frac{1}{M} \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)}. \tag{11.68}$$

11.5.1 Forces on the particles

We conceive of two contributions to the forces acting on each particle. The first arises from *external force* fields that are independent of the N particles, $\boldsymbol{F}_{(i)}^{(\mathrm{ext})}$. For example, we may consider a system of particles moving in the gravitational field of the planet, with the planet's gravitational field assumed to be independent of the particles. The second force arises from the interactions between the particles, which we refer to as an *internal force*. We write the internal force vector as $\boldsymbol{F}_{(ji)}$, which is taken to be the force on particle i due to interactions with particle j. We furthermore assume that there are no self-forces so that

$$\boldsymbol{F}_{(ii)} = 0. \tag{11.69}$$

The net force acting on particle i is thus written

$$\boldsymbol{F}_{(i)} = \boldsymbol{F}_{(i)}^{(\mathrm{ext})} + \sum_{j=1}^{N} \boldsymbol{F}_{(ji)}, \tag{11.70}$$

and the net force acting on the full system of particles is

$$\sum_{i=1}^{N} \boldsymbol{F}_{(i)} = \sum_{i=1}^{N} \boldsymbol{F}_{(i)}^{(\mathrm{ext})} + \sum_{i=1}^{N}\sum_{j=1}^{N} \boldsymbol{F}_{(ji)}. \tag{11.71}$$

The final sum can be written

$$\sum_{i=1}^{N}\sum_{j=1}^{N} \boldsymbol{F}_{(ji)} = \frac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N} (\boldsymbol{F}_{(ji)} + \boldsymbol{F}_{(ij)}), \tag{11.72}$$

where, again, $\boldsymbol{F}_{(ji)}$ is the force on particle i due to interactions with particle j, and $\boldsymbol{F}_{(ij)}$ is the force on particle j due to interactions with particle i. This identity follows since the sums are finite so that limits on double sums can be swapped.

11.5.2 Weak and strong form of Newton's third law

Newton's third law states that the force acting on particle i due to particle j is equal to, yet oppositely directed, the force acting on particle j due to particle i:

$$\boldsymbol{F}_{(ij)} = -\boldsymbol{F}_{(ji)}. \tag{11.73}$$

[7] We place the particle index within parentheses to emphasize that it is not a tensor index. Correspondingly, particle indices do not follow the summation convention of tensor indices.

For those forces satisfying Newton's third law, the total force acting on the N particle system arises from just the external force, since the internal forces cancel pairwise

$$\sum_{i=1}^{N}\sum_{j=1}^{N}\boldsymbol{F}_{(ij)} = \sum_{i=1}^{N}\boldsymbol{F}_{(i)}^{(\mathrm{ext})} = \boldsymbol{F}^{(\mathrm{ext})}. \tag{11.74}$$

As discussed in Section 13.10.2, the gravitational force acting between two point masses offers an example force that satisfies Newton's third law, in which case the force is given by the inverse square expression

$$\boldsymbol{F}_{(ji)} = -\frac{G\, m_{(i)}\, m_{(j)}\, (\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)})}{|\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}|^3} = -\boldsymbol{F}_{(ji)}, \tag{11.75}$$

where G is Newton's gravitational constant discussed in Section 13.10.1. Notice how the gravitational force acts along the line connecting the two particles, so that

$$(\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)} = 0. \tag{11.76}$$

The electrostatic force acting on charged particles in an electric field is given by Coulombs law, which is also an inverse squared force and that acts along the line between the two particles.

Newton's gravity force and the Coulomb electrostatic force are known as *central forces*. Central forces are said to satisfy the *strong form* of Newton's third law, in that both $\boldsymbol{F}_{(ij)} = -\boldsymbol{F}_{(ji)}$ and $(\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)} = 0$. Slightly more general forces arise that satisfy $\boldsymbol{F}_{(ji)} = -\boldsymbol{F}_{(ij)}$ and yet $(\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)} \neq 0$, with such forces said to satisfy the *weak form* of Newton's third law:

$$\boldsymbol{F}_{(ij)} = -\boldsymbol{F}_{(ji)} \quad \text{and} \quad (\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)} = 0 \Longrightarrow \text{central force; strong 3rd law} \tag{11.77a}$$

$$\boldsymbol{F}_{(ij)} = -\boldsymbol{F}_{(ji)} \quad \text{and} \quad (\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)} \neq 0 \Longrightarrow \text{non-central force; weak 3rd law.} \tag{11.77b}$$

Any force that depends on the velocity of the particle is not a central force.[8] The distinction between the weak and strong form of Newton's third law becomes important when studying particle angular momentum in Section 11.5.4. When studying stresses in fluids in Chapter 26, we assume the strong form of Newton's third law.

11.5.3 Newton's second law of motion

The linear momentum of a particle is its mass times the velocity

$$\boldsymbol{P}_{(i)} = m_{(i)}\, \boldsymbol{V}_{(i)} \quad \text{no implied summation.} \tag{11.78}$$

Assuming the mass of the particle is constant, the corresponding equation of motion is given by Newton's second law

$$\dot{\boldsymbol{P}}_{(i)} = m_{(i)}\, \dot{\boldsymbol{V}}_{(i)} = \boldsymbol{F}_{(i)}^{(\mathrm{ext})} + \sum_{j=1}^{N}\boldsymbol{F}_{(ji)}. \tag{11.79}$$

Assuming the internal forces satisfy either the weak or strong form of Newton's third law as in equations (11.77a)-(11.77b), we find that the total momentum for the N particle system evolves

[8] The force acting on a classical charged particle moving in an electromagnetic field is known as the Lorentz force. The Lorentz force depends on the velocity of the charged particle and so it is not a central force, with the Lorentz force only satisfying the weak form of Newton's third law. See page 45 of *Marion and Thornton* (1988) for more discussion.

according to just the total external force

$$\dot{\boldsymbol{P}} = \sum_{i=1}^{N} \dot{\boldsymbol{P}}_{(i)} = \frac{\mathrm{d}^2}{\mathrm{d}t^2} \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)} = M\, \ddot{\boldsymbol{X}} = \boldsymbol{F}^{(\mathrm{ext})}. \tag{11.80}$$

That is, the time change in the total linear momentum is given by the total mass times the acceleration of the center of mass, which equals, through Newton's second and third laws, to the total external force acting on the system. We thus find that the center of mass maintains a fixed velocity if there is no net external force acting on the many particle system. This result accords with common experience whereby we cannot lift ourselves up by our own bootstraps.

11.5.4 Angular momentum

The total angular momentum for the many particle system is given by

$$\boldsymbol{L} = \sum_{i=1}^{N} \boldsymbol{L}_{(i)} = \sum_{i=1}^{N} \boldsymbol{X}_{(i)} \times \boldsymbol{P}_{(i)} = \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)} \times \boldsymbol{V}_{(i)}, \tag{11.81}$$

and its time derivative is given by

$$\dot{\boldsymbol{L}} = \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)} \times \dot{\boldsymbol{V}}_{(i)} = \sum_{i=1}^{N} \boldsymbol{X}_{(i)} \times \boldsymbol{F}_{(i)}^{(\mathrm{ext})} + \sum_{i=1}^{N} \sum_{j=1}^{N} \boldsymbol{X}_{(i)} \times \boldsymbol{F}_{(ji)}, \tag{11.82}$$

where we set $\dot{\boldsymbol{X}}_{(i)} \times \boldsymbol{V}_{(i)} = \dot{\boldsymbol{X}}_{(i)} \times \dot{\boldsymbol{X}}_{(i)} = 0$, and made use of the particle equation of motion (11.79). We identify the term

$$\boldsymbol{\Gamma}^{(\mathrm{ext})} \equiv \sum_{i=1}^{N} \boldsymbol{X}_{(i)} \times \boldsymbol{F}_{(i)}^{(\mathrm{ext})} \tag{11.83}$$

as the total torque acting on the N particle system arising from the external force acting on each particle. The internal torque contribution can be written

$$\sum_{i=1}^{N} \sum_{j=1}^{N} \boldsymbol{X}_{(i)} \times \boldsymbol{F}_{(ji)} = \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} (\boldsymbol{X}_{(i)} \times \boldsymbol{F}_{(ji)} + \boldsymbol{X}_{(j)} \times \boldsymbol{F}_{(ij)}) = \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} (\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}) \times \boldsymbol{F}_{(ji)}, \tag{11.84}$$

where the first equality follows from interchanging particle indices, and the second equality follows from the weak form of Newton's third law given by equation (11.77b). If we furthermore assume the force satisfies the strong form of Newton's third law (11.77a), as for a central force, then the total angular momentum evolves according to just the total external torque

$$\dot{\boldsymbol{L}} = \boldsymbol{\Gamma}^{(\mathrm{ext})}. \tag{11.85}$$

That is, we require the strong form of Newton's third law to ensure that the total angular momentum is only affected by the torques created by external forces. If the forces only satisfy the weak form of Newton's third law, then evolution of the total angular momentum is generally affected by internal torques. Such torques arise in the presence of nonmechanical forces, such as a magnetic force between charged particles when the electromagnetic field contains intrinsic angular momentum. We have no occasion to study internal torques in this book, so that all physical systems are assumed to satisfy the strong form of Newton's third law.

11.5.5 Center of mass coordinates

It is sometimes preferable to move to an internal set of coordinates that dispenses with the arbitrary fixed origin. In this case we place the coordinate origin at the moving center of mass,

$$\boldsymbol{X}_{(i)} = \boldsymbol{X} + \boldsymbol{X}'_{(i)}, \tag{11.86}$$

with a corresponding velocity expression

$$\boldsymbol{V}_{(i)} = \boldsymbol{V} + \boldsymbol{V}'_{(i)}. \tag{11.87}$$

Making use of the definition of the center of mass coordinate (11.68), we readily find that the relative position and relative velocity each have a vanishing mass weighted sum over all the particles

$$\sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}'_{(i)} = 0 \quad \text{and} \quad \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{V}'_{(i)} = 0. \tag{11.88}$$

11.5.6 Angular momentum in center of mass coordinates

The total angular momentum of the N particle system, expressed in the center of mass coordinates, is given by

$$\boldsymbol{L} = \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)} \times \boldsymbol{V}_{(i)} \tag{11.89a}$$

$$= \sum_{i=1}^{N} m_{(i)}\, (\boldsymbol{X} + \boldsymbol{X}'_{(i)}) \times (\boldsymbol{V} + \boldsymbol{V}'_{(i)}) \tag{11.89b}$$

$$= M\, \boldsymbol{X} \times \boldsymbol{V} + \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}'_{(i)} \times \boldsymbol{V}'_{(i)} \tag{11.89c}$$

$$= \boldsymbol{L}^{(\mathrm{cm})} + \boldsymbol{L}', \tag{11.89d}$$

where we used equation (11.88) to reach the third equality. The first term is the angular momentum of the center of mass relative to the fixed origin

$$\boldsymbol{L}^{(\mathrm{cm})} = M\, \boldsymbol{X} \times \boldsymbol{V}, \tag{11.90}$$

whereas the second term is the internal angular momentum measured relative to the center of mass

$$\boldsymbol{L}' = \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}'_{(i)} \times \boldsymbol{V}'_{(i)}. \tag{11.91}$$

Evolution of the center of mass angular momentum takes on the form

$$\dot{\boldsymbol{L}}^{(\mathrm{cm})} = M\, \boldsymbol{X} \times \dot{\boldsymbol{V}} = \boldsymbol{X} \times \boldsymbol{F}^{(\mathrm{ext})}, \tag{11.92}$$

with the right hand side the torque from the net external force computed relative to the center

of mass position. Correspondingly, evolution of the total angular momentum is

$$\dot{\boldsymbol{L}} = \sum_{i=1}^{N} m_{(i)}\, \boldsymbol{X}_{(i)} \times \dot{\boldsymbol{V}}_{(i)} \tag{11.93a}$$

$$= \sum_{i=1}^{N} (\boldsymbol{X} + \boldsymbol{X}'_{(i)}) \times \boldsymbol{F}^{\text{ext}}_{(i)} \tag{11.93b}$$

$$= \boldsymbol{X} \times \boldsymbol{F}^{\text{ext}} + \sum_{i=1}^{N} \boldsymbol{X}'_{(i)} \times \boldsymbol{F}^{\text{ext}}_{(i)} \tag{11.93c}$$

$$= \dot{\boldsymbol{L}}^{(\text{cm})} + \dot{\boldsymbol{L}}'. \tag{11.93d}$$

We thus see that the rate of change for the angular momentum computed relative to the center of mass is given by the torques from the external forces applied to each particle, computed relative to the center of mass

$$\dot{\boldsymbol{L}}' = \sum_{i=1}^{N} \boldsymbol{X}'_{(i)} \times \boldsymbol{F}^{\text{ext}}_{(i)}. \tag{11.94}$$

11.5.7 Energy in center of mass coordinates

Making use of the identity (11.88), we find that the total kinetic energy is given by

$$K = \frac{1}{2}\sum_{i=1}^{N} m_{(i)}\, \boldsymbol{V}_{(i)} \cdot \boldsymbol{V}_{(i)} = \frac{M}{2}\boldsymbol{V}\cdot\boldsymbol{V} + \frac{1}{2}\sum_{i=1}^{N} m_{(i)}\, \boldsymbol{V}'_{(i)} \cdot \boldsymbol{V}'_{(i)} = K^{(\text{cm})} + K', \tag{11.95}$$

which is the sum of the center of mass kinetic energy, $K^{(\text{cm})}$, plus the kinetic energy of the internal motions relative to the center of mass, K'.

Consider two configurations of the N particle system, configuration A at time t_A and configuration B at time t_B. Let $\boldsymbol{X}_{(iA)}$ be the position of particle i in configuration A, and $\boldsymbol{X}_{(iB)}$ the position of this particle in configuration B, and assume the two configurations are connected by trajectories determined by the equation of motion for each particle. Extending our discussion of work in Section 11.1.4, we see that the work done by forces acting on the N particle system as it moves between these two configurations is given by

$$W_{AB} = \sum_{i=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \boldsymbol{F}_{(i)} \cdot \mathrm{d}\boldsymbol{x}_{(i)} \tag{11.96a}$$

$$= \sum_{i=1}^{N} \int_{t_A}^{t_B} \boldsymbol{F}_{(i)} \cdot \boldsymbol{V}_{(i)}\, \mathrm{d}t \tag{11.96b}$$

$$= \sum_{i=1}^{N} \int_{t_A}^{t_B} m_{(i)}\, \dot{\boldsymbol{V}}_{(i)} \cdot \boldsymbol{V}_{(i)}\, \mathrm{d}t \tag{11.96c}$$

$$= \frac{1}{2}\sum_{i=1}^{N} \int_{t_A}^{t_B} m_{(i)} \frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{V}_{(i)} \cdot \boldsymbol{V}_{(i)})\, \mathrm{d}t \tag{11.96d}$$

$$= K_A - K_B, \tag{11.96e}$$

where K_A and K_B are the kinetic energies in the two configurations.

Rather than making use of Newton's law of motion to introduce the kinetic energy, we can

decompose the force vector in the expression for work, thus giving

$$W_{AB} = \sum_{i=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \boldsymbol{F}_{(i)} \cdot \mathrm{d}\boldsymbol{x}_{(i)} \tag{11.97a}$$

$$= \sum_{i=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \boldsymbol{F}_{(i)}^{(\mathrm{ext})} \cdot \mathrm{d}\boldsymbol{x}_{(i)} + \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \boldsymbol{F}_{(ji)} \cdot (\mathrm{d}\boldsymbol{x}_{(i)} - \mathrm{d}\boldsymbol{x}_{(j)}), \tag{11.97b}$$

where the minus sign on the final term arises from Newton's third law satisfied by the internal forces. Now assume that both the internal and external forces are conservative, so that they can separately be written as the gradient of respective potential energies. For the external potential energy acting on particle i, we assume it is a function just of the position of that particle

$$\boldsymbol{F}_{(i)}^{\mathrm{ext}} = -\nabla_i P^{\mathrm{ext}}(\boldsymbol{X}_{(i)}), \tag{11.98}$$

where ∇_i is the gradient operator acting on the position in space $\boldsymbol{x}_{(i)}$ of the trajectory at a particular time, $\boldsymbol{x}_{(i)} = \boldsymbol{X}_{(i)}(t)$. Furthermore, assume the interparticle potential energy between particles i and j is a function just of the distance between the two particles, which is a property of central forces. In this case we have

$$\boldsymbol{F}_{(ji)} = -\nabla_{ij} P(|\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}|), \tag{11.99}$$

where ∇_{ij} is the gradient operator acting on the relative position $\boldsymbol{x}_{(i)} - \boldsymbol{x}_{(j)}$ of the two particles at a particular time instance. These assumptions then bring the work into the form

$$W_{AB} = -\sum_{i=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \nabla_i P^{(\mathrm{ext})} \cdot \mathrm{d}\boldsymbol{x}_{(i)} - \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \nabla_{ij} P \cdot (\mathrm{d}\boldsymbol{x}_{(i)} - \mathrm{d}\boldsymbol{x}_{(j)}) \tag{11.100a}$$

$$= -\sum_{i=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \mathrm{d}P_{(i)}^{(\mathrm{ext})} - \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} \int_{\boldsymbol{X}_{(iA)}}^{\boldsymbol{X}_{(iB)}} \mathrm{d}P(|\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}|) \tag{11.100b}$$

$$\equiv -[P^{(\mathrm{tot})}(A) - P^{(\mathrm{tot})}(B)], \tag{11.100c}$$

where the total potential energy is

$$P^{(\mathrm{tot})} = \sum_{i=1}^{N} P_{(i)}^{(\mathrm{ext})} + \frac{1}{2} \sum_{i=1}^{N} \sum_{j=1}^{N} P(|\boldsymbol{X}_{(i)} - \boldsymbol{X}_{(j)}|). \tag{11.101}$$

Combining this result and the expression of work in terms of kinetic energy leads to the conservation of mechanical energy for the conservative N particle system

$$K + P^{(\mathrm{tot})} = \text{constant}. \tag{11.102}$$

11.5.8 Comments and further reading

This section largely follows Section 2 of *Fetter and Walecka* (2003). Note that when considering a continuous fluid in Part V, the interparticle forces manifest as pressure and friction, whereas the external force is given by gravitation, planetary centrifugal, and planetary Corioliis. Furthermore, we always assume the fluids in this book satisfy the strong form of Newton's third law.

11.6 Exercises

EXERCISE 11.1: ACCELERATION WITH $\mathrm{d}\boldsymbol{\Omega}/\mathrm{d}t \neq 0$

Geophysical applications warrant taking the planetary rotation to be a constant vector, $\mathrm{d}\boldsymbol{\Omega}/\mathrm{d}t = 0$, and that assumption is made throughout this book. However, for some applications, such as for rotating machines, we cannot make that assumption. What extra term appears in the acceleration vector (11.48) when $\mathrm{d}\boldsymbol{\Omega}/\mathrm{d}t \neq 0$? Hint: rework the derivation of equation (11.65c) retaining $\mathrm{d}\boldsymbol{\Omega}/\mathrm{d}t \neq 0$.

Chapter 12

Analytical mechanics

In this chapter we formulate the equations describing classical particle motion according to *Lagrangian mechanics* as well as *Hamiltonian mechanics*. We also make use of *Hamilton's principle of stationary action*, which offers a basis for classical mechanics that is distinct from, though consistent with, Newton's laws of motion. That is, within classical mechanics, neither Newton's laws of motion nor Hamilton's principle are derived from more fundamental physical principles. As we see in this chapter, as well as Chapters 15 and 16, the lens afforded by Lagrangian and Hamiltonian mechanics, as well as Hamilton's principle, render deep insights into the nature of motion, while also providing powerful tools for its quantitative and qualitative description.

We refer to this formulation of mechanics as *analytical mechanics*. The name is motivated since a great deal of effort is placed up front in carefully formulating the equations of motion beyond that associated with Newton's law of motion. As we will see, such as through examples discussed in Chapter 15, the formulations of analytical mechanics allow us to sidestep difficulties of Newtonian mechanics arising from the need to determine forces, even forces of constraint that are generally inaccessible to direct measurement.

CHAPTER GUIDE

We make use of Newton's law of motion from Chapter 11. We also use a modest level of tensor notation for some of the manipulations. Book supplements to this chapter include intermediate and advanced treatments of classical mechanics, such as *Landau and Lifshitz* (1976), *Goldstein* (1980), *Marion and Thornton* (1988), *Fetter and Walecka* (2003), *José and Saletan* (1998), and *Taylor* (2005).

- Liouville's theorem and motion in phase space in Section 12.10.7.
- Adiabatic invariants: prove the general theorem as in *José and Saletan* (1998) or *Landau and Lifshitz* (1976).
- Hamilton-Jacobi theory in brief.

12.2 Motivation for studying analytical mechanics

We offer the following characteristics of Lagrangian mechanics, Hamiltonian mechanics, and Hamilton's principle as motivation for its study.

Generalized coordinates

As seen in Chapter 11, Newtonian mechanics is naturally expressed using Cartesian coordinates, whereas it takes some work (using tensor methods) to develop the equations using non-Cartesian coordinates (such as the spherical coordinates used in Chapter 13). In contrast, the equation of motion arising in Lagrangian mechanics, referred to as the *Euler-Lagrange equation*, has the same form using any coordinate system. Lagrangian mechanics is thus suited to the use of *generalized coordinates*, with such coordinates tailored to the particulars of each physical system. Hamiltonian mechanics goes one further step to render insights into the geometry of classical motion.

Dynamical constraints

Noether's theorem connects space-time symmetries of a physical system to the dynamical conservation laws maintained by motion of the system. These conservation laws provide *dynamical constraints* on the motion. The deduction of these constraints is naturally arrived at using Lagrangian mechanics coupled to *Hamilton's principle of stationary action.*

Forces of constraint

In addition to dynamical constraints, there are any number of further constraints that arise from details of the particular motion, such as the imposition of spatial boundaries, rods or springs connecting particles, or other geometric conditions. From the perspective of classical mechanics, such constraints might be considered purely kinematical. For example, the motion of a frictionless bead threaded by a wire is constrained to move along a trajectory defined by the shape of the wire. Such constraints reduce the spatial degrees of freedom of the particle motion. However, it is rarely simple, and often impossible in practice, to provide an *a priori* determination of the *forces of constraint* (also called *reactive forces*) that maintain the constraints. Since Newtonian mechanics requires all forces for determining the motion, it offers an impractical basis for studying systems where the forces of constraint are unknown *a priori.* In contrast, the equations of motion from Lagrangian mechanics do not require forces, neither those from external fields nor the forces of constraint. As such, Lagrangian mechanics provides the basis for the formulation of a huge range of phenomena. Indeed, it is for this reason that it forms the core of engineering mechanics.

Diagnosing forces

Although Lagrangian mechanices does not need forces, it does provide the means to determine forces if so desired, including forces of constraint. It does so through the method of *Lagrange multipliers.*

Continuum mechanics

Each of the above motivations, developed in this chapter for particle mechanics, has its generalizations to continuum mechanics. That is, Lagrangian mechanics and Hamilton's principle are suited to continuum field theories such as geophysical fluid mechanics. Further motivation is provided when we study waves in Part IX of this book and then instabilities in Part X.

Analytical mechanics

As encountered in this chapter, the formulation of Lagrangian mechanics requires a nontrivial effort in general formalism. Most of this effort is required to account for constraints and to remove the need to know anything about forces of any kind, including forces of constraint. *Hamiltonian mechanics* is another approach that parallels Lagrangian mechanics in that it also accounts for constraints and has no concern for forces. We refer to *analytical mechanics* as the study of constrained motion using the methods of Lagrange and Hamilton. Analytical mechanics, particularly Hamiltonian mechanics, proved foundational to the invention of quantum mechanics in the 1920s.

As payoff for the extra formalism needed beyond that of Newtonian mechanics, analytical mechanics provides an extremely straightforward means to derive the Euler-Lagrange equation of motion for physical systems. The key reason for the simplification is that with analytical mechanics we only need energies to derive the equation of motion. Energy is a scalar and thus is invariant under coordinate transformations, so that the equations of motion take on the same form regardless the coordinates. In contrast, Newton's laws are simple to state in principle. However, since they are vector equations and they require information about forces, they can be very difficult to formulate for any mechanical systems beyond the simplest.

Philosophically, we observe that the Newtonian approach is concerned with motion of a system arising from an outside agency, namely a net force that brings about a change in the linear momentum, or a net torque that changes the angular momentum. In contrast, the Lagrangian approach is concerned with properties of the physical system, namely its potential and kinetic energies. We propose that a complete understanding of a classical physical system comes from pursuing both the energy approaches of analytical mechanics (of Lagrange and Hamilton) and the force approach of Newtonian mechanics.

12.3 Constraints

A particle that moves in three dimensional Euclidean space has at most three independent *degrees of freedom*, meaning that three numbers are needed to specify the particle's spatial position at a particular time. If the particle moves without any forces then it is said to be a *free particle*, and we describe free particle motion in Section 12.9.1. Even without forces on the particle, the motion of a free particle is constrained by *dynamical constraints* that arise from symmetries of the space and time through which the particle moves; e.g., linear momentum, angular momentum, and mechanical energy are conserved (Section 12.9). In addition, there are further constraints that arise from *forces of constraint*, as we now discuss.

12.3.1 Holonomic constraints

When constraints are placed on the spatial position of the particles, then they are referred to as *holonomic constraints*. For example, consider the motion of a particle restricted to a frictionless two dimensional surface. As a result, its three Cartesian coordinates are related by a function of the form

$$\Psi[x(t), y(t), z(t)] = \mathcal{C}, \tag{12.1}$$

where $\mathcal{C}$ is a constant. If, for example, the particle is confined to move on the surface of a sphere of radius, R, then the constraint takes the form

$$\Psi[x(t), y(t), z(t)] = x(t)^2 + y(t)^2 + z(t)^2 = R^2. \tag{12.2}$$

By this restriction the particle has two independent spatial degrees of freedom rather than the three available without the constraint.

Holonomic constraints are enforced by *forces of constraint*, which are also known as *reactive forces*. Forces of constraint reduce the degrees of freedom possessed by the motion. According to *d'Alembert's principle*, forces of constraint instantaneously perform no work on the physical system, which is the property that we use to define forces of constraint.[1] For the particle moving on a surface, we readily see that the forces of constraint that keep the particle on the surface perform no work since the forces act, at each time instance, in a direction that is perpendicular to the surface and hence perpendicular to the trajectory. Furthermore, note that the forces of constraint can be conservative (written as the gradient of a scalar potential energy function) or non-conservative (such as friction). Indeed, within the confines of classical mechanics, we generally have little fundamental knowledge of the forces of constraints. Rather, we only see their impact on the motion.

An equivalent expression for the algebraic constraint (12.1) is given by differential expressions

$$\mathrm{d}\Psi = 0 \quad \text{or} \quad \frac{\mathrm{d}\Psi}{\mathrm{d}t} = \frac{\partial \Psi}{\partial x^a}\,\dot{x}^a + \frac{\partial \Psi}{\partial t} = 0, \tag{12.3}$$

where we wrote $(x, y, z) = (x^1, x^2, x^3)$ and made use of the summation convention from tensor alegebra (Section 1.2). We refer to holonomic constraints as *integrable* since the differential constraint (12.3) can be integrated to yield the algebraic constraint (12.1).

12.3.2 Non-holonomic constraints

There are physical systems where the constraints take on a more general *non-holonomic* form. The canonical non-holonomic constraint involves both the position and velocity and so it is written

$$\Psi(\boldsymbol{X}, \dot{\boldsymbol{X}}, t) = C. \tag{12.4}$$

The exact differential of this constraint includes the position, velocity, and time, so that

$$\mathrm{d}\Psi = \frac{\partial \Psi}{\partial x^a}\,\dot{x}^a + \frac{\partial \Psi}{\partial \dot{x}^a}\,\ddot{x}^a + \frac{\partial \Psi}{\partial t} = 0. \tag{12.5}$$

We note that some non-holonomic constraints are, in effect, holonomic in that they can be integrated. For example, consider the contraint

$$H_a\,\dot{x}^a + I = 0, \tag{12.6}$$

where H_a and I are functions of time that can be written as

$$H_a = \frac{\partial \Psi}{\partial x^a} \quad \text{and} \quad I = \frac{\partial \Psi}{\partial t}. \tag{12.7}$$

For this special case, the constraint (12.6) takes the form of the differential holonomic constraint (12.3), in which we say that the constraint (12.6) is *semi-holonomic*. But more generally non-holonomic constraints are non-integrable and require methods that are not fully covered by the generalized coordinates or Lagrange multipliers considered in this chapter.

[1] Recall from Section 11.1.4 that mechanical work arises when a force acts in a direction aligned with the motion of a physical system. If the force is perpendicular to the motion, then that force performs no work and so does not alter the kinetic energy of the system. Hence, d'Alembert's principle says that forces of constraint act perpendicular to the motion. See Section 14 of *Fetter and Walecka* (2003) for more on d'Alembert's principle.

12.3.3 Dynamical constraints

At the start of this section we noted the possibility of a dynamical constraint. Such constraints typically involve both the position and velocity of the particle, and so might at first be considered non-holonomic. However, they do not arise from an external force of constraint. Rather, they arise from space and time symmetries. For example, in Section 12.9.4 we detail conditions under which the mechanical energy is a constant of the motion, whereby the sum of the kinetic and potential energies are constant. For a particle, this dynamical constraint takes the form

$$m\,\dot{\boldsymbol{X}}\cdot\dot{\boldsymbol{X}}/2 + V(\boldsymbol{X}) = K(\boldsymbol{X},\dot{\boldsymbol{X}}). \tag{12.8}$$

Evidently, this constraint involves the position of the particle, through the potential energy $V(\boldsymbol{X})$, and the velocity, through the kinetic energy, $m\,\dot{\boldsymbol{X}}\cdot\dot{\boldsymbol{X}}/2$. It holds everywhere along the particle's trajectory as determined by the equation of motion

$$m\,\ddot{\boldsymbol{X}} = -\nabla V. \tag{12.9}$$

12.3.4 Comments

In this chapter we only consider dynamical constraints and holonomic constraints. The study of non-holonomic constraints can be rather subtle, and it is outside our scope.

12.4 Coordinate description of motion

We here review the Cartesian coordinate formalism needed to describe the motion of a system of N particles, and then transform to generalized coordinates that are optimized to describing constrained motion.

12.4.1 Cartesian coordinates for N particles

Following the notation from Section 11.5, we specify the position of each discrete particle by its Cartesian position vector,

$$\boldsymbol{X}_{(i)} = \hat{\boldsymbol{x}}\,x^1_{(i)} + \hat{\boldsymbol{y}}\,x^2_{(i)} + \hat{\boldsymbol{z}}\,x^3_{(i)} = \vec{e}_a\,x^a_{(i)}, \tag{12.10}$$

where $i = 1,..N$ is the particle index, $x^a_{(i)}$ is the a'th Cartesian coordinate for particle i, and $\vec{e}_a$ is the a'th Cartesian basis vector where $a = 1,2,3$. We place the particle index inside a parentheses to distinguish it from the coordinate indices, and we make use of the Einstein summation convention for the Cartesian index in the final equality. Each of the Cartesian coordinates for the particle position are functions of time, though we sometimes suppress time dependence for brevity.

The notation in equation (12.10) is somewhat cluttered on many occasions. To help de-clutter the notation we sometimes find it convenient to meld each of the Cartesian position vectors together into an ordered list of length $3N$

$$\boldsymbol{X} = (x^1, x^2, x^3, x^4, x^5, ..., x^{3N-2}, x^{3N-1}, x^{3N}). \tag{12.11}$$

This list is organized so that the first triplet, $n = 1,2,3$, contains the coordinates for the first particle, the second triplet, $n = 4,5,6$, is for the second particle, and so on up to the final triplet where $n = 3N-2, 3N-1, 3N$ is for particle N. In so ordering the indices we are able to drop

the particle label since there is a clear mapping between particle number and position within the list.

12.4.2 An introduction to generalized coordinates

Cartesian coordinates are sufficient for describing motion through Euclidean space, and they offer a suitable description particularly when there are no constraints on the motion. However, when constraints reduce the degrees of freedom, we are motivated to choose each coordinate to directly correspond to an independent degree of freedom. We refer to such coordinates as *generalized coordinates*. Generalized coordinates can be any coordinate that specifies the spatial position of the matter comprising the physical system. For example, latitude and longitude provide generalized coordinates for a particle moving on the surface of a sphere, whereas the polar angle serves as a generalized coordinate for motion around the circumference of a planar circle. In these two examples, we see that generalized coordinates are typically not Cartesian coordinates.

A further example of the value of generalized coordinates arises in the description of *rigid body* motion. A rigid body is comprised of a huge number of particles that are each constrained by inter-particle forces that keep the particles rigidly fixed relative to one another.[2] Internal forces of constraint that maintain the rigid spacing provide no net force nor net torqe on the body as a whole, so that only externally applied forces and torques lead to time changes in the body's translation and/or rotation. Correspondingly, the internal forces of constraint perform no net work on the body, which reflects d'Alembert's principle. Given that the particles are rigidly fixed relative to one another, the spatial configuration of the rigid body is specified by the position of the center of mass (three coordinates) and the orientation of the rigid body in space (three angles). The spatial configuration of a rigid body is thus fully described by just six degrees of freedom.[3]

12.4.3 Cartesian and generalized coordinates for N particles

Assume there are C holonomic constraints placed on the spatial coordinates of the system that are written in the form

$$\Psi_c(x^1, ..., x^{3N}, t) = \mathcal{C}_c, \quad \text{for} \quad c = 1, ..., C, \tag{12.12}$$

where $\mathcal{C}_c$ are constants. As a result, there are

$$D = 3N - C \tag{12.13}$$

spatial degrees of freedom. We can thus choose D generalized coordinates, $\xi^\sigma, \sigma = 1, 2, ..., D$, that are linearly independent and so fully describe the spatial position of the constrained system. For example, if a particle is constrained to move on a spherical shell of radius R, then the two spherical angular coordinates are suitable generalized coordinates corresponding to the single constraint equation, $r = R$.

With the spatial configuration of the physical system fully described by the generalized coordinates, we can determine the Cartesian position, $\boldsymbol{X}$, for the particles according to the functional relation

$$\boldsymbol{X} = \boldsymbol{X}(\xi^1, \xi^2, ..., \xi^D, t), \tag{12.14}$$

[2] In any real solid, the atoms are not rigidly fixed. But when concerned only with the macroscopic (classical) motion of a solid body, we can readily approximate its matter constituents as rigidly fixed relative to each other.

[3] See any of the references at the start of this chapter for detailed analysis of rigid body motion.

where the explicit time dependence in this relation offers generality that can be useful (e.g., motion on a spherical shell whose radius is time dependent). In turn, the exact differential of the Cartesian position is related to that of the generalized coordinates according to the chain rule

$$\mathrm{d}\boldsymbol{X} = \sum_{\sigma=1}^{D} \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma}\,\mathrm{d}\xi^\sigma + \frac{\partial \boldsymbol{X}}{\partial t}\,\mathrm{d}t. \tag{12.15}$$

12.4.4 Virtual displacements

When discussing forces of constraint in Section (12.3), we included the qualifier "instantaneous" or "time instance" when referring to the inability of a force of constraint to do work on the physical system. This qualifier is needed when the constraints are explicit functions of time, such as for motion on a spherical shell whose radius changes in time. We formalize this qualifier by introducing the concept of a *virtual displacement*. A virtual displacement is a tiny spatial displacement of a physical system that occurs at a fixed time instance. Furthermore, virtual displacements respect the forces of constraint, which means they are *kinematically admissable* displacements.

Conceptually, we imagine freezing the physical system at a specific time instance, and then probing alternative realizations of the physical system by considering tiny kinematically admissable displacements; i.e., displacements that are consistent with the forces of constraints. By choosing a particular time instance, virtual displacements are not concerned with the dynamics since dynamics requires information about time changes. For a particle moving on a spherical shell, spherical angle displacements at a fixed time respect the constraint that the particle remains on the shell, so that tiny displacements of the spherical angles provide suitable virtual displacements.

Any perturbation of generalized coordinates represents a possible virtual displacement. In turn, a virtual displacement written in terms of Cartesian coordinates follows from the exact differential (12.15) with $\mathrm{d}t = 0$

$$\delta\boldsymbol{X} = \sum_{\sigma=1}^{D} \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma}\,\delta\xi^\sigma. \tag{12.16}$$

In this expression we introduced the δ symbol for a virtual displacement as distinct from an exact differential. Virtual displacements hold a prominent role in Lagrangian mechanics as well as Hamilton's principle. In the context of Hamilton's principle, virtual displacements are generalized to the *variations* considered when probing alternative trajectories of a physical system.

Note that the δ symbol is commonly used in this book for tiny displacements or perturbations of a physical system that allow one to probe dynamical stability and examine alternative realizations of the motion. Not all cases where we use the δ symbol are virtual displacements. For example, in Section 14.7.2 we examined the constraints imposed by axial angular momentum conservation, with the use of δ in that context distinctly not virtual since the perturbations generally occur over a time interval.

12.4.5 Particle moving on a spherical shell

As an example of the ideas presented in this section, consider a particle constrained to move a constant radial distance from a fixed center. This motion on a spherical shell is enabled through the imposition of forces of constaint that keep the particle from either moving radially outward or radially inward. The forces of constraint can perform no work on the particle since they act in the radial direction, whereas the motion is in the spherical angular directions. For a particular

realization, consider particle motion on the surface of a solid massive and frictionless spherical shell. The gravitational force from the shell provides a radially inward force that keeps the particle from moving outward, whereas the solid surface of the shell provides the radially outward force that keeps the particle from moving inward.[4] It is as if the particle was confined to a narrow gap between two spherical surfaces that only allow motion in the angular directions. Neither of the constraining forces performs work on the particle since they act perpendicular to the particle's motion.

The coordinates used to specify the particle position are constrained to the spherical shell with fixed radius, R. Hence, the particle spatial position is fully specified by the latitude, ϕ, and longitude, λ, which are related to Cartesian coordinates via equations (10.18a)–(10.18c) (see also Figure 10.1)

$$x = R\cos\phi\,\cos\lambda \quad \text{and} \quad y = R\cos\phi\,\sin\lambda \quad \text{and} \quad z = R\sin\phi, \tag{12.17}$$

which manifests the constraint placed on the three Cartesian coordinates

$$\boldsymbol{X}(t)\cdot\boldsymbol{X}(t) = x(t)^2 + y(t)^2 + z(t)^2 = R^2. \tag{12.18}$$

Note that the corresponding exact differentials

$$\mathrm{d}x = R\left(-\mathrm{d}\phi\sin\phi\cos\lambda - \mathrm{d}\lambda\cos\phi\sin\lambda\right) \tag{12.19a}$$
$$\mathrm{d}y = R\left(-\mathrm{d}\phi\sin\phi\sin\lambda + \mathrm{d}\lambda\cos\phi\cos\lambda\right) \tag{12.19b}$$
$$\mathrm{d}z = R\,\mathrm{d}\phi\cos\phi, \tag{12.19c}$$

are within the spherical shell since they are orthogonal to the radial unit vector

$$\hat{\boldsymbol{r}}\cdot\left(\hat{\boldsymbol{x}}\,\mathrm{d}x + \hat{\boldsymbol{y}}\,\mathrm{d}y + \hat{\boldsymbol{z}}\,\mathrm{d}z\right) = 0, \tag{12.20}$$

where the radial unit vector is given by equation (10.30c)

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}}\,\cos\lambda\,\cos\phi + \hat{\boldsymbol{y}}\sin\lambda\,\cos\phi + \hat{\boldsymbol{z}}\sin\phi. \tag{12.21}$$

12.5 Lagrange's equations of motion

In this section we step through the derivation of *Lagrange's equation of motion*. This equation is equivalent to Newton's equation of motion, and yet it eliminates the forces of constraint and is written fully in terms of generalized coordinates. A key facet of the derivation concerns the need to articulate the functional dependency of the Cartesian position and velocity, $\boldsymbol{X}$ and $\dot{\boldsymbol{X}}$, on the generalized coordinates, generalized velocities, and time, $(\xi^\sigma, \dot{\xi}^\sigma, t)$.

12.5.1 Eliminating the forces of constraint

The inability of forces of constraint to perform work under virtual displacements (d'Alembert's principle) provides the key insight needed to eliminate the forces of constraint from the equations of motion. For this purpose, start by writing Newton's equation of motion using Cartesian coordinates

$$\dot{P}^n = F^n + F^n_{\text{constraint}} \quad \text{for } n = 1, ..., 3N, \tag{12.22}$$

[4] The constraint against moving inward arises from inter-atomic forces that keep the particle from penetrating into the solid shell. From the perspective of the classical particle motion, we are unconcerned with such inter-atomic forces, but instead only concerned with their effects on the classical motion of the particle.

where F^n is the n'th component of the net applied force (e.g., gravity, electromagnetism) and $F^n_{\text{constraint}}$ is the n'th component of the force of constraint. It is convenient to make use of the $3N$ ordered list notation of equation (12.11), in which we organize the linear momentum time derivatives and applied forces

$$\dot{\boldsymbol{P}} = (\dot{P}^1, \dot{P}^2, \dot{P}^3, \dot{P}^4, \dot{P}^5, ..., \dot{P}^{3N-2}, \dot{P}^{3N-1}, \dot{P}^{3N}) \tag{12.23a}$$

$$\boldsymbol{F} = (F^1, F^2, F^3, F^4, F^5, ..., F^{3N-2}, F^{3N-1}, F^{3N}), \tag{12.23b}$$

so that Newton's equation (12.22) for the N particle system becomes

$$\dot{\boldsymbol{P}} = \boldsymbol{F} + \boldsymbol{F}_{\text{constraint}}. \tag{12.24}$$

Through d'Alembert's principle we eliminate the forces of constraint by multiplying Newton's equation (12.24) by the vector of Cartesian virtual displacements, $\delta\boldsymbol{X}$, and summing over all $3N$ Cartesian coordinates

$$(\dot{\boldsymbol{P}} - \boldsymbol{F}) \cdot \delta\boldsymbol{X} = 0. \tag{12.25}$$

To reach this equation we set

$$\boldsymbol{F}_{\text{constraint}} \cdot \delta\boldsymbol{X} = 0, \tag{12.26}$$

due to d'Alembert's principle. To help appreciate d'Alembert's principle written as equation (12.26), again refer to the case of a particle moving on a spherical shell from Section 12.4.5, whereby the force of constraint is directed radially whereas a virtual displacement is directed along an angle within the shell.

Equation (12.25) is a statement of d'Alembert's principle using Cartesian coordinates. It succeeds in eliminating the forces of constraint, which is one of our goals. However, we cannot set each of the $3N$ terms individually to zero since each Cartesian component of the virtual displacement, $\delta\boldsymbol{X}$, is not generally independent of the other. To provide a more useful expression requires us to transform the Cartesian virtual displacements into generalized coordinate virtual displacements. This part of the derivation requires a few steps, and we do so by separately considering $\boldsymbol{F} \cdot \delta\boldsymbol{X}$ and $\dot{\boldsymbol{P}} \cdot \delta\boldsymbol{X}$.

12.5.2 Work by the applied forces acting on virtual displacements

Although the forces of constraint perform no work on the virtual displacements, the applied forces generally do perform work, as given by

$$\delta W = \boldsymbol{F} \cdot \delta\boldsymbol{X} = \boldsymbol{F} \cdot \sum_{\sigma=1}^{D} \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma} \, \delta\xi^\sigma = \sum_{\sigma=1}^{D} Q_\sigma \, \delta\xi^\sigma. \tag{12.27}$$

The second equality made use of equation (12.16) to write the Cartesian virtual displacement in terms of the generalized coordinate displacements. The third equality defined the *generalized force*, which is the representation of the applied force using generalized coordinates

$$Q_\sigma = \boldsymbol{F} \cdot \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma}. \tag{12.28}$$

We thus identify the product, $Q_\sigma \, \delta\xi^\sigma$ (no implied sum), as the work done by the generalized force, Q_σ, on the generaliized virtual displacement, $\delta\xi^\sigma$. Correspondingly, the total work done by all generalized forces is given by the sum in equation (12.27). Observe that the generalized force can be computed from the defining expression (12.28), given knowledge of the force vector, $\boldsymbol{F}$, and

coordinate transformation matrix, $\partial \boldsymbol{X}/\partial \xi^\sigma$. Alternatively, and often more conveniently, recall that the virtual displacements of the generalized coordinates are linearly independent so that we can compute the generalized force by computing the virtual work arising from a single virtual displacement, with all other displacements set to zero.

12.5.3 Massaging $\dot{\boldsymbol{P}} \cdot \delta \boldsymbol{X}$

As for equation (12.27), we transform the Cartesian virtual displacements into generalized coordinate virtual displacements according to

$$\dot{\boldsymbol{P}} \cdot \delta \boldsymbol{X} = \dot{\boldsymbol{P}} \cdot \sum_{\sigma=1}^{D} \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma} \, \delta \xi^\sigma = \sum_{n=1}^{3N} \sum_{\sigma=1}^{D} \dot{p}^n \, \frac{\partial x^n}{\partial \xi^\sigma} \, \delta \xi^\sigma, \tag{12.29}$$

which takes on the following form if each particle has the same constant mass, m,

$$\dot{\boldsymbol{P}} \cdot \delta \boldsymbol{X} = m \sum_{n=1}^{3N} \sum_{\sigma=1}^{D} \ddot{x}^n \, \frac{\partial x^n}{\partial \xi^\sigma} \, \delta \xi^\sigma \tag{12.30a}$$

$$= m \sum_{n=1}^{3N} \sum_{\sigma=1}^{D} \left[\frac{\mathrm{d}}{\mathrm{d}t} \left(\dot{x}^n \, \frac{\partial x^n}{\partial \xi^\sigma} \right) - \dot{x}^n \, \frac{\mathrm{d}}{\mathrm{d}t} \left(\frac{\partial x^n}{\partial \xi^\sigma} \right) \right] \delta \xi^\sigma. \tag{12.30b}$$

To massage this expression further requires us to be careful about the functional dependencies for the terms inside the square bracket.

Alternative expression for the transformation matrix elements

For the first right hand side term in equation (12.30b), recall that the functional dependence for the Cartesian expression of the particle velocity is found by making use of the exact differential (12.15), where division by $\mathrm{d}t$ leads to

$$\dot{\boldsymbol{X}} = \sum_{\sigma=1}^{D} \frac{\partial \boldsymbol{X}}{\partial \xi^\sigma} \, \dot{\xi}^\sigma + \frac{\partial \boldsymbol{X}}{\partial t}. \tag{12.31}$$

The Cartesian position, $\boldsymbol{X}$, is a function of the generalized coordinates and time as per equation (12.14), which then means that the partial derivatives, $\partial \boldsymbol{X}/\partial \xi^\sigma$ and $\partial \boldsymbol{X}/\partial t$, each have the same functional dependence. We thus conclude that the Cartesian velocity is a function of the generalized coordinates, the generalized velocities, and time

$$\dot{\boldsymbol{X}} = \dot{\boldsymbol{X}}(\xi^1, ..., \xi^D, \dot{\xi}^1, ..., \dot{\xi}^D, t). \tag{12.32}$$

Furthermore, equation (12.31) says that each element of $\dot{\boldsymbol{X}}$ is a linear function of the generalized velocities, $\dot{\xi}^\sigma$, from which it follows that

$$\frac{\partial \dot{x}^n}{\partial \dot{\xi}^\sigma} = \frac{\partial x^n}{\partial \xi^\sigma}. \tag{12.33}$$

This rather remarkable identity says that component-wise, the partial derivative of the Cartesian velocity, with respect to the generalized coordinate velocity, equals to the partial derivative of the Cartesian coordinate with respect to the generalized coordinate.

Making use of the identity (12.33) for the first right hand side term in equation (12.30b) leads

to

$$m\sum_{n=1}^{3N}\sum_{\sigma=1}^{D}\frac{\mathrm{d}}{\mathrm{d}t}\left[\dot{x}^n\,\frac{\partial x^n}{\partial\xi^\sigma}\right] = m\sum_{n=1}^{3N}\sum_{\sigma=1}^{D}\frac{\mathrm{d}}{\mathrm{d}t}\left[\dot{x}^n\,\frac{\partial\dot{x}^n}{\partial\dot{\xi}^\sigma}\right] \tag{12.34a}$$

$$= \frac{m}{2}\sum_{n=1}^{3N}\sum_{\sigma=1}^{D}\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial(\dot{x}^n\,\dot{x}^n)}{\partial\dot{\xi}^\sigma}\right] \tag{12.34b}$$

$$= \sum_{\sigma=1}^{D}\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial K}{\partial\dot{\xi}^\sigma}\right], \tag{12.34c}$$

where we introduced the kinetic energy of the N particle system

$$K = \frac{m}{2}\sum_{n=1}^{3N}\dot{x}^n\,\dot{x}^n = \frac{m}{2}\sum_{i=1}^{N}\dot{\boldsymbol{X}}_{(i)}\cdot\dot{\boldsymbol{X}}_{(i)} = \frac{m}{2}\sum_{i=1}^{N}\dot{x}^a_{(i)}\,\delta_{ab}\,\dot{x}^b_{(i)}, \tag{12.35}$$

with the final equality introducing the Kronecker metric, δ_{ab}, for Euclidean space. Note that the functional dependence (12.32) for the Cartesian velocities is transferred to the kinetic energy so that

$$K = K(\xi^1, ..., \xi^D, \dot{\xi}^1, ..., \dot{\xi}^D, t). \tag{12.36}$$

Proving that $\mathrm{d}/\mathrm{d}t(\partial x^n/\partial\xi^\sigma) = \partial\dot{x}^n/\partial\xi^\sigma$

For the next step we prove the identity

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial x^n}{\partial\xi^\sigma} = \frac{\partial}{\partial\xi^\sigma}\frac{\mathrm{d}x^n}{\mathrm{d}t} \tag{12.37}$$

by evaluating both sides and showing they are equal. For the left hand side, recall from the derivation of equation (12.33) that the transformation matrix element, $\partial x^n/\partial\xi^\sigma$, is a function of the generalized coordinates and time, so that its total time derivative is

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial x^n}{\partial\xi^\sigma} = \left[\frac{\partial}{\partial t} + \sum_{\mu=1}^{D}\dot{\xi}^\mu\,\frac{\partial}{\partial\xi^\mu}\right]\frac{\partial x^n}{\partial\xi^\sigma}. \tag{12.38}$$

Next, evaluate the right hand side of equation (12.37) directly by expanding the total time derivative. Importantly, recall the functional dependence of the Cartesian velocity in equation (12.32), and note that the partial derivative, $\partial/\partial\xi^\sigma$, is computed while holding fixed the explicit time dependence and the dependence on the generalized velocity, $\dot{\xi}^\sigma$. We thus find

$$\frac{\partial}{\partial\xi^\sigma}\frac{\mathrm{d}x^n}{\mathrm{d}t} = \frac{\partial}{\partial\xi^\sigma}\left[\frac{\partial}{\partial t} + \sum_{\mu=1}^{D}\dot{\xi}^\mu\,\frac{\partial}{\partial\xi^\mu}\right]x^n = \left[\frac{\partial}{\partial t} + \sum_{\mu=1}^{D}\dot{\xi}^\mu\,\frac{\partial}{\partial\xi^\mu}\right]\frac{\partial x^n}{\partial\xi^\sigma}, \tag{12.39}$$

which follows since (i) partial derivative operators commute, and (ii) the partial derivative, $\partial/\partial\xi^\sigma$, is computed while holding the generalized velocity, $\dot{\xi}^\mu$, fixed. Since equations (12.38) and (12.39) are identical, we have proven the identity (12.37).

Making use of equation (12.37) for the second right hand side term in equation (12.30b) leads

to

$$\sum_{n=1}^{3N}\sum_{d=1}^{D} m^n \dot{x}^n \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial x^n}{\partial \xi^\sigma}\right)\delta\xi^\sigma = m\sum_{n=1}^{3N}\sum_{\sigma=1}^{D}\dot{x}^n \frac{\partial}{\partial \xi^\sigma}\frac{\mathrm{d}x^n}{\mathrm{d}t}\,\delta\xi^\sigma = \sum_{d=1}^{D}\frac{\partial K}{\partial \xi^\sigma}\,\delta\xi^\sigma, \tag{12.40}$$

where we again introduced the kinetic energy (12.35) of the N particle system.

12.5.4 Lagrange's equation of motion

We now combine the expression (12.27) for the work done by the generalized force against the virtual displacements, along with the identities (12.34c) and (12.40), to find

$$\sum_{d=1}^{D}\left[\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial K}{\partial \dot{\xi}^\sigma}\right] - \frac{\partial K}{\partial \xi^\sigma} - Q_\sigma\right]\delta\xi^\sigma = 0. \tag{12.41}$$

We have thus succeeded in eliminating the forces of constraint *and* expressing the equations in terms of just the generalized coordinates. Since each of the virtual displacements of the generalized coordinates, $\delta\xi^\sigma, \sigma = 1, ...D$, are linearly independent, satisfying equation (12.41) for arbitrary virtual displacements requires *Lagrange's equations of motion*

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial K}{\partial \dot{\xi}^\sigma}\right] - \frac{\partial K}{\partial \xi^\sigma} = Q_\sigma \quad \text{for } \sigma = 1, ..., D. \tag{12.42}$$

Lagrange's equation is a partial differential equation for the kinetic energy that is driven by generalized forces. This equation holds separately for each of the D generalized coordinates.

12.5.5 Conservative forces and the Lagrangian function

Conservative forces are those that can be derived as minus the spatial gradient of a potential energy scalar, P. We commonly assume conservative forces when working with Lagrangian mechanics as discussed in Section 12.5.5. When written using Cartesian coordinates, the potential energy for a conservative system is time independent. However, when transforming to generalized coordinates as per equation (12.14), the potential energy can pick up an explicit time dependence along with the expected dependence on generalized coordinates. We thus write the potential energy as

$$\text{potential energy} = P^{\text{cartesian}}(\boldsymbol{X}) = P^{\text{generalized}}(\xi^1, ..., \xi^D, t), \tag{12.43}$$

where $P^{\text{cartesian}}$ and $P^{\text{generalized}}$ are distinct scalar functions that both measure the potential energy. Notably, the potential energy is not a function of the Cartesian velocity nor the generalized velocity, so that

$$\frac{\partial P^{\text{cartesian}}}{\partial \dot{x}^n} = 0 \quad \text{and} \quad \frac{\partial P^{\text{generalized}}}{\partial \dot{\xi}^\sigma} = 0. \tag{12.44}$$

As per our discussion of scalar functions in Section 1.1, we drop the extra superscript notation on the potential energy in equation (12.43), with the understanding that the functional dependency determines which particularl function is meant. In this manner, the generalized force takes the form

$$Q_\sigma = \sum_{n=1}^{3N} F^n \frac{\partial x^n}{\partial \xi^\sigma} = -\sum_{n=1}^{3N}\frac{\partial P(\boldsymbol{X})}{\partial x^n}\frac{\partial x^n}{\partial \xi^\sigma} = -\frac{\partial P(\xi^1, ..., \xi^D, t)}{\partial \xi^\sigma}, \tag{12.45}$$

where the second equality follows from the chain rule. Consequently, we can rewrite Lagrange's

equation (12.42) as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial(K-P)}{\partial\dot{\xi}^\sigma}\right]-\frac{\partial(K-P)}{\partial\xi^\sigma}=0 \quad \text{for } \sigma=1,...,D. \tag{12.46}$$

The difference between the kinetic energy and potential energy is referred to as the *Lagrangian*

$$L=K-P, \tag{12.47}$$

so that Lagrange's equation of motion (12.46) takes on the more commonly written form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{\xi}^\sigma}\right]-\frac{\partial L}{\partial\xi^\sigma}=0 \quad \text{for } \sigma=1,...,D. \tag{12.48}$$

The Lagrangian inherits the functional dependence of the kinetic energy as given by equation (12.36)

$$L=L(\xi^1,...,\xi^D,\dot{\xi}^1,...,\dot{\xi}^D,t). \tag{12.49}$$

Furthermore, we refer to the space defined by the $\xi^\sigma,\dot{\xi}^\sigma,\sigma=1,...,D$ as *configuration space*. As such, Lagrange's equation (12.48) is a partial differential equation for motion in configuration space.

In Lagrange's equation (12.48), when computing the partial derivatives, $\partial/\partial\xi^\sigma$ and $\partial/\partial\dot{\xi}^\sigma$, all other variables are held fixed. When computing the total time derivative, $\mathrm{d}/\mathrm{d}t$, we must be sure to account for the functional dependence of L according to equation (12.49), so that

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{\xi}^\mu}\right]=\left[\frac{\partial}{\partial t}+\dot{\xi}^\sigma\frac{\partial}{\partial\xi^\sigma}+\ddot{\xi}^\sigma\frac{\partial}{\partial\dot{\xi}^\sigma}\right]\frac{\partial L}{\partial\dot{\xi}^\mu}. \tag{12.50}$$

12.5.6 Connection to Newton's equation of motion

As a partial differential equation for the scalar Lagrangian function, Lagrange's equation (12.48) is quite distinct from Newton's equation of motion, which is a vector ordinary differential equation for the acceleration determined by the forces. However, these two equations are directly connected since we used Newton's equation to derive Lagrange's equation.

To further reveal the equivalance, consider the unconstrained case for a single particle, in which the Lagrangian as written in Cartesian coordinates as

$$L=(m/2)\,(\dot{x}^2+\dot{y}^2+\dot{z}^2)-P(x,y,z), \tag{12.51}$$

which leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{x}}\right]=m\,\ddot{x} \quad \text{and} \quad \frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{y}}\right]=m\,\ddot{y} \quad \text{and} \quad \frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{z}}\right]=m\,\ddot{z}. \tag{12.52}$$

Lagrange's equation thus becomes Newton's equation of motion

$$\boldsymbol{F}=m\,\ddot{\boldsymbol{X}} \quad \text{with} \quad \boldsymbol{F}=-\nabla_{\boldsymbol{x}}P. \tag{12.53}$$

12.5.7 Kinetic energy in terms of generalized velocities

We wrote the kinetic energy in equation (12.35) in terms of the Cartesian velocities. Here we make use of the coordinate transformation (12.31) to expose the generalized velocities according

to

$$K = \frac{m}{2}\sum_{i=1}^{N} \dot{x}^a_{(i)}\,\delta_{ab}\,\dot{x}^b_{(i)} \tag{12.54a}$$

$$= \frac{m}{2}\sum_{i=1}^{N}\left[\frac{\partial x^a_{(i)}}{\partial t} + \sum_{\sigma=1}^{D}\dot{\xi}^\sigma\,\frac{\partial x^a_{(i)}}{\partial \xi^\sigma}\right]\delta_{ab}\left[\frac{\partial x^b_{(i)}}{\partial t} + \sum_{\mu=1}^{D}\dot{\xi}^\mu\,\frac{\partial x^b_{(i)}}{\partial \xi^\mu}\right], \tag{12.54b}$$

where we made use of the notation in equation (12.10) with the implied summation over $a, b = 1, 2, 3$. Expanding this product leads to three terms, two of which arise from the time dependent coordinate transformation, whereby $\partial_t \boldsymbol{X}_{(i)} \neq 0$. The third term is given by the quadratic form

$$\frac{m}{2}\sum_{i=1}^{N}\sum_{\sigma=1}^{D}\sum_{\mu=1}^{D}\frac{\partial x^a_{(i)}}{\partial \xi^\sigma}\,\delta_{ab}\,\frac{\partial x^b_{(i)}}{\partial \xi^\mu}\,\dot{\xi}^\sigma\,\dot{\xi}^\mu = \frac{m}{2}\sum_{\sigma=1}^{D}\sum_{\mu=1}^{D} G_{\sigma\mu}(\boldsymbol{\xi})\,\dot{\xi}^\sigma\,\dot{\xi}^\mu. \tag{12.55}$$

We here introduced the symmetric tensor

$$G_{\sigma\mu} = \sum_{i=1}^{N}\frac{\partial x^a_{(i)}}{\partial \xi^\sigma}\,\delta_{ab}\,\frac{\partial x^b_{(i)}}{\partial \xi^\mu}, \tag{12.56}$$

which is the metric tensor for the space of generalized coordinates. For the special (and common) case of a time independent coordinate transformation, the metric is a function just of the generalized coordinates

$$G_{\sigma\mu} = G_{\sigma\mu}(\boldsymbol{\xi}), \tag{12.57}$$

and the kinetic energy reduces to the quadratic form

$$K = \frac{m}{2}\sum_{\sigma=1}^{D}\sum_{\mu=1}^{D} G_{\sigma\mu}(\boldsymbol{\xi})\,\dot{\xi}^\sigma\,\dot{\xi}^\mu \quad \text{if } \partial_t \boldsymbol{X}_{(i)} = 0. \tag{12.58}$$

12.5.8 Comments

The derivation in this section closely follows sections 13, 14, and 15 of *Fetter and Walecka* (2003). In summary, the approach started from Newton's equation of motion and then introduced virtual displacements, d'Alembert's principle, generalized coordinates, and then pursues a series of manipulations that carefully account for the functional dependencies of various quantities. In the next section we take an alternative approach that starts from *Hamilton's stationary action principle*, which is a more streamlined approach that renders Lagrange's equation and is thus consistent with Newton's equation of motion. The more tedious approach of the current section serves to expose certain details about are both useful for understanding the foundation of the theory, and find use in different contexts within this book.

12.6 Hamilton's principle of stationary action

In this section we show that Lagrange's equations of motion (12.48) for a conservative physical system can be derived from a variational principle, known as *Hamilton's principle of stationary action*. Hamilton's principle states that the *action*, which is the time integral of the Lagrangian, is stationary if and only if Lagrange's equation of motion are satisfied. Hamilton's principle is logically on the same level as Newton's laws of motion in that neither are derived from more

fundamental principles. Rather, they each offer the starting point for two distinct, but consistent, formulations of mechanics.

12.6.1 Notation

As for our derivation of Lagrange's equations in Section 12.5, it is useful to work with generalized coordinates in order to seamlessly account for constraints. To reduce notation clutter we use the boldface notation introduced in equation (12.11) for Cartesian coordinates. Here, the generalized coordinates and generalized velocities for a system with D degrees of freedom are organized into a list of length D according to

$$\boldsymbol{\xi} = (\xi^1, ..., \xi^D) \quad \text{and} \quad \dot{\boldsymbol{\xi}} = (\dot{\xi}^1, ..., \dot{\xi}^D). \tag{12.59}$$

In this manner, the kinetic energy, potential energy, and Lagrangian are written with the functional dependence

$$K = K(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t) \quad \text{and} \quad P = P(\boldsymbol{\xi}, t) \quad \text{and} \quad L = L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t). \tag{12.60}$$

We also assume the following shorthand for partial derivatives

$$\frac{\partial K}{\partial \boldsymbol{\xi}} = (\partial K/\partial \xi^1, \partial K/\partial \xi^2, ..., \partial K/\partial \xi^D) \quad \text{and} \quad \frac{\partial K}{\partial \dot{\boldsymbol{\xi}}} = (\partial K/\partial \dot{\xi}^1, \partial K/\partial \dot{\xi}^2, ..., \partial K/\partial \dot{\xi}^D). \tag{12.61}$$

With this notation, Lagrange's equations of motion (12.48) take the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial \dot{\boldsymbol{\xi}}}\right] - \frac{\partial L}{\partial \boldsymbol{\xi}} = 0. \tag{12.62}$$

12.6.2 The action

Consider the trajectory of an N particle system with $D \leq 3N$ degrees of freedom, and assume knowledge of the trajectory at two points in time, $t_A < t_B$. The action is the time integral of the Lagrangian[5]

$$\mathcal{S} = \int_{t_A}^{t_B} L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)\, \mathrm{d}t, \tag{12.63}$$

where we exposed the functional dependence (12.49) for the Lagrangian function.[6] *Hamilton's principle* states that the physically realized trajectory is an extremum of the action. The action integral (12.63) must have an extremum arising from the physically realized trajectory, regardless the time interval. However, the extremum is not necessarily a minimum.[7] Indeed, it is typically nontrivial to deduce the nature of the extremum given that one must compute the second variation of the action. Even so, we only rely on there being an extremum of the action in order to derive the equations of motion. It is for this reason that we prefer the name *Hamilton's principle of stationary action* rather than the commonly used *Hamilton's principle of least action.*

[5] In some chapters of this book (e.g., Chapters 23, 23, and 27), $\mathcal{S}$ is the entropy per mass. The distinct meanings for the same symbol will be clear from the context.

[6] It is notable that the action has the same physical dimensions as the angular momentum $\mathcal{S}$ $[\equiv]$ M L^2 T^{-1}.

[7] This point is emphasized in a footnote in Section 2 of *Landau and Lifshitz* (1976).

12.6.3 Variation of the action

To prove that the action is stationary for the physical trajectory, $\boldsymbol{\xi}(t)$, consider a perturbed trajectory via

$$\boldsymbol{\xi}'(t) = \boldsymbol{\xi}(t) + \epsilon\,\boldsymbol{\chi}(t). \tag{12.64}$$

As so defined, we have the perturbation written

$$\delta\boldsymbol{\xi}(t) = \boldsymbol{\xi}'(t) - \boldsymbol{\xi}(t) = \epsilon\,\boldsymbol{\chi}(t), \tag{12.65}$$

and the corresponding perturbation to the generalized velocity

$$\delta\dot{\boldsymbol{\xi}}(t) = \dot{\boldsymbol{\xi}}'(t) - \dot{\boldsymbol{\xi}}(t) = \epsilon\,\dot{\boldsymbol{\chi}}(t) = (\mathrm{d}/\mathrm{d}t)\,\delta\boldsymbol{\xi}. \tag{12.66}$$

In these equations, ϵ is a small non-dimensional constant that scales the perturbation function, $\boldsymbol{\chi}(t)$. Furthermore, the perturbation function vanishes at the initial time and final time

$$\boldsymbol{\chi}(t_A) = \boldsymbol{\chi}(t_B) = 0, \tag{12.67}$$

and $\boldsymbol{\chi}(t)$ is consistent with the constraints applied to the system. For example, if the motion is constrained to the surface of a spherical shell, then so too is $\boldsymbol{\chi}$. Furthermore, note that equation (12.66) reveals that variations in the generalized velocities are not independent of variations of the generalized coordinates.

We refer to $\delta\boldsymbol{\xi}(t)$ as the *variation* of the trajectory, with Figure 12.1 providing an example. Variations provide a method to probe physically unrealized paths for the purpose of characterizing and understanding what is special about the physically realized path. This approach builds from the virtual displacements considered in Section 12.4.4. Indeed, the path variations are virtual displacements from the physical path. Like a virtual displacement, path variations are made during a single time instance so that $\mathrm{d}t = 0$.

FIGURE 12.1: The physically realized trajectory, $\boldsymbol{\xi}(t)$, is depicted by the black line, with a sampling of the infinite number of possible variations, $\boldsymbol{\xi}'(t) = \boldsymbol{\xi}(t) + \delta\boldsymbol{\xi}(t)$, depicted in red. We assume knowledge of the trajectory at the start time, t_A, and end time, t_B. Hence, the physical trajectory and its variations are coincident at times t_A and t_B. Variations provide a means to probe physically unrealized paths for the purpose of characterizing and understanding what is special about the physically realized path.

The Lagrangian function takes on the following form when evaluated with the modified tra-

jectory (12.64)

$$L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t) = L(\boldsymbol{\xi} + \epsilon\boldsymbol{\chi}, \dot{\boldsymbol{\xi}} + \epsilon\dot{\boldsymbol{\chi}}, t) \approx L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t) + \epsilon\left[\boldsymbol{\chi}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\boldsymbol{\xi}} + \dot{\boldsymbol{\chi}}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\dot{\boldsymbol{\xi}}}\right]. \tag{12.68}$$

We only expand the Taylor series to leading order since ϵ is tiny so that all higher order terms are negligible. The notation in equation (12.68) is a shorthand for the more complete sums over the degrees of freedom

$$\boldsymbol{\chi}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\boldsymbol{\xi}} = \sum_{\sigma=1}^{D}\chi^{\sigma}\,\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\xi^{\sigma}} \quad \text{and} \quad \dot{\boldsymbol{\chi}}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\dot{\boldsymbol{\xi}}} = \sum_{\sigma=1}^{D}\dot{\chi}^{\sigma}\,\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\dot{\xi}^{\sigma}}. \tag{12.69}$$

From equation (12.68) we deduce the variation of the Lagrangian that arises from variation of the trajectories

$$\delta L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t) = L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t) - L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t) \approx \epsilon\left[\boldsymbol{\chi}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\boldsymbol{\xi}} + \dot{\boldsymbol{\chi}}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\dot{\boldsymbol{\xi}}}\right], \tag{12.70}$$

along with the corresponding variation of the action

$$\delta\mathcal{S} = \int_{t_A}^{t_B}\delta L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)\,\mathrm{d}t. \tag{12.71}$$

Integrating by parts on the final term in equation (12.70) leads to the equivalent expression for variation of the Lagrangian

$$\delta L = \epsilon\boldsymbol{\chi}\cdot\left[\frac{\partial L}{\partial\boldsymbol{\xi}} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial\dot{\boldsymbol{\xi}}}\right)\right] + \frac{\mathrm{d}}{\mathrm{d}t}\left[\epsilon\boldsymbol{\chi}\cdot\frac{\partial L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t)}{\partial\dot{\boldsymbol{\xi}}}\right]. \tag{12.72}$$

Since the perturbation function, $\boldsymbol{\chi}$, vanishes at t_A and t_B according to equation (12.67), the total time derivative plays no role in the action variation, in which case

$$\delta\mathcal{S} = \epsilon\int_{t_A}^{t_B}\boldsymbol{\chi}\cdot\left[\frac{\partial L}{\partial\boldsymbol{\xi}} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial\dot{\boldsymbol{\xi}}}\right)\right]\mathrm{d}t. \tag{12.73}$$

12.6.4 Stationary action and the Euler-Lagrange equations

Equation (12.73) says that variation of the action vanishes (i.e., the action is stationary) for all values of $\boldsymbol{\chi}$ if and only if the integrand is zero for each of the generalized coordinates. We are thus led to the condition

$$\delta\mathcal{S} = 0 \Longleftrightarrow \frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{\xi}^{\sigma}}\right] - \frac{\partial L}{\partial\xi^{\sigma}} = 0 \quad \text{for } \sigma = 1, ..., D, \tag{12.74}$$

which is Lagrange's equation of motion (12.48) derived in Section 12.5 starting from Newton's equation of motion. In the context of Hamilton's principle, Lagrange's equations (12.74) are referred to as the *Euler-Lagrange* equations, given the work by Euler on variational principles.

12.6.5 Derivative of the action with respect to ϵ

The discussion in Section 12.6.3 illustrates the how to vary the action, and its usage becomes second nature once doing it a few times. We here present a slightly alternative approach that, in the end, is totally equivalant to the variation approach but which offers a few more insights.

Consider the action evaluated on the perturbed trajectory

$$\mathcal{S}' = \int_{t_A}^{t_B} L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)\,\mathrm{d}t = \int_{t_A}^{t_B} L(\boldsymbol{\xi} + \epsilon\,\boldsymbol{\chi}, \dot{\boldsymbol{\xi}} + \epsilon\,\dot{\boldsymbol{\chi}}', t)\,\mathrm{d}t. \tag{12.75}$$

Now take the derivative of the perturbed action with respect to ϵ

$$\frac{\mathrm{d}\mathcal{S}'}{\mathrm{d}\epsilon} = \int_{t_A}^{t_B} \left[\frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \boldsymbol{\xi}'} \cdot \frac{\partial \boldsymbol{\xi}'}{\partial \epsilon} + \frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \dot{\boldsymbol{\xi}}'} \cdot \frac{\partial \dot{\boldsymbol{\xi}}'}{\partial \epsilon} \right] \mathrm{d}t. \tag{12.76}$$

Now evaluate the derivatives of the trajectory and the velocity to find

$$\frac{\mathrm{d}\mathcal{S}'}{\mathrm{d}\epsilon} = \int_{t_A}^{t_B} \left[\frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \boldsymbol{\xi}'} \cdot \boldsymbol{\chi} + \frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \dot{\boldsymbol{\xi}}'} \cdot \dot{\boldsymbol{\chi}} \right] \mathrm{d}t, \tag{12.77}$$

with integration by parts and use of the initial and final conditions yielding

$$\frac{\mathrm{d}\mathcal{S}'}{\mathrm{d}\epsilon} = \int_{t_A}^{t_B} \boldsymbol{\chi} \cdot \left[\frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \boldsymbol{\xi}'} - \frac{\mathrm{d}}{\mathrm{d}t} \left(\frac{\partial L(\boldsymbol{\xi}', \dot{\boldsymbol{\xi}}', t)}{\partial \dot{\boldsymbol{\xi}}'} \right) \right] \mathrm{d}t. \tag{12.78}$$

This expression has the same look as the variation in equation (12.73), and yet here the action is evaluated on the perturbed trajectory rather than the physically realized trajectory. Hamilton's principle says that the action is extremal for the physically realized trajectory, which means that

$$\left[\frac{\mathrm{d}\mathcal{S}'}{\mathrm{d}\epsilon} \right]_{\epsilon=0} = 0. \tag{12.79}$$

That is, Hamilton's principle says that the physically realized trajectory extremizes the action, which means that the action has a zero derivative at $\epsilon = 0$. As expected, this statement leads to the same Euler-Lagrange equations (12.74) as derived using the variational approach.

Considering the small parameter to be continuous, we can formally connect this discussion to the δ variation operator by writing

$$\left[\frac{\mathrm{d}\mathcal{S}'}{\mathrm{d}\epsilon} \right] \mathrm{d}\epsilon = \delta\mathcal{S}' \quad \text{and} \quad \frac{\mathrm{d}\boldsymbol{\xi}'}{\mathrm{d}\epsilon}\,\mathrm{d}\epsilon = \delta\boldsymbol{\xi}'. \tag{12.80}$$

12.6.6 Mechanical equivalence of Lagrangians

The Euler-Lagrange equation (12.74) remains unchanged if we multiply the Lagrangian by a constant. This property, though seemingly trivial, has important implications for scaling properties of the energy of physical systems. We deduce such properties in Section 12.7. Additionally, the Euler-Lagrange equation is unchanged by adding the total time derivative of an arbitrary function of the generalized coordinates and time

$$L^{\text{new}} = L^{\text{old}} + \frac{\mathrm{d}\Gamma(\boldsymbol{\xi}, t)}{\mathrm{d}t}. \tag{12.81}$$

To show the equivalance, note that the action transforms into

$$\mathcal{S}^{\text{new}} = \mathcal{S}^{\text{old}} + \Gamma[\boldsymbol{\xi}(t_B), t_B] - \Gamma[\boldsymbol{\xi}(t_A), t_A]. \tag{12.82}$$

The added terms are evaluated at t_A and t_B, where the trajectories are held fixed. Hence, these terms have zero variation so that

$$\delta\mathcal{S}^{\text{new}} = \delta\mathcal{S}^{\text{old}}, \tag{12.83}$$

which then means that the associated Euler-Lagrange equation is unchanged.

12.6.7 Summary of the method

As a recap, we here defined the action (12.63) as the time integral of the Lagrangian between a start time and end time, $t_A < t_B$, with the trajectory specified at these two time instances. We then considered how the action is modified by varying the trajectory (except at the start and end times). We thus found that the Euler-Lagrange equations (12.74) are satisfied if and only if the action is stationary. This result constitutes Hamilton's principle of stationary action, in which the physically realized trajectory is an extremum of the action.

Since the physically realized trajectory is the one that satisfies the Euler-Lagrange equations, all other trajectories are unphysical and as such they are not constrained by dynamical principles. Instead, these virtual trajectories are only constrained by the geometry of the system and by the need to respect the initial and final conditions. As such, Hamilton's principle tests all kinematically possible trajectories and selects the dynamically unique trajectory through insisting on stationarity of the action.

12.6.8 Some philosophical points

As already noted, Hamilton's principle provides an alternative to Newton's laws for the formulation of mechanics. Indeed, it is remarkable how complementary these two approaches are. Namely, Newton's laws are concerned with forces and accelerations acting at a point in space. In contrast, Hamilton's principle says that the difference between the kinetic and potential energies, as integrated on the trajectory over a time interval, is extremized by the physically realized trajectory.

The Newtonian description offers the canonical cause and effect perspective, whereby a force (the cause) creates an effect (the acceleration). In contrast, Hamilton's principle states that motion takes place in a manner whereby the action (an integral over time) is an extrema (typically a minima). From this view, Hamilton's principle can be viewed as offering a purpose for the motion, namely to minimize the action.[8] We do not pursue this discussion further as it goes well beyond our goals, though point the interested reader to Chapter 14 of *Yourgrau and Mandelstam* (1968) for philosophical insights and critiques.

12.7 Mechanical similarity and the virial theorem

As noted in Section 12.6.6, the Euler-Lagrange equation (12.74) remains unchanged if we multiply the Lagrangian by a constant. In this section we uncover a suite of rather general scaling properties that can be inferred as a result of this seemingly trivial symmetry. Remarkably, these properties are found without solving the equations of motion.

[8] A *teleological* explanation considers phenomena in terms of the purpose it serves rather than of the cause by which it arises.

12.7.1 Potential energy as a homogeneous function

To derive the advertised results, we must assume that the potential energy is a homogeneous function, which means that it scales according to

$$P(\lambda\, x^1, \lambda\, x^2, \lambda\, x^3) = \lambda^\gamma\, P(x^1, x^2, x^3), \tag{12.84}$$

where λ is a non-dimensional scale factor and γ is an integer that sets the degree of homogeneity. The left hand side of equation (12.84) is the potential energy evaluated with each of its Cartesian coordinates scaled by the same number, λ. That is, the left hand side has length scales modified by λ. The right hand side is the potential energy evaluated with the unscaled coordinates (unscaled length), but it is multiplied by the scale, λ, raised to the power γ.

Note that we represented the potential energy in equation (12.84) in terms of the Cartesian coordinates, since doing so readily ensures that scaling is consistently applied to each of the distinct coordinates by the same number. We also only considered the potential energy for a single particle. Extending to an arbitrary number of particles simply means adding more coordinates to the potential energy, with the scale, λ, also applied to these additional coordinates.

We prove Euler's theorem for homogeneous functions in Section 3.8, which for potential energy constitutes the identity

$$\gamma\, P(\boldsymbol{X}) = x^a\, \partial P(\boldsymbol{X})/\partial x^a. \tag{12.85}$$

This equation says that the potential energy, as multiplied by the degree of homogeneity, γ, has an equivalent expression in terms of the coordinates multiplied by the corresponding partial derivative of the potential energy. Introducing the conservative force associated with the potential energy

$$\boldsymbol{F} = -\nabla P, \tag{12.86}$$

we see that Euler's theorem for potential energy means that

$$\gamma\, P = -\boldsymbol{X} \cdot \boldsymbol{F} \tag{12.87}$$

We emphasize that the rather simple expression (12.87) for the potential energy holds only for potential energies that are homogeneous functions. Though restrictive, there are a number of physically interesting systems with homogeneous potential energies, including the following.

- $\gamma = -1$: the potential energy of particles in a gravity field or electrostatic field is inversely related to the distance between the particles, so that $\gamma = -1$.
- $\gamma = 1$: for a particle moving in a uniform field, such as a uniform gravity field, the potential energy has $\gamma = 1$.
- $\gamma = 2$: Small amplitude oscillations, such as those exhibited by a pendulum (Section 15.1) or simple harmonic oscillator (Section 15.6), have $\gamma = 2$.

Note that the trivial case of $\gamma = 0$ corresponds to a potential energy that is a constant, and thus leads to a zero force.

12.7.2 Mechanical similarity

Consider a physical system in which we scale the length by λ, just as considered for the potential energy in equation (12.84). This scaling alters the Lagrangian in a manner that alters the Euler-Lagrange equations. However, if we couple scaling of the length with a corresponding scaling of the time, then it is conceivable that we can find a combination of these two scalings that results

in an overall factor multiplying the Lagrangian, in which case the Euler-Lagrange equation are unaltered. We refer to this confluence of scaling as *mechanical similarity*.

We are thus led to examine symmetry of the Lagrangian under the space-time scaling transformation

$$x^a \to \lambda\, x^a \Longleftrightarrow x^{a'}/x^a = \lambda \quad \text{and} \quad t \to \beta\, t \Longleftrightarrow t'/t = \beta, \tag{12.88}$$

where λ and β are two non-dimensional scales. This space-time scaling leads to a scaling of the velocity components

$$\dot{x}^a \to (\lambda/\beta)\, \dot{x}^a. \tag{12.89}$$

Since the kinetic energy is proportional to the square of the velocity, the scaling of space and time given by equation (12.88) renders the Lagrangian scaling

$$L = K - P \to \lambda^\gamma\, P - (\lambda/\beta)^2\, K. \tag{12.90}$$

In order for this scaling to not alter the Euler-Lagrange equations requires

$$\beta = \lambda^{1-\gamma/2} \Longrightarrow (t'/t) = \beta = \lambda^{1-\gamma/2} = (x'/x)^{1-\gamma/2}. \tag{12.91}$$

which we refer to as *mechanical similarity*. This equation means that if we scale time by β, so that $(t'/t) = \beta$, then we do not change the equations of motion if length is scaled according to $(l/l')^{1-\gamma/2}$. We can now infer the following results according to the scaling of the potential energy presented in Section 12.7.1.

- $\gamma = -1$ leads to $(t'/t) = (x'/x)^{3/2}$, or $(t'/t)^2 = (x'/x)^3$. This equality accords with *Kepler's third law*, which states that the square of the orbit period scales as the cube of the orbit size.

- $\gamma = 1$ leads to $(t'/t) = (x'/x)^{1/2}$, or $(t'/t)^2 = (x'/x)$. This equality accords with the quadratic time dependence for a particle freely falling through a uniform gravity field.

- $\gamma = 2$ leads to $(t'/t) = 1$, which accords with the amplitude independence for the period of small oscillations exhibited by a pendulum.

12.7.3 Virial theorem and time averaged energy

To derive the *virial theorem*, we assume that the physical system maintains motion within a bounded region of space and with bounded velocity. This assumption is maintained by geophysical motion. The virial theorem provides a relation between the time averaged kinetic energy and time averaged potential energy for such bounded motion.

The kinetic energy is a quadratic function of velocity. Hence, as a function of velocity, the kinetic energy is a homogeneous function of degree two. Euler's theorem for homogeneous functions thus means that

$$2\, K = m\, \delta_{ab}\, \dot{x}^a\, \dot{x}^b/2 = \dot{x}^a\, (\partial K/\partial \dot{x}^a) = \dot{x}^a\, \mathcal{P}_a, \tag{12.92}$$

where we introduced the Cartesian momentum,

$$\mathcal{P}_a \equiv \frac{\partial L}{\partial \dot{x}^a} = \frac{\partial K}{\partial \dot{x}^a}, \tag{12.93}$$

which is generalized in Section 12.10 for generalized coordinates. Here it merely represents a

useful shorthand, allowing us to write

$$2\,K = \dot{x}^a\,\mathcal{P}_a \tag{12.94a}$$

$$= \frac{\mathrm{d}(x^a\,\mathcal{P}_a)}{\mathrm{d}t} - x^a\,\dot{\mathcal{P}}_a \tag{12.94b}$$

$$= \frac{\mathrm{d}(x^a\,\mathcal{P}_a)}{\mathrm{d}t} + x^a\,\partial P/\partial x^a \tag{12.94c}$$

$$= \frac{\mathrm{d}(x^a\,\mathcal{P}_a)}{\mathrm{d}t} + \gamma\,P. \tag{12.94d}$$

In the penultimate step (12.94c) we set

$$\dot{\mathcal{P}}_a = -\partial P/\partial x^a \tag{12.95}$$

according to Newton's law of motion, and in the final step (12.94d) we made use of Euler's theorem (12.85) for the potential energy. Taking the time average of equation (12.94d), and assuming the time average of the time derivative vanishes, then leads to the relation between the time averaged kinetic energy and time averaged potential energy

$$2\,\overline{K} = \gamma\,\overline{P}. \tag{12.96}$$

Note that the time average of the derivative vanishes if the time average is computed over a long enough time, given that the motion is assumed to be bounded. Additionally, if the motion is periodic then we can exactly remove the time derivative by taking the time average over the period of the motion.

The virial theorem (12.96) relates the time averaged kinetic energy and the time averaged potential energy in physical systems with a potential energy that is a homogeneous function of degree γ. In this book we find particular use for the case of $\gamma = 2$, which corresponds to motion of a simple harmonic oscillator, in which the virial theorem says that the potential and kinetic energies have equal time averages. This result is referred to as the *equipartition of energy*. In addition to harmonic oscillators and small amplitude pendula, we find in Part IX of this book that the equipartition of energy holds for linear wave motion, with the potential energy of linear waves generally a homogeneous function of degree two.

12.7.4 Further reading

This section shares much with Section 10 of *Landau and Lifshitz* (1976) as well as Section 6.13 of *Marion and Thornton* (1988).

12.8 Lagrange multipliers and forces of constraint

Derivation of Lagrange's equation of motion in Section 12.5 succeeded in eliminating the forces of constraint from the formulation. Likewise in the discussion of Hamilton's principle in Section 12.6, we assumed the $D = 3N - C$ generalized coordinates directly correspond to the D degrees of freedom available to the constrained physical system. In this section we present a method to infer the C forces of constraint through the method of *Lagrange multipliers*, with this inference of use when aiming to study force balances.

12.8.1 Holonomic constraints and their variation

Following equation (12.12), consider $3N$ coordinates, $\xi^\sigma, \sigma = 1, ..., 3N$, and assume they are constrained by C holonomic constraints of the form

$$\Psi_c(\xi^1, ..., \xi^{3N}, t) = \mathcal{C}_c, \quad \text{for} \quad c = 1, ..., C, \tag{12.97}$$

where $\mathcal{C}_c$ are constants. This equation is nearly the same as equation (12.12), only now we allow the coordinates to be non-Cartesian if that is suits to the problem.[9] Varying the trajectory then leads to a variation of the constraint equations (12.97) that takes the form

$$\delta\Psi_c = \sum_{\sigma=1}^{3N} \frac{\partial \Psi_c}{\partial \xi^\sigma}\, \delta\xi^\sigma = 0, \quad \text{for} \quad c = 1, ..., C. \tag{12.98}$$

This equation provides C constraints that must be satisfied by the $3N$ variations, $\delta\xi^\sigma$. Recall that a variation is a virtual process (Section 12.4.4) and so it occurs at a time instance, which explains why there is no $\mathrm{d}t$ term in equation (12.98). Also note that variation of a constant vanishes, so that $\delta\,\mathcal{C}_c = 0$, thus rendering a zero on the right hand side of equation (12.98).

12.8.2 Lagrange multipliers and the modified Euler-Lagrange equations

Recall the variation of the action given by equation (12.73), only now write this variation assuming there are $3N$ coordinates

$$\delta\mathcal{S} = \int_{t_A}^{t_B} \sum_{\sigma=1}^{3N} \delta\xi^\sigma \left[\frac{\partial L}{\partial \xi^\sigma} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{\xi}^\sigma}\right)\right] \mathrm{d}t = 0. \tag{12.99}$$

Contrary to what we did in Section 12.6.4, we cannot separately set $\delta\xi^\sigma$ to zero to then render the Euler-Lagrange equations (12.74). The reason is that the $3N$ variations, $\delta\xi^\sigma$, are constrained according to equation (12.100), thus making the variations dependent on one another. The method of Lagrange multipliers allows for us to incorporate the constraints while keeping all $3N$ coordinates.

To do so, introduce C Lagrange multipliers, $\Lambda^c(t)$, which are functions of time and whose form is to be specified below. Multiply each of the C constraint equations (12.98) by Λ^c and sum over all of the constraints

$$\sum_{c=1}^{C} \Lambda^c\, \delta\Psi_c = \sum_{c=1}^{C}\sum_{\sigma=1}^{3N} \Lambda^c\, \frac{\partial \Psi_c}{\partial \xi^\sigma}\, \delta\xi^\sigma = 0. \tag{12.100}$$

Now the action variation in equation (12.99) is unchanged by adding zero to the right hand side, and if we add zero in the form of equation (12.100) then that brings the constraints into the action variation via

$$\delta\mathcal{S} = \int_{t_A}^{t_B} \sum_{\sigma=1}^{3N} \delta\xi^\sigma \left[\frac{\partial L}{\partial \xi^\sigma} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{\xi}^\sigma}\right) + \sum_{c=1}^{C} \Lambda^c\, \frac{\partial \Psi_c}{\partial \xi^\sigma}\right] \mathrm{d}t = 0. \tag{12.101}$$

This equation has $D = 3N - C$ independent variations and C constrained variations. Let us organize the coordinates, ξ^σ, so that the $\sigma = 1, ...D$ coordinates have independent variations, whereas the remaining are constrained. Hence, coefficients of the independent variations in equation (12.101) must vanish in order to satisfy Hamilton's stationary action principle, using the

[9] Strictly, the $3N$ coordinates, ξ^σ, are not "generalized coordinates" since that term refers to coordinates that directly correspond to the $D = 3N - C$ degrees of freedom. Even so, that distinction is not important for what follows.

same logic as for Section 12.6.4. For the remaining $\sigma = D+1, ..., D+C$ constrained variations, we can *choose* the C Lagrange multipliers so that the coefficients of these dependent variations also vanish. In this manner the coefficients multiplying *all* of the $3N$ variations, $\delta\xi^\sigma$, vanish, which then leads to the modified Euler-Lagrange equations along with the C holonomic constraints

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial \dot{\xi}^\sigma}\right] - \frac{\partial L}{\partial \xi^\sigma} = \sum_{c=1}^{C} \Lambda^c \frac{\partial \Psi_c}{\partial \xi^\sigma} \quad \text{for } \sigma = 1, ..., 3N \tag{12.102a}$$

$$\Psi_c(\xi^1, ..., \xi^{3N}, t) = C_c, \quad \text{for} \quad c = 1, ..., C. \tag{12.102b}$$

12.8.3 The extended Lagrangian with multipliers

The modified Euler-Lagrange equation (12.102a) and corresponding holonomic constraints (12.102b) can be summarized by defining the extended Lagrangian as

$$L^* = L + \sum_{c=1}^{C} \Lambda^c \Psi_c. \tag{12.103}$$

As defined, the extended Lagrangian has the functional depedence

$$L^* = L(\xi^1, ...\xi^{3N}, \dot{\xi}^1, ...\dot{\xi}^{3N}, t, \Lambda^1, ...\Lambda^C), \tag{12.104}$$

so that it is a function of the coordinates, ξ^σ, velocities, $\dot{\xi}^\sigma$, and time, t, as well as the Lagrange multipliers, $\Lambda^1, ..., \Lambda^C$. We thus find the partial derivatives

$$\frac{\partial L^*}{\partial \dot{\xi}^\sigma} = \frac{\partial L}{\partial \dot{\xi}^\sigma} \tag{12.105a}$$

$$\frac{\partial L^*}{\partial \xi^\sigma} = \frac{\partial L}{\partial \xi^\sigma} + \sum_{c=1}^{C} \Lambda^c \frac{\partial \Psi_c}{\partial \xi^\sigma} \tag{12.105b}$$

$$\frac{\partial L^*}{\partial \Lambda^c} = \Psi_c. \tag{12.105c}$$

In this manner we can write the Euler-Lagrange equation (12.102a) and corresponding holonomic constraints (12.102b) as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L^*}{\partial \dot{\xi}^\sigma}\right] = \frac{\partial L^*}{\partial \xi^\sigma} \tag{12.106a}$$

$$\frac{\partial L^*}{\partial \Lambda^c} = \Psi_c. \tag{12.106b}$$

12.8.4 Determining the forces of constraint

There are $3N$ equations in the modified Euler-Lagrange equation (12.102a), and C constraints in equation (12.102b). By adding to the burden of what is to be determined, we now have the means to infer the forces of constraint. For that purpose, re-introduce the kinetic energy and potential energy to write equation (12.102a) as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial K}{\partial \dot{\xi}^\sigma}\right] - \frac{\partial K}{\partial \xi^\sigma} = -\frac{\partial P}{\partial \xi^\sigma} + \sum_{c=1}^{C} \Lambda^c \frac{\partial \Psi_c}{\partial \xi^\sigma} \quad \text{for } \sigma = 1, ..., 3N, \tag{12.107}$$

where the potential energy is independent of the coordinate velocities, $\partial P/\partial \dot{\xi}^\sigma = 0$, as follows from equation (12.44). Recalling the Lagrange's equation in the form (12.42), we identify the right hand side of equation (12.107) as the generalized force

$$Q_\sigma = -\frac{\partial P}{\partial \xi^\sigma} + \sum_{c=1}^{C} \Lambda^c \frac{\partial \Psi_c}{\partial \xi^\sigma} \quad \text{for } \sigma = 1, ..., 3N. \tag{12.108}$$

Now $-\partial P/\partial \xi^\sigma$ is the applied conservative force, so we identify the remaining term is the force of constraint

$$Q_\sigma^{\text{constraint}} = \sum_{c=1}^{C} \Lambda^c \frac{\partial \Psi_c}{\partial \xi^\sigma} \quad \text{for } \sigma = 1, ..., 3N. \tag{12.109}$$

12.9 Symmetries and conservation laws

Part of the allure of Hamilton's principle and the corresponding Euler-Lagrange equations concerns the ability to deduce conserved quantities associated with symmetries. The connection between symmetries (kinematics) and conservation laws (dynamics) was made by *Noether* (1918) (see *Noether and Tavel* (2018) for an English translation). In this section we connect the conservation of linear momentum to *space homogeneity*; conservation of angular momentum to *space isotropy*; and conservation of mechanical energy to *time homogeneity*. We study implications of these conservation laws in Chapter 14, with the present section focused on deriving the mathematical expressions of the conservation law. In so doing, we further our understanding of Hamilton's principle and the associated manipulations needed for its practical use.

To connect a symmetry to a conservation law, we focus on the Lagrangian since it encapsulates the mechanics. In particular, we examine how the Lagrangian is affected by the chosen symmetry operation. Furthermore, we only consider continuous space and time symmetries in this section. Therefore, to determine the implications of a symmetry it is sufficient to examine how the Lagrangian varies under an infinitesimal symmetry transformation, with infinitesimal transformations far simpler mathematically than finite transformations. Additionally, we remove all forces of constraint, so that it is sufficient, and more convenient, to work with Cartesian coordinates. For the mechanical system to respect a particular symmetry, then the action must remain invariant under the symmetry transformation; i.e., its variation must vanish. The variation of the action vanishes if the variation of the Lagrangian vanishes, with a zero variation of the Lagrangian directly leading to the differential conservation law associated with the symmetry.[10]

12.9.1 Free particle motion

Before we work through the conservation laws arising from space-time symmetries, we here study what is perhaps the simplest physical system, the *free particle*. Doing so provides a warm-up to the more general systems considered next. Free particle motion occurs when a particle experiences no forces at all (neither applied nor constraining) in an inertial reference frame, and as such it moves in an empty space that is homogeneous and isotropic.[11]

[10] In Section 12.6.6 we found that the action is unaffected the total time derivative of a function that depends only on the generalized coordinates and time. Even so, to derive the conservation laws in this section, we set the Lagrangian variation to zero.

[11] Free particle motion appears to be forced when viewed from a non-inertial reference frame (Sections 11.3 and 11.4). As such, the symmetries of a non-inertial reference frame are generally distinct from the inertial reference frame. We here focus on inertial reference frames since it is here that free particle motion in empty space experiences no force, and velocity remains constant.

For the particle to experience space as homogeneous (the particle does not care about the point in space) and time as homogeneous (the particle does not care about the origin of time), then the free particle Lagrangian cannot contain any explicit dependence on space or time,

$$\frac{\partial L}{\partial t} = 0 \quad \text{and} \quad \frac{\partial L}{\partial x} = \frac{\partial L}{\partial y} = \frac{\partial L}{\partial z} = 0, \tag{12.110}$$

where it is convenient to use Cartesian coordinates since there are no constraints. For mechanics to be the same for all space directions (isotropic space), then the Lagrangian must be independent of the velocity direction. We are led to a Lagrangian that is a function just of the velocity magnitude, or more conveniently the velocity squared. That is, the free particle Lagrangian is given by the kinetic energy

$$L = m\,(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)/2, \tag{12.111}$$

where we chose Cartesian coordinates since the motion is unconstrained. We already knew this result must hold since the potential energy is zero in the absence of forces. Even so, this discussion serves to illustrate the power of arguments based on symmetry, with such arguments fundamental to how we make practical use of Hamilton's principle.

With the Lagrangian given by just the kinetic energy for unconstrained motion, then the Euler-Lagrange equation leads to constancy of the velocity

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{x}} = \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{y}} = \frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{z}} = 0 \Longrightarrow \dot{\boldsymbol{X}} = \text{constant}. \tag{12.112}$$

This result is *Newton's first law* discussed in Chapter 11, and sometimes referred to as the *law of inertia*.

12.9.2 Space homogeneity and linear momentum conservation

We here examine the implications of an N particle system moving through a space that is homogeneous in an inertial reference frame. Moving beyond the free particle case of Section 12.9.1, we allow for conservative forces of interaction between the particles as measured by the potential energy function, $P(\boldsymbol{X})$. To respect spatial homogeneity requires mechanical properties of the system to be unchanged if we shift the coordinate position for each particle by an arbitrary amount. For ease in deriving the associated conservation law we examine how the Lagrangian changes when considering an infinitesimal shift in all of the particle positions

$$\boldsymbol{X}_{(i)} \to \boldsymbol{X}_{(i)} + \boldsymbol{\epsilon} \Longrightarrow \delta \boldsymbol{X}_{(i)} = \boldsymbol{\epsilon}, \tag{12.113}$$

where $\boldsymbol{\epsilon}$ is a constant displacement vector that is the same for all particles. A constant shift in particle positions does nothing to the particle velocities. Hence, upon shifting all particle positions by a constant, the Lagrangian becomes, to first order in $\boldsymbol{\epsilon}$,

$$L(\boldsymbol{X}', \dot{\boldsymbol{X}}', t) = L(\boldsymbol{X} + \boldsymbol{\epsilon}, \dot{\boldsymbol{X}}, t) \approx L(\boldsymbol{X}, \dot{\boldsymbol{X}}, t) + \epsilon^a \sum_{i=1}^{N} \frac{\partial L}{\partial x^a_{(i)}}, \tag{12.114}$$

so that variation of the Lagrangian is

$$\delta L = \epsilon^a \sum_{i=1}^{N} \frac{\partial L}{\partial x^a_{(i)}}. \tag{12.115}$$

A zero variation of the Lagrangian ensures that the physical system is unaffected by shifts in the particle positions. Since the perturbation vector, $\boldsymbol{\epsilon}$, is arbitrary, the Lagrangian has zero variation only if

$$\delta L = 0 \Longrightarrow \sum_{i=1}^{N} \frac{\partial L}{\partial x^a_{(i)}} = 0 \quad \text{for } a = 1, 2, 3. \tag{12.116}$$

Using this result in the Euler-Lagrange equation (12.74) leads to a conservation law for each of the three spatial directions

$$\frac{\mathrm{d}}{\mathrm{d}t} \sum_{i=1}^{N} \frac{\partial L}{\partial \dot{x}_{(i)}} = \frac{\mathrm{d}}{\mathrm{d}t} \sum_{i=1}^{N} \frac{\partial L}{\partial \dot{y}_{(i)}} = \frac{\mathrm{d}}{\mathrm{d}t} \sum_{i=1}^{N} \frac{\partial L}{\partial \dot{z}_{(i)}} = 0. \tag{12.117}$$

Evidently, when space is homogeneous and an N particle system respects this symmetry, then the linear momentum of the system is a constant of the motion

$$\sum_{i=1}^{N} \frac{\partial L}{\partial \dot{x}^a_{(i)}} = m \sum_{i=1}^{N} \dot{x}^a_{(i)} = \text{constant}. \tag{12.118}$$

This result is the law of inertia for the N particle system. Note that if there is spatial symmetry in only a select number of directions, then only the corresponding momenta are conserved.

Another implication for the homogeneity condition (12.116) is that the sum of the forces acting on the N particle system vanishes

$$\sum_{i=1}^{N} \frac{\partial L}{\partial x^a_{(i)}} = -\sum_{i=1}^{N} \frac{\partial P}{\partial x^a_{(i)}} = \sum_{i=1}^{N} F^a_{(i)} = 0. \tag{12.119}$$

For the case of $N = 1$ we recover the free particle discussed in Section 12.9.1, whereby the particle has no forces if the space is homogeneous. However, an N particle system respects spatial homogeneity if the sum of all the inter-particle forces vanishes. Equation (12.119) is a statement of *Newton's third law* as studied in Section 11.5.2, where we also noted that a central force between particles provides a prominent example of a force that respects the third law.

12.9.3 Space isotropy and angular momentum conservation

We now consider the conservation law associated with the isotropy of space. Spatial isotropy means that the mechanical system is invariant under the same rotation of both the positions and velocities for the N particles. Let $\delta\boldsymbol{\phi}$ be an infinitesimal rotation vector and consider the following variation of the Cartesian representations of the particle positions and velocities

$$\delta \boldsymbol{X}_{(i)} = \delta\boldsymbol{\phi} \times \boldsymbol{X}_{(i)} \quad \text{and} \quad \delta \dot{\boldsymbol{X}}_{(i)} = \delta\boldsymbol{\phi} \times \dot{\boldsymbol{X}}_{(i)}, \tag{12.120}$$

which made use of Section 11.2 for how infinitesimal rigid rotations affect changes to vectors. The corresponding variation of the Lagrangian is given by

$$\delta L = \sum_{i=1}^{N} \left[\frac{\partial L}{\partial x^a_{(i)}} \delta x^a_{(i)} + \frac{\partial L}{\partial \dot{x}^a_{(i)}} \delta \dot{x}^a_{(i)} \right] = \sum_{i=1}^{N} \frac{\mathrm{d}}{\mathrm{d}t} \left[\frac{\partial L}{\partial \dot{x}^a_{(i)}} \delta \dot{x}^a_{(i)} \right], \tag{12.121}$$

where we used the Euler-Lagrange equation (12.74) to reach the second equality. With the kinetic energy in terms of Cartesian coordinates given by equation (12.35), we can introduce the Cartesian

component of linear momentum

$$P^a_{(i)} = \frac{\partial L}{\partial \dot{x}^a_{(i)}}, \tag{12.122}$$

in which case the Lagrangian has zero variation under infinitesimal rotations if

$$\sum_{i=1}^{N} \frac{\mathrm{d}}{\mathrm{d}t}\left[P^a_{(i)}\,\delta\dot{x}^a_{(i)}\right] = \delta\boldsymbol{\phi}\cdot\sum_{i=1}^{N}\frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{X}_{(i)}\times\boldsymbol{P}_{(i)}) = 0. \tag{12.123}$$

With $\delta\boldsymbol{\phi}$ arbitrary, we are left with conservation of angular momentum for the N particle system

$$\sum_{i=1}^{N}\frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{X}_{(i)}\times\boldsymbol{P}_{(i)}) = 0. \tag{12.124}$$

For a space that possesses partial isotropy, that component of angular momentum associated with the isotropy is conserved. This case is particularly relevant for planetary physics, whereby planetary rotation reduces spatial isotropy to just that of the rotational axis (see Section 14.6.1).

12.9.4 Time homogeneity and Hamiltonian evolution

Time homogeneity

We now consider how a mechanical system behaves under a shift in time, $t \to t+\epsilon$, while keeping the generalized positions and generalized velocities unchanged. In this case the Lagrangian becomes

$$L(\boldsymbol{\xi},\dot{\boldsymbol{\xi}},t+\epsilon) \approx L(\boldsymbol{\xi},\dot{\boldsymbol{\xi}},t) + \epsilon\,\partial_t L \Longrightarrow \delta L = \epsilon\,\partial_t L. \tag{12.125}$$

Hence, for a mechanical system to manifest time homogeneity the Lagrangian must have no explicit time dependence,

$$\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma} = 0 \Longleftrightarrow \text{time symmetry}. \tag{12.126}$$

Derivation of the Hamiltonian evolution

The total time derivative of the Lagrangian (following equation (12.50)) takes on the form

$$\frac{\mathrm{d}L}{\mathrm{d}t} - \left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma} = \sum_{\sigma=1}^{D}\left[\dot{\xi}^\sigma\,\frac{\partial L}{\partial \xi^\sigma} + \ddot{\xi}^\sigma\,\frac{\partial L}{\partial \dot{\xi}^\sigma}\right] \tag{12.127a}$$

$$= \sum_{\sigma=1}^{D}\left[\dot{\xi}^\sigma\,\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{\xi}^\sigma} + \ddot{\xi}^\sigma\,\frac{\partial L}{\partial \dot{\xi}^\sigma}\right] \tag{12.127b}$$

$$= \sum_{\sigma=1}^{D}\frac{\mathrm{d}}{\mathrm{d}t}\left[\dot{\xi}^\sigma\,\frac{\partial L}{\partial \dot{\xi}^\sigma}\right], \tag{12.127c}$$

where the second equality used the Euler-Lagrange equation (12.74). We are thus led to

$$\frac{\mathrm{d}H}{\mathrm{d}t} = -\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma} \quad \text{with} \quad H = \left[\sum_{\sigma=1}^{D}\dot{\xi}^\sigma\,\frac{\partial L}{\partial \dot{\xi}^\sigma} - L\right], \tag{12.128}$$

where H is known as the *Hamiltonian*. Evidently, if there is no explicit time dependence in the Lagrangian then the Hamiltonian is a constant of the motion

$$\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma} = 0 \Longrightarrow \frac{\mathrm{d}H}{\mathrm{d}t} = 0. \tag{12.129}$$

Connecting the Hamiltonian to the mechanical energy

From Section 12.5.7 we wrote the kinetic energy in terms of generalized coordinates. In the special case of a time independent transformation between Cartesian and generalized coordinates, the kinetic energy is given by equation (12.55)

$$K = \frac{m}{2}\sum_{\sigma=1}^{D}\sum_{\mu=1}^{D} G_{\sigma\mu}(\boldsymbol{\xi})\,\dot{\xi}^\sigma\,\dot{\xi}^\mu. \tag{12.130}$$

We thus find

$$\frac{\partial L}{\partial \dot{\xi}^\nu} = \frac{\partial K}{\partial \dot{\xi}^\nu} = \frac{m}{2}\sum_{\sigma=1}^{D}\sum_{\mu=1}^{D} G_{\sigma\mu}\left(\delta^\sigma_\nu\,\dot{\xi}^\mu + \delta^\mu_\nu\,\dot{\xi}^\sigma\right) = m\sum_{\sigma=1}^{D} G_{\sigma\nu}\,\dot{\xi}^\sigma, \tag{12.131}$$

where we used $G_{\sigma\mu} = G_{\mu\sigma}$ for the final equality. In this case, the Hamiltonian equals to the total mechanical energy

$$H = \sum_{\nu=1}^{D}\dot{\xi}^\nu\,\frac{\partial L}{\partial \dot{\xi}^\nu} - L = m\sum_{\nu=1}^{D}\sum_{\sigma=1}^{D} G_{\sigma\nu}\,\dot{\xi}^\nu\,\dot{\xi}^\sigma - \frac{m}{2}\sum_{\nu=1}^{D}\sum_{\sigma=1}^{D} G_{\sigma\nu}\,\dot{\xi}^\nu\,\dot{\xi}^\sigma + P = K + P, \tag{12.132}$$

which is the familiar form of mechanical energy found in our study of energetics in Newtonian mechanics from Section 11.1.5.

Further distinguishing the Hamiltonian and the mechanical energy

We emphasize that the Hamiltonian is a constant of the motion if the Lagrangian has no explicit time dependence; e.g., equation (12.129). However, the Hamiltonian equals to the mechanical energy only if there is a time independent coordinate transformation between Cartesian and generalized coordinates. Typically $\partial_t L = 0$ means that $\partial_t \boldsymbol{X}_{(i)} = 0$. However, such is not always that case (e.g., see page 82 of *Fetter and Walecka* (2003)). So when $\partial_t L = 0$ but $\partial_t \boldsymbol{X}_{(i)} \neq 0$, the Hamiltonian remains a constant of the motion, but the mechanical energy is time dependent. Hence, we must qualify our earlier statement that time homogeneity leads to a constant mechanical energy. The more precise statement is that the Hamiltonian is a constant of the motion when time does not explicitly appear in the Lagrangian; however, the Hamiltonian is equal to the mechanical energy only if there is a time independent relation between Cartesian coordinates and generalized coordinates.

12.9.5 Further study

Conservation laws and symmetries in classical mechanics are lucidly discussed in Chapters 1 and 2 of *Landau and Lifshitz* (1976). Pedagogical presentations on these topics can be found in this online lecture from the Space Time series and this online lecture from Physics with Elliot. This essay about Emmy Noether provides insights into this mathematician whose work, conducted under some very unfortunate circumstances, forever connected symmetry and conservation laws, with this connection providing the basis for nearly all modern theories of physics.

12.10 Hamiltonian mechanics

In this section we develop the rudiments of *Hamiltonian mechanics*, which is related to Lagrangian mechanics through a Legendre transformation.[12]

12.10.1 Generalized momenta

Define the *generalized momenta*, also known as the *canonical momenta*, according to

$$\mathcal{P}_\sigma \equiv \frac{\partial L}{\partial \dot{\xi}^\sigma} = \mathcal{P}_\sigma(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t), \tag{12.133}$$

where the functional dependence is inherited from the Lagrangian. Also note the care in placing the σ index downstairs in the covariant position, which is quite useful in the following. With the generalized momenta, the Euler-Lagrange equations (12.74) take the form

$$\dot{\mathcal{P}}_\sigma = \frac{\partial L}{\partial \xi^\sigma}. \tag{12.134}$$

Evidently, if the Lagrangian has no explicit dependence on a particular generalized coordinate, then the corresponding generalized momenta is a constant of the motion. Such generalized coordinates are termed *cyclic*, and we more to say about cyclic coordinates in Section 12.10.5.

12.10.2 Legendre transformation

In terms of the generalized momenta, the Hamiltonian function (12.129) is written

$$H = -L + \sum_{\sigma=1}^{D} \dot{\xi}^\sigma \, \mathcal{P}_\sigma. \tag{12.135}$$

This definition of the Hamiltonian represents a *Legendre transformation* from the Lagrangian to the Hamiltonian, whereby we swap around some of the functional dependence. Namely, we already know that the Lagrangian has functional dependence on generalized coordinates, generalized velocities, and time. In this subsection we show that the Hamiltonian is a functional of the generalized coordinates, generalized momenta, and time. We say that the Legendre transformation (12.135) moves from the configuration space of Lagrangian mechanics to the *phase space* of *Hamiltonian mechanics*.

Exact differential of the Hamiltonian

The Lagrangian functional dependence (12.49)

$$L = L(\boldsymbol{\xi}, \dot{\boldsymbol{\xi}}, t), \tag{12.136}$$

leads to the exact differential of the Hamiltonian (12.135)

$$\mathrm{d}H = -\frac{\partial L}{\partial t}\,\mathrm{d}t + \sum_{\sigma=1}^{D}\left[-\frac{\partial L}{\partial \xi^\sigma}\,\mathrm{d}\xi^\sigma - \frac{\partial L}{\partial \dot{\xi}^\sigma}\,\mathrm{d}\dot{\xi}^\sigma + \mathcal{P}_\sigma\,\mathrm{d}\dot{\xi}^\sigma + \dot{\xi}^\sigma\,\mathrm{d}\mathcal{P}_\sigma\right]. \tag{12.137}$$

[12] We also encounter Legendre transformations in our study of thermodynamics in Part IV of this book.

With the generalized momenta given by equation (12.133), the exact differential reduces to

$$\mathrm{d}H = -\frac{\partial L}{\partial t}\,\mathrm{d}t + \sum_{\sigma=1}^{D}\left[-\frac{\partial L}{\partial \xi^\sigma}\,\mathrm{d}\xi^\sigma + \dot{\xi}^\sigma\,\mathrm{d}\mathcal{P}_\sigma\right]. \tag{12.138}$$

This relation means that the Hamiltonian has the following functional dependence

$$H = H(\xi^1, ..., \xi^D, \mathcal{P}_1, ..., \mathcal{P}_D, t). \tag{12.139}$$

Namely, the Hamiltonian is a functional of the generalized coordinates, generalized momenta, and a (possibly) explicit function of time. Furthermore, as for the Lagrangian function, the Hamiltonian is an implicit function of time as realized through time dependence to the generalized coordinates and generalized momenta.

Relations between partial derivatives

The functional dependence (12.139) means that the exact differential of the Hamiltonian is given by

$$\mathrm{d}H = \left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma,\mathrm{P}_\sigma}\mathrm{d}t + \sum_{\sigma=1}^{D}\left(\left[\frac{\partial H}{\partial \xi^\sigma}\right]_{\mathcal{P}_\sigma,t}\mathrm{d}\xi^\sigma + \left[\frac{\partial H}{\partial \mathcal{P}_\sigma}\right]_{\xi^\sigma,t}\mathrm{d}\mathcal{P}_\sigma\right), \tag{12.140}$$

which is equal also to equation (12.138), here rewritten as

$$\mathrm{d}H = -\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma}\mathrm{d}t + \sum_{\sigma=1}^{D}\left(-\left[\frac{\partial L}{\partial \xi^\sigma}\right]_{\dot{\xi}^\sigma,t}\mathrm{d}\xi^\sigma + \dot{\xi}^\sigma\,\mathrm{d}\mathcal{P}_\sigma\right). \tag{12.141}$$

In both equations (12.140) and (12.141) we exposed subscripts on the partial derivatives to be clear on what coordinates are held fixed when computing the derivatives. Equating terms between equations (12.140) and (12.141) leads to

$$\left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma,\mathrm{P}_\sigma} = -\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma,\dot{\xi}^\sigma} \tag{12.142a}$$

$$\left[\frac{\partial H}{\partial \xi^\sigma}\right]_{\mathcal{P}_\sigma,t} = -\left[\frac{\partial L}{\partial \xi^\sigma}\right]_{\dot{\xi}^\sigma,t} \tag{12.142b}$$

$$\left[\frac{\partial H}{\partial \mathcal{P}_\sigma}\right]_{\xi^\sigma,t} = \frac{\mathrm{d}\xi^\sigma}{\mathrm{d}t}. \tag{12.142c}$$

12.10.3 Hamilton's equations of motion

The manipulations in Section 12.10.2 are mathematical identities that arise from the functional dependencies of the Lagrangian and Hamiltonian, and the Legendre transformation (12.135). We return to physics by assuming the Lagrangian satisfies the Euler-Lagrange equations as written in the form (12.134)

$$\dot{\mathcal{P}}_\sigma = \left[\frac{\partial L}{\partial \xi^\sigma}\right]_{\dot{\xi}^\sigma,t}, \tag{12.143}$$

which brings the exact differential (12.141) to

$$\mathrm{d}H = \left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma,\mathrm{P}_\sigma}\mathrm{d}t + \sum_{\sigma=1}^{D}\left(-\dot{\mathcal{P}}_\sigma\,\mathrm{d}\xi^\sigma + \dot{\xi}^\sigma\,\mathrm{d}\mathcal{P}_\sigma\right). \tag{12.144}$$

We are thus led to *Hamilton's equations of motion*

$$\dot{\mathcal{P}}_\sigma = \frac{\mathrm{d}\mathcal{P}_\sigma}{\mathrm{d}t} = -\left[\frac{\partial H}{\partial \xi^\sigma}\right]_{\mathcal{P}_\sigma, t} \tag{12.145a}$$

$$\dot{\xi}^\sigma = \frac{\mathrm{d}\xi^\sigma}{\mathrm{d}t} = \left[\frac{\partial H}{\partial \mathcal{P}_\sigma}\right]_{\xi^\sigma, t}, \tag{12.145b}$$

which are $2\,D$ first order differential equations for the time derivatives of the generalized coordinates and generalized momenta. These equations are to be compared to the Euler-Lagrange equations (12.74), which are D second order differential equations for the generalized coordinates.

As a result of Hamilton's equations (12.145a) and (12.145b), we can readily compute the time derivative of the Hamiltonian

$$\frac{\mathrm{d}H}{\mathrm{d}t} = \left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma, \mathrm{P}_\sigma} + \sum_{\sigma=1}^{D}\left(\left[\frac{\partial H}{\partial \xi^\sigma}\right]_{\mathcal{P}_\sigma, t}\dot{\xi}^\sigma + \left[\frac{\partial H}{\partial \mathcal{P}_\sigma}\right]_{\xi^\sigma, t}\dot{\mathcal{P}}_\sigma\right) \tag{12.146a}$$

$$= \left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma, \mathrm{P}_\sigma} + \sum_{\sigma=1}^{D}\left(-\dot{\mathcal{P}}_\sigma\,\dot{\xi}^\sigma + \dot{\mathcal{P}}_\sigma\,\dot{\xi}^\sigma\right) \tag{12.146b}$$

$$= \left[\frac{\partial H}{\partial t}\right]_{\xi^\sigma, \mathrm{P}_\sigma} \tag{12.146c}$$

$$= -\left[\frac{\partial L}{\partial t}\right]_{\xi^\sigma, \dot{\xi}^\sigma}, \tag{12.146d}$$

where the final equality follows from equation (12.128). Evidently, the Hamiltonian is a constant of the motion if it has no explicit time dependence. This result corresponds to Noether's theorem as discussed in Section 12.9.4.

12.10.4 Operational steps

When deriving Hamilton's equations of motion for a particular physical problem, we typically start by writing down the Lagrangian and then using the Legendre transformation (12.135) to derive the Hamiltonian. Before performing the partial derivatives in Hamilton's equations (12.146c)-(12.145b), it is essential to express the Hamiltonian as a function of the generalized coordinates and generalized momenta. Doing so requires removing all appearances of the generalized velocity in favor of the generalized momenta.

In much of this section, we exposed subscripts on the partial derivatives to identify what variables are held fixed when taking the derivatives. Such care is important for developing a proper understanding of the equations and their manipulation. We also found such care important for developing Lagrangian mechanics earlier in this chapter. For both formulations, some exposure to the methodology readily allows one to dispense with the extra clutter of the subscripts. Even so, it can be quite valuable to expose the subscripts when debugging any particular formulation.

12.10.5 Cyclic versus ignorable coordinates

We commented in section 12.10.1 that if the Lagrangian is independent of a coordinate, referred to as a *cyclic coordinate*, then its corresponding generalized momenta is a constant of the motion. Even so, the corresponding generalized velocity is not necessarily zero and so it cannot be ignored. However, in the Hamiltonian formulation we can ignore a cyclic coordinate since the generalized momenta now a time-independent parameter of the Hamiltonian. As such, there is

no corresponding equation of motion. We thus find the Hamiltonian dynamical system has two less degrees of freedom, one for the cyclic coordinate and one for the corresponding constant generalized momenta, thus motivating the name *ignorable coordinate* when a cyclic coordinate is encountered in the Hamiltonian formulation.

12.10.6 Modified Hamilton's principle

Hamilton's variational principle in the form of equation (12.74) leads to the Euler-Lagrange equations. We can derive a related variational principle that leads to Hamilton's equations. To do so, insert the definition of the Hamiltonian from equation (12.135) into the action to render

$$\mathcal{S} = \int_{t_A}^{t_B} L(\xi^\sigma, \dot{\xi}^\sigma, t)\,\mathrm{d}t = \int_{t_A}^{t_B} \left[-H(\xi^\sigma, \mathcal{P}_\sigma, t) + \sum_{\sigma=1}^{D} \dot{\xi}^\sigma\,\mathcal{P}_\sigma \right] \mathrm{d}t. \tag{12.147}$$

We now consider a variation of the generalized coordinates and generalized momenta, in which the action is varied according to

$$\delta\mathcal{S} = \sum_{\sigma=1}^{D} \int_{t_A}^{t_B} \left[-\frac{\partial H}{\partial \xi^\sigma}\,\delta\xi^\sigma - \frac{\partial H}{\partial \mathcal{P}_\sigma}\,\delta\mathcal{P}_\sigma + \delta\dot{\xi}^\sigma\,\mathcal{P}_\sigma + \dot{\xi}^\sigma\,\delta\mathcal{P}_\sigma \right] \mathrm{d}t. \tag{12.148}$$

Variations of the generalized momenta and generalized coordinates are independent. However, variation of the generalized coordinates and generalized velocities are connected just like when deriving the Euler-Lagrange equations in Section 12.6.3. Hence, an integration by parts leads to

$$\int_{t_A}^{t_B} \delta\dot{\xi}^\sigma\,\mathcal{P}_\sigma\,\mathrm{d}t = \int_{t_A}^{t_B} \frac{\mathrm{d}(\delta\xi^\sigma)}{\mathrm{d}t}\,\mathcal{P}_\sigma\,\mathrm{d}t = \int_{t_A}^{t_B} \left[\frac{\mathrm{d}(\delta\xi^\sigma\,\mathcal{P}_\sigma)}{\mathrm{d}t} - \delta\xi^\sigma\,\dot{\mathcal{P}}_\sigma \right] \mathrm{d}t. \tag{12.149}$$

The total time derivative in the final expression vanishes since the coordinate variation vanishes at the initial and final times. We are thus left with the action variation

$$\delta\mathcal{S} = \sum_{\sigma=1}^{D} \int_{t_A}^{t_B} \left[-\left(\dot{\mathcal{P}}_\sigma + \frac{\partial H}{\partial \xi^\sigma} \right) \delta\xi^\sigma + \left(\dot{\xi}^\sigma - \frac{\partial H}{\partial \mathcal{P}_\sigma} \right) \delta\mathcal{P}_\sigma \right] \mathrm{d}t. \tag{12.150}$$

Since $\delta\xi^\sigma$ and $\delta\mathcal{P}_\sigma$ are independent, we realize a stationary action if and only if Hamilton's equations are satisfied

$$\dot{\xi}^\sigma = \frac{\partial H}{\partial \mathcal{P}_\sigma} \quad \text{and} \quad \dot{\mathcal{P}}_\sigma = -\frac{\partial H}{\partial \xi^\sigma}. \tag{12.151}$$

12.10.7 Incompressible motion in phase space

Chapter 13

Particle mechanics around a rotating planet

In this chapter we study the mechanics of a point particle of fixed mass that moves around a rotating and massive planet, making use of the Newtonian mechanics from Chapter 11. The motion of a point particle provides a model for objects such as satellites moving around rotating planets. For this analysis, the motion of the planet is prescribed with a fixed kinetic energy and fixed angular momentum around a fixed axis of rotation. Hence, we are concerned just mechanics of the moving particle.

Our description of the particle is examined from the rigid-body rotating (non-inertial) reference frame (Section 11.4), which is the natural frame for an observer fixed on the planet surface. Notably, a particle at rest in the rotating reference frame has both kinetic energy and angular momentum merely due to rotation of the planet. We generally ignore friction and other non-gravitational forces, so that the only force appearing in an inertial reference frame is that from the gravitational field induced by the massive spherical planet. As discussed in Section 11.4, there are two extra accelerations (planetary centrifugal and planetary Coriolis) that appear when viewing motion from the rigid-body rotating terrestrial reference frame.[1]

CHAPTER GUIDE

This chapter builds from the Newtonian mechanics of Chapter 11, here specializing to the geophysically relevant case of a particle moving around a rotating planet. Introducing the spherical coordinate equations of motion represent a key technical element of this chapter, thus going beyond the Cartesian coordinates used in Chapter 11. The use of spherical coordinates prompts the introduction of basic Cartesian and general tensor algebra as presented in Chapters 1, 8, 9, and Section 10.2. We offer the salient features of tensor technology in this chapter where needed, thus providing a reasonably self-contained presentation.

[1] As emphasized by *Early* (2012), the acceleration from gravity, in the face of general relativity, cannot be distinguished from accelerations encountered when describing motion in a non-inertial reference frame. *Early* (2012) provides an accounting of such motion while clarifying what is meant by "inertial oscillations" for particles constrained to move around the earth along a constant geopotential (we also consider this motion in Section 15.5). Even so, we here consider gravity as distinct from Coriolis and centrifugal since it appears when the particle is viewed from an inertial reference frame.

13.1 The rotating earth

The earth's *angular velocity* is comprised of two main contributions: the spin of the earth about its axis and the orbit of the earth about the sun (see Figure 13.1). Other astronomical motions can be neglected for geophysical fluid mechanics. Therefore, in the course of a single period of 24 hours, or $24 \times 3600 = 86400$ seconds, the earth experiences an angular rotation of $(2\pi + 2\pi/365.24)$ radians. As such, the angular rotation rate is given by

$$\Omega = \frac{2\pi + 2\pi/365.24}{86400\text{s}} = \left[\frac{\pi}{43082}\right] \text{s}^{-1} = 7.2921 \times 10^{-5}\ \text{s}^{-1}. \tag{13.1}$$

FIGURE 13.1: The angular velocity of the earth arises from the spin about the polar axis plus the orbit of the planet around the sun. This angular velocity determines the strength of the Coriolis acceleration and the planetary centrifugal acceleration.

The earth's angular velocity, both its direction through the polar axis and its magnitude, is assumed constant in time for purposes of geophysical fluid mechanics

$$\frac{\mathrm{d}\boldsymbol{\Omega}}{\mathrm{d}t} = 0. \tag{13.2}$$

The angular velocity (13.1) seems quite small. However, a terrestrial reference frame on the earth surface undergoes *rigid-body rotation* with speed

$$U_{\text{rigid-body}}(\phi) = \Omega\, R_{\text{e}} \cos\phi \approx 465 \text{ m s}^{-1} \cos\phi = 1672 \text{ km hr}^{-1} \cos\phi, \tag{13.3}$$

where we set the earth's radius to

$$R_{\text{e}} = 6.371 \times 10^6 \text{ m}. \tag{13.4}$$

This speed is quite large relative to a fixed frame outside the planet (see Figure 13.2)

$$U_{\text{rigid-body}}(0^\circ) = 1672 \text{ km hr}^{-1} \tag{13.5a}$$
$$U_{\text{rigid-body}}(30^\circ) = 1448 \text{ km hr}^{-1} \tag{13.5b}$$
$$U_{\text{rigid-body}}(60^\circ) = 826 \text{ km hr}^{-1}. \tag{13.5c}$$

Motion of the atmosphere and ocean are generally close to rigid-body motion, so that their speeds relative to the planet are much smaller than the speed of the rotating planet itself. So in addition to being directly relevant to terrestrial observers, we find it most interesting to study geophysical motion in the rotating planetary frame (a non-inertial frame) rather than a frame fixed relative to the stars (an approximate inertial frame).

13.2 Changes to basis vectors under rigid-body rotation

In Section 11.2, we studied the kinematics of a vector with fixed length that is rotating about a fixed origin. The key kinematic result (11.34) exposes how rotation generates a time change to the rigid-body rotation of a vector

$$\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \boldsymbol{Q}, \tag{13.6}$$

FIGURE 13.2: For an observer at rest on the earth's surface, the rigid-body speed is $\Omega\, R_e \cos\phi = 7.2921 \times 10^{-5}\ \mathrm{s}^{-1} \times 6.371 \times 10^6\ \mathrm{m} \cos\phi \approx 465\ \mathrm{m\ s}^{-1} \cos\phi = 1672\ \mathrm{km\ hr}^{-1} \cos\phi$. We here display rigid-body speeds for motion at the equator, 30° latitude, and 60° latitude. These speeds are much larger than motion of the ocean and atmosphere relative to the earth, thus motivating a description of geophysical fluid motion from the rotating terrestrial frame moving with the rigid-body.

where $\boldsymbol{Q}$ is an arbitrary vector. We here make use of this relation to determine how the basis vectors for Cartesian, cylindrical-polar, and spherical coordinates change under rotation.

13.2.1 Changes to Cartesian basis vectors under rotation

With $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$ as for a rotating spherical earth, equation (13.6) says that the change in planetary Cartesian unit vectors under rigid-body rotation is given by

$$\frac{\mathrm{d}\hat{\boldsymbol{x}}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \hat{\boldsymbol{x}} = \Omega\,\hat{\boldsymbol{y}} \qquad \text{and} \qquad \frac{\mathrm{d}\hat{\boldsymbol{y}}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \hat{\boldsymbol{y}} = -\Omega\,\hat{\boldsymbol{x}} \qquad \text{and} \qquad \frac{\mathrm{d}\hat{\boldsymbol{z}}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \hat{\boldsymbol{z}} = 0. \tag{13.7}$$

13.2.2 Changes to cylindrical-polar coordinate unit vectors under rotation

As another example of how unit vectors change under rigid-body rotation, consider the polar coordinates from Section 10.3 with rotation continuing to be about the vertical axis, $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$. In the horizontal plane we have the radial and angular unit vectors

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}} \cos\vartheta + \hat{\boldsymbol{y}} \sin\vartheta \tag{13.8a}$$

$$\hat{\boldsymbol{\vartheta}} = -\hat{\boldsymbol{x}} \sin\vartheta + \hat{\boldsymbol{y}} \cos\vartheta. \tag{13.8b}$$

We can directly verify that the time derivative of these unit vectors is given by

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = (\Omega + \dot{\vartheta})\,\hat{\boldsymbol{\vartheta}} = (\Omega + \dot{\vartheta})\,(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}}) \tag{13.9a}$$

$$\frac{\mathrm{d}\hat{\boldsymbol{\vartheta}}}{\mathrm{d}t} = -(\Omega + \dot{\vartheta})\,\hat{\boldsymbol{r}} = (\Omega + \dot{\vartheta})\,(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{\vartheta}}). \tag{13.9b}$$

Notice how these unit vectors change both due to the rotation of the reference frame, Ω, plus the change in the angular position relative to the reference frame, $\dot{\vartheta}$. We thus see that unit vectors, such as those for spherical coordinates and cylindrical-polar coordinates, change due to the rigid-body rotation, just like the Cartesian unit vectors. Additionally, non-Cartesian unit

vectors change when their orientation is modified relative to the Cartesian coordinate axes at a rate distinct from the rigid-body. This situation occurs when a trajectory moves relative to the rigid-body. We further discuss this notion in Section 13.2.2 and detail the spherical coordinate case in Sections 13.7.2 and 13.9.

13.2.3 Changes to spherical coordinate unit vectors under rotation

As a third example, consider the rotation of spherical coordinate unit vectors, whose form was derived in Section 10.2.2

$$\hat{\boldsymbol{\lambda}} = -\hat{\boldsymbol{x}} \sin\lambda + \hat{\boldsymbol{y}} \cos\lambda \tag{13.10a}$$

$$\hat{\boldsymbol{\phi}} = -\hat{\boldsymbol{x}} \cos\lambda \, \sin\phi - \hat{\boldsymbol{y}} \sin\lambda \, \sin\phi + \hat{\boldsymbol{z}} \cos\phi \tag{13.10b}$$

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}} \, \cos\lambda \, \cos\phi + \hat{\boldsymbol{y}} \sin\lambda \, \cos\phi + \hat{\boldsymbol{z}} \sin\phi. \tag{13.10c}$$

Again, each of the basis vectors are normalized, so that their evolution arises just from rotations.

Start with deriving the time derivative of the radial unit vector, $\hat{\boldsymbol{r}}$. We know that it can rotate either through rigid-body motion of the rotating reference frame, or through changes in the spherical angles, (λ, ϕ), relative to the rotating reference frame. We see these two forms of time changes by taking the time derivative

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}(\hat{\boldsymbol{x}} \, \cos\lambda \, \cos\phi + \hat{\boldsymbol{y}} \sin\lambda \, \cos\phi + \hat{\boldsymbol{z}} \sin\phi). \tag{13.11}$$

Expanding the right hand side leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}(\hat{\boldsymbol{x}} \, \cos\lambda \, \cos\phi) = \frac{\mathrm{d}\hat{\boldsymbol{x}}}{\mathrm{d}t} \cos\lambda \cos\phi - \hat{\boldsymbol{x}} \, \dot{\lambda} \sin\lambda \cos\phi - \hat{\boldsymbol{x}} \, \dot{\phi} \cos\lambda \sin\phi \tag{13.12a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}(\hat{\boldsymbol{y}} \sin\lambda \, \cos\phi) = \frac{\mathrm{d}\hat{\boldsymbol{y}}}{\mathrm{d}t} \sin\lambda \cos\phi + \hat{\boldsymbol{y}} \, \dot{\lambda} \cos\lambda \cos\phi - \hat{\boldsymbol{y}} \, \dot{\phi} \sin\lambda \sin\phi \tag{13.12b}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}(\hat{\boldsymbol{z}} \sin\phi) = \hat{\boldsymbol{z}} \, \dot{\phi} \cos\phi. \tag{13.12c}$$

Making use of equation (13.7) for the change in planetary Cartesian unit vectors due to rotation, and substituting the expressions (10.30a)-(10.30c) for the spherical unit vectors, leads to

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = \hat{\boldsymbol{\lambda}} \, (\dot{\lambda} + \Omega) \cos\phi + \hat{\boldsymbol{\phi}} \, \dot{\phi}. \tag{13.13}$$

We thus confirm that changes to $\hat{\boldsymbol{r}}$ arise just from changes to its angular orientation. To help understand this expression, take the case of rigid-body motion, in which $\dot{\lambda} = \dot{\phi} = 0$, so that $\hat{\boldsymbol{r}}$ changes only through motion of the rotating reference frame. Any additional longitudinal motion arising from $\dot{\lambda} \neq 0$ renders further changes in the $\hat{\boldsymbol{\lambda}}$ direction. Finally, meridional motion through $\dot{\phi} \neq 0$ modifies the unit vector in the $\hat{\boldsymbol{\phi}}$ direction. Similar manipulations and considerations lead to the time derivatives for the angular unit vectors

$$\frac{\mathrm{d}\hat{\boldsymbol{\phi}}}{\mathrm{d}t} = -\hat{\boldsymbol{\lambda}} \, (\Omega + \dot{\lambda}) \sin\phi - \hat{\boldsymbol{r}} \, \dot{\phi} \tag{13.14a}$$

$$\frac{\mathrm{d}\hat{\boldsymbol{\lambda}}}{\mathrm{d}t} = (\Omega + \dot{\lambda}) \, (\hat{\boldsymbol{\phi}} \sin\phi - \hat{\boldsymbol{r}} \cos\phi). \tag{13.14b}$$

Further details for deriving equations (13.13), (13.14a), and (13.14b) are given in the solution to Exercise 13.2.

13.3 A synopsis of tensor algebra

In Part I of this book, we detailed the use of tensor analysis for geophysical motions. We here summarize some of the salient points that are of use in this chapter for manipulating spherical coordinates.

13.3.1 Why we need general tensors

Cartesian tensors are sufficient for many purposes of fluid mechanics, such as when using Cartesian coordinates for a tangent plane approximation to study geophysical fluid motion (e.g., Section 25.5). However, we make routine use of spherical coordinates when describing geophysical motion, and cylindrical-polar coordinates for studies of rotating tank experiments (see Section 37.8). Finally, we use generalized vertical coordinates in the description of stratified flows (Part XI). The basis vectors for curvilinear coordinates and generalized vertical coordinates change direction when moving through space. In contrast, Cartesian basis vectors always point in the same direction. This distinction between the basis vectors is the key reason curvilinear coordinates and generalized vertical coordinates require a more general formalism than afforded by Cartesian tensors.

Even though general tensors are of use in this book, we can keep much of the heavy technology at a modest distance, with exposure only in selected places. The key crutch we rely on is that the planet is assumed to be embedded in a background three-dimensional Euclidean space. That is, we are not considering the curved space-time of general relativity nor the marriage of space and time afforded by special relativity. Rather, we restrict our concern to *Galilean relatively*, which is based on three-dimensional Euclidean space plus universal Newtonian time. These assumptions simplify our use of general tensors.

13.3.2 The coordinate representation of a vector

The coordinate representation of a vector follows from decomposing the vector into components aligned according to a set of basis vectors, in which case we write

$$\vec{Q} = \sum_{a=1}^{3} Q^a \, \vec{e}_a = Q^a \, \vec{e}_a, \tag{13.15}$$

where the Einstein summation convention is defined by the final equality. In this equation,

$$\vec{e}_a = (\vec{e}_1, \vec{e}_2, \vec{e}_3) \tag{13.16}$$

is a set of linearly independent basis vectors, and Q^a are the corresponding coordinate representations of the vector $\vec{Q}$. The basis vectors may be normalized to unit magnitude, as in the case of Cartesian coordinates, or may be unnormalized as for spherical coordinates (see Section 10.2.2). Note that we commonly make use of the boldface notation for a vector rather than the arrowed symbol (Section 8.5)

$$\boldsymbol{Q} = \vec{Q} = Q^a \, \vec{e}_a. \tag{13.17}$$

The basis vectors in equation (13.15) have a lower index while the coordinate representation of a vector has an upper index. Why? For arbitrary coordinates (e.g., spherical), we make a distinction between a coordinate representation with an index upstairs (*contravariant*) versus the downstairs (*covariant*) representation. Moving between the covariant and contravariant representations requires a metric tensor.

When working with general coordinates, it is necessary to distinguish between a basis vector, $\vec{e}_a$, and its dual partner known as a *one-form*, $\widetilde{e}^a$. Duality is here defined by the familiar

(Euclidean) inner product that leads to the bi-orthogonality relation

$$\vec{e}_a \cdot \vec{e}^b = \delta^b_{\ a}, \tag{13.18}$$

with $\delta^b_{\ a}$ the Kronecker delta tensor

$$\delta^b_{\ a} = \begin{cases} 1 & \text{if } b = a \\ 0 & \text{if } b \neq a. \end{cases} \tag{13.19}$$

In linear algebra, a row vector is dual to its column vector, with that analog appropriate for the present context. Cartesian basis vectors equal to the basis one-forms, in which case there is no distinction between contravariant and covariant. However, the distinction is important for more general coordinates used in geophysical fluids.

13.3.3 Generalized coordinates

We find it convenient to write ξ^a as the a'th component of a *generalized coordinate* used to describe space. In this chapter we choose the unbarred generalized coordinates as planetary Cartesian coordinates, so that

$$(\xi^1, \xi^2, \xi^3) = (x, y, z), \tag{13.20}$$

whereas the barred generalized coordinates are the planetary spherical coordinates[2]

$$(\xi^{\bar{1}}, \xi^{\bar{2}}, \xi^{\bar{3}}) = (\lambda, \phi, r). \tag{13.21}$$

These two sets of coordinates are related by the coordinate transformation provided in Section 10.2 (see in particular Figure 10.1)

$$x = r\cos\phi\,\cos\lambda \qquad \text{and} \qquad y = r\cos\phi\,\sin\lambda \qquad \text{and} \qquad z = r\sin\phi. \tag{13.22}$$

The equation set (13.22) provides the coordinate transformation between a particular point in three-dimensional Euclidean space that is represented by Cartesian coordinates and spherical coordinates.

13.3.4 Transformation between coordinate representations

The coordinate representation of a tensor is a subjective analytical description of an objective geometric object. That is, the subjectively chosen coordinate representation of a vector, such as that given by equation (13.15), does not affect the vector as a geometric object. Hence, we can represent the vector using any arbitrary set of coordinates

$$\vec{Q} = Q^a\,\vec{e}_a = Q^{\bar{a}}\,\vec{e}_{\bar{a}}. \tag{13.23}$$

In this equation, $Q^{\bar{a}}$ is the representation of the vector $\vec{Q}$ in a coordinate system defined by the basis vector $\vec{e}_{\bar{a}}$, whereas Q^a is the representation in the unbarred coordinate system with basis vectors $\vec{e}_a$.

The coordinate representation of a vector transforms when changing coordinates. The transformation is mediated by the *transformation matrix*, which is the matrix composed of the partial derivatives of one coordinate set with respect to the other. For example, the relation between the

[2] We will have occasion to use other generalized coordinates in this book, with particular attention given to generalized vertical coordinates in Part XI.

coordinate representation of the velocity vector and acceleration vector, as well as the coordinate basis vectors, are given by

$$V^{\overline{a}} = \Lambda^{\overline{a}}_{\ a}\, V^a \qquad \text{and} \qquad A^{\overline{a}} = \Lambda^{\overline{a}}_{\ a}\, A^a \qquad \text{and} \qquad \vec{e}_{\overline{a}} = \Lambda^{a}_{\ \overline{a}}\, \vec{e}_a. \tag{13.24}$$

The general expression for the transformation matrix is given by the matrix of partial derivatives

$$\Lambda^{a}_{\ \overline{a}} = \begin{bmatrix} \partial\xi^1/\partial\xi^{\overline{1}} & \partial\xi^1/\partial\xi^{\overline{2}} & \partial\xi^1/\partial\xi^{\overline{3}} \\ \partial\xi^2/\partial\xi^{\overline{1}} & \partial\xi^2/\partial\xi^{\overline{2}} & \partial\xi^2/\partial\xi^{\overline{3}} \\ \partial\xi^3/\partial\xi^{\overline{1}} & \partial\xi^3/\partial\xi^{\overline{2}} & \partial\xi^3/\partial\xi^{\overline{3}} \end{bmatrix}. \tag{13.25}$$

For the particular case where the unbarred coordinates are Cartesian and the barred are spherical, we have from Section 10.2.1 the transformation matrix along with its inverse

$$\Lambda^{a}_{\ \overline{a}} = \begin{bmatrix} -r\cos\phi\sin\lambda & -r\sin\phi\,\cos\lambda & \cos\phi\cos\lambda \\ r\cos\phi\cos\lambda & -r\sin\phi\,\sin\lambda & \cos\phi\sin\lambda \\ 0 & r\cos\phi & \sin\phi \end{bmatrix} \tag{13.26}$$

$$\Lambda^{\overline{a}}_{\ a} = \frac{1}{r^2\cos\phi} \begin{bmatrix} -r\sin\lambda & r\cos\lambda & 0 \\ -r\cos\phi\,\sin\phi\,\cos\lambda & -r\cos\phi\sin\phi\sin\lambda & r\cos^2\phi \\ r^2\cos^2\phi\cos\lambda & r^2\,\cos^2\phi\sin\lambda & r^2\cos\phi\sin\phi \end{bmatrix}. \tag{13.27}$$

It is straightforward to verify the orthonormality relations satisfied by these matrices

$$\Lambda^{\overline{a}}_{\ a}\,\Lambda^{a}_{\ \overline{b}} = \delta^{\overline{a}}_{\ \overline{b}} \qquad \text{and} \qquad \Lambda^{a}_{\ \overline{a}}\,\Lambda^{\overline{a}}_{\ b} = \delta^{a}_{\ b}. \tag{13.28}$$

Hence, if we have the Cartesian representation of a vector, such as the velocity or acceleration, then we can use these transformation rules to derive the spherical representation through matrix multiplication, as per equation (13.24).

13.3.5 Two meanings for the same symbol

We highlight the need to hold two meanings in mind for (x, y, z) and (r, λ, ϕ), or for any set of generalized coordinates (ξ^1, ξ^2, ξ^3). One meaning specifies a point in Euclidean space. The other meaning refers to the position in space for a moving material particle, in which case the coordinate position is a function of time. We commonly write the second meaning using the capital, $\boldsymbol{X}(t)$, to denote the particle trajectory. To accord with common usage for the Cartesian and spherical coordinates, we write the components to $\boldsymbol{X}(t)$ using the smaller case, so that the Cartesian position of the particle is

$$\boldsymbol{X}(t) = \hat{\boldsymbol{x}}\, x(t) + \hat{\boldsymbol{y}}\, y(t) + \hat{\boldsymbol{z}}\, z(t), \tag{13.29}$$

whereas the spherical position is

$$\boldsymbol{X}(t) = \hat{\boldsymbol{r}}(t)\, r(t). \tag{13.30}$$

Time dependence of the unit vectors depends on the reference frame. For an inertial reference frame, the Cartesian unit vectors are fixed in space, whereas for the rigid-body rotating frame, the Cartesian basis vectors rotate around the vertical axis. Likewise, the spherical unit vector rotates with the rotating reference frame. Yet even in an inertial reference frame, $\hat{\boldsymbol{r}}$ is a function of time since it points from the origin towards the moving particle.

13.4 The velocity vector

The velocity is the time derivative of the position vector

$$\boldsymbol{V} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t}. \tag{13.31}$$

This equation is manifestly geometric in that the velocity at a space-time point is the tangent vector to the trajectory at that point. When expressing this relation using a coordinate representation we note that time dependence lives with both the coordinate representation of the position vector as well as the basis vectors

$$\boldsymbol{V} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \frac{\mathrm{d}\left(\xi^a\,\vec{e}_a\right)}{\mathrm{d}t} = \frac{\mathrm{d}\xi^a}{\mathrm{d}t}\,\vec{e}_a + \xi^a\,\frac{\mathrm{d}\vec{e}_a}{\mathrm{d}t}. \tag{13.32}$$

13.4.1 Coordinate velocity

The first term on the right hand side of equation (13.32) is the velocity as measured within the chosen reference frame using the chosen coordinates

$$\boldsymbol{V}_{\text{coord}} \equiv \frac{\mathrm{d}\xi^a}{\mathrm{d}t}\,\vec{e}_a. \tag{13.33}$$

This is the contribution to velocity as measured in the reference frame that moves with the basis vectors. In the context of geophysical motions, this is the velocity measured in the rotating terrestrial reference frame using Cartesian, spherical, or other chosen coordinates.

13.4.2 Changes to the basis vectors

The second term on the right hand side of equation (13.32) arises from changes to the basis vectors. There are three means for a basis vector to change, and we encounter them when considering coordinate representations later in this chapter. Two changes arise from rotations, each of which change the basis vector's direction without changing its magnitude. The third change leads to a modification of the basis vector's magnitude.

- RIGID-BODY ROTATION: For a rigid-body rotation of the reference frame, the rigid-body velocity is given by (see Section 11.2.2)

$$\boldsymbol{U}_{\text{rigid}} = \boldsymbol{\Omega} \times \boldsymbol{X}. \tag{13.34}$$

- ROTATION RELATIVE TO RIGID-BODY: A vector can also rotate at a rate that differs from the rigid-body.

- CHANGE IN MAGNITUDE: Finally, if the basis vectors are not normalized to have unit magnitude, then they can change their magnitude during motion.

13.5 Decomposition of the inertial frame acceleration

The acceleration measured in an inertial reference frame is given by the time derivative of the velocity measured in this frame, so that the acceleration is the second derivative of the position vector

$$\boldsymbol{A} = \frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = \frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2}. \tag{13.35}$$

This equation is independent of any coordinate representation so that the physical and geometrical content are manifest. When introducing a coordinate representation, the resulting expression becomes subject to details of the chosen coordinates and those details possibly obscure the underlying geometric meaning. Hence, it is important to keep the geometric expression in mind when offering an interpretation for coordinate dependent terms.

Introducing a coordinate representation $\boldsymbol{X} = \xi^a \, \vec{e}_a$ into the acceleration (13.35), and making use of the chain rule, leads to

$$\boldsymbol{A} = \frac{\mathrm{d}}{\mathrm{d}t} \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} \tag{13.36a}$$

$$= \frac{\mathrm{d}}{\mathrm{d}t} \frac{\mathrm{d}\left(\xi^a \, \vec{e}_a\right)}{\mathrm{d}t} \tag{13.36b}$$

$$= \frac{\mathrm{d}}{\mathrm{d}t} \left[\frac{\mathrm{d}\,\xi^a}{\mathrm{d}t} \, \vec{e}_a + \xi^a \, \frac{\mathrm{d}\,\vec{e}_a}{\mathrm{d}t} \right] \tag{13.36c}$$

$$= \frac{\mathrm{d}^2 \xi^a}{\mathrm{d}t^2} \, \vec{e}_a + 2 \, \frac{\mathrm{d}\xi^a}{\mathrm{d}t} \, \frac{\mathrm{d}\vec{e}_a}{\mathrm{d}t} + \xi^a \, \frac{\mathrm{d}^2 \vec{e}_a}{\mathrm{d}t^2}. \tag{13.36d}$$

The first term on the right hand side is the acceleration of the coordinate representation as measured in the rotating reference frame

$$\boldsymbol{A}_{\text{coord}} \equiv \frac{\mathrm{d}^2 \xi^a}{\mathrm{d}t^2} \, \vec{e}_a. \tag{13.37}$$

It is the acceleration measured by an observer in the rotating frame using coordinates ξ^a. The remaining two terms arise from changes to the basis vectors, and they give rise to the Coriolis and planetary centrifugal accelerations associated with the rotating reference frame. In non-Cartesian coordinates, they also give rise to a *metric acceleration* arising from the change in directions of the unit vectors associated with motion of the particle relative to the rotating reference frame (Section 13.4.2). Note that the factor of two on the middle term (the Coriolis term) in equation (13.36d) results from the two time derivatives that act on the basis vectors that arise when computing the acceleration. We already encountered this factor of two when deriving the Cartesian expression of the Coriolis acceleration in Section 11.4.3.

13.6 Representing the position vector

We make use of some results from Section 10.2 relating Cartesian and spherical coordinates and as defined by Figure 10.1. In particular, we use the *planetary* Cartesian basis vectors, $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$, and corresponding spherical basis vectors, $(\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{r}})$, thus leading to the coordinate representations of the position vector relative to the center of a rotating sphere

$$\boldsymbol{X} = x \, \hat{\boldsymbol{x}} + y \, \hat{\boldsymbol{y}} + z \, \hat{\boldsymbol{z}} \tag{13.38a}$$

$$= (r \cos\phi \, \cos\lambda) \, \hat{\boldsymbol{x}} + (r \cos\phi \, \sin\lambda) \, \hat{\boldsymbol{y}} + (r \sin\phi) \, \hat{\boldsymbol{z}} \tag{13.38b}$$

$$= r \, \hat{\boldsymbol{r}} \tag{13.38c}$$

$$= |\boldsymbol{X}| \, \hat{\boldsymbol{r}}. \tag{13.38d}$$

The expression for the position vector is quite simple when written in spherical coordinates, as it is merely the distance from the origin with a direction that points radially from the origin to the particle.

13.7 Representing the velocity vector

As seen in Section 13.4, the inertial frame velocity vector has a coordinate representation written as

$$\boldsymbol{V} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \frac{\mathrm{d}(\xi^a\,\vec{e}_a)}{\mathrm{d}t} = \frac{\mathrm{d}\xi^a}{\mathrm{d}t}\,\vec{e}_a + \xi^a\,\frac{\mathrm{d}\vec{e}_a}{\mathrm{d}t}. \tag{13.39}$$

Contributions arise from both the time changes in the coordinates, ξ^a, and time changes to the basis vectors, $\vec{e}_a$. We now consider the Cartesian and spherical forms for these changes.

13.7.1 Planetary Cartesian coordinate representation

The basis vectors for the Cartesian coordinates, $(\vec{e}_1, \vec{e}_2, \vec{e}_3) = (\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$, are normalized, so they do not change their magnitude. Furthermore, they move only through rigid-body motion of the rotating reference frame. We refer to these coordinates as *planetary Cartesian coordinates* since they are oriented according to the rotating planet with origin at the planet's center. In Section 25.5 we introduce the distinct *tangent plane Cartesian coordinates*. Tangent plane Cartesian coordinates are also moving with the rotating planet. Yet they are defined according to a tangent plane at a point on the surface of the sphere. It is important to distinguish these two uses for Cartesian coordinates in geophysical fluid mechanics.

The angular velocity is oriented around the polar axis

$$\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}, \tag{13.40}$$

so that the rigid-body velocity of the rotating reference frame only has components in the $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$ directions

$$\boldsymbol{U}_{\text{rigid}} = \boldsymbol{\Omega} \times \boldsymbol{X} = \Omega\,(-\hat{\boldsymbol{x}}\,y + \hat{\boldsymbol{y}}\,x). \tag{13.41}$$

The inertial frame velocity thus has the following representation in terms of planetary Cartesian coordinates

$$\begin{aligned}
\boldsymbol{V} &= \frac{\mathrm{d}}{\mathrm{d}t}\,[\hat{\boldsymbol{x}}\,x + \hat{\boldsymbol{y}}\,y + \hat{\boldsymbol{z}}\,z] && \text{(13.42a)}\\
&= \left[\hat{\boldsymbol{x}}\,\frac{\mathrm{d}x}{\mathrm{d}t} + \hat{\boldsymbol{y}}\,\frac{\mathrm{d}y}{\mathrm{d}t} + \hat{\boldsymbol{z}}\,\frac{\mathrm{d}z}{\mathrm{d}t}\right] + x\,\frac{\mathrm{d}\hat{\boldsymbol{x}}}{\mathrm{d}t} + y\,\frac{\mathrm{d}\hat{\boldsymbol{y}}}{\mathrm{d}t} + z\,\frac{\mathrm{d}\hat{\boldsymbol{z}}}{\mathrm{d}t} && \text{(13.42b)}\\
&= \left[-y\,\Omega + \frac{\mathrm{d}x}{\mathrm{d}t}\right]\hat{\boldsymbol{x}} + \left[x\,\Omega + \frac{\mathrm{d}y}{\mathrm{d}t}\right]\hat{\boldsymbol{y}} + \frac{\mathrm{d}z}{\mathrm{d}t}\,\hat{\boldsymbol{z}} && \text{(13.42c)}\\
&= \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{\Omega} \times \boldsymbol{X} && \text{(13.42d)}\\
&= \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{U}_{\text{rigid}}, && \text{(13.42e)}
\end{aligned}$$

where we defined the Cartesian velocity vector

$$\boldsymbol{V}_{\text{Cartesian}} \equiv \frac{\mathrm{d}x}{\mathrm{d}t}\,\hat{\boldsymbol{x}} + \frac{\mathrm{d}y}{\mathrm{d}t}\,\hat{\boldsymbol{y}} + \frac{\mathrm{d}z}{\mathrm{d}t}\,\hat{\boldsymbol{z}}, \tag{13.43}$$

which is the velocity as measured in the rotating reference frame when using planetary Cartesian coordinates. We also made use of equation (13.7) to express the time rate of change for the planetary Cartesian unit vectors, with this change arising solely from the planetary rotation. Note that the results here hold whether $\boldsymbol{\Omega}$ is constant or varying in time.

13.7.2 Planetary spherical coordinate representation

The position vector in the planetary spherical coordinate representation is given by

$$\boldsymbol{X} = r\,\hat{\boldsymbol{r}}. \tag{13.44}$$

The basis vector $\hat{\boldsymbol{r}}$ is normalized, so that its evolution arises just from rotations, and we determined that time evolution in equation (13.13)

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = \hat{\boldsymbol{\lambda}}\,(\dot{\lambda} + \Omega)\cos\phi + \hat{\boldsymbol{\phi}}\,\dot{\phi}. \tag{13.45}$$

Consequently, the velocity as viewed in the inertial frame has the following spherical coordinate representation

$$\begin{aligned}
\boldsymbol{V} &= \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} && (13.46\text{a})\\
&= \frac{\mathrm{d}(r\,\hat{\boldsymbol{r}})}{\mathrm{d}t} && (13.46\text{b})\\
&= r\,\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} + \frac{\mathrm{d}r}{\mathrm{d}t}\,\hat{\boldsymbol{r}} && (13.46\text{c})\\
&= r_\perp\,(\dot{\lambda} + \Omega)\,\hat{\boldsymbol{\lambda}} + r\,\dot{\phi}\,\hat{\boldsymbol{\phi}} + \dot{r}\,\hat{\boldsymbol{r}} && (13.46\text{d})\\
&= (u + r_\perp\,\Omega)\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}} && (13.46\text{e})\\
&= \boldsymbol{V}_{\text{spherical}} + \boldsymbol{U}_{\text{rigid}}. && (13.46\text{f})
\end{aligned}$$

In this equation we introduced the spherical coordinate velocity vector

$$\boldsymbol{V}_{\text{spherical}} = r_\perp\,\dot{\lambda}\,\hat{\boldsymbol{\lambda}} + r\,\dot{\phi}\,\hat{\boldsymbol{\phi}} + \dot{r}\,\hat{\boldsymbol{r}} \equiv u\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}, \tag{13.47}$$

where we defined the components to the spherical velocity vector

$$u \equiv r_\perp\,\frac{\mathrm{d}\lambda}{\mathrm{d}t} \qquad \text{and} \qquad v \equiv r\,\frac{\mathrm{d}\phi}{\mathrm{d}t} \qquad \text{and} \qquad w \equiv \frac{\mathrm{d}r}{\mathrm{d}t}, \tag{13.48}$$

and with

$$r_\perp = |\boldsymbol{X}|\cos\phi = r\cos\phi \tag{13.49}$$

the distance to the polar axis. The spherical velocity, $\boldsymbol{V}_{\text{spherical}}$, is the velocity measured in the rotating reference frame when using planetary spherical coordinates. We also noted that the rigid-body velocity has the spherical coordinate representation

$$\boldsymbol{U}_{\text{rigid}} = \boldsymbol{\Omega} \times \boldsymbol{X} = r_\perp\,\Omega\,\hat{\boldsymbol{\lambda}}. \tag{13.50}$$

That is, the rigid-body velocity is purely zonal.

13.7.3 Transforming from Cartesian to spherical

We can make use of the tensor algebra from Section 13.3 to transform from the Cartesian representation of the velocity vector to the spherical representation. This approach leads to an equivalent result to that pursued thus far in this section, but it is somewhat more systematic and it offers useful experience with the formalities of coordinate transformations. In particular, we make use of the transformation rule (13.24) along with the transformation matrix (13.26) and its inverse

(13.27) to have

$$V^{\bar{1}} = V^r = \Lambda^{\bar{1}}_{\ 1}\, V^1 + \Lambda^{\bar{1}}_{\ 2}\, V^2 + \Lambda^{\bar{1}}_{\ 3}\, V^3 \tag{13.51a}$$

$$V^{\bar{2}} = V^\lambda = \Lambda^{\bar{2}}_{\ 1}\, V^1 + \Lambda^{\bar{2}}_{\ 2}\, V^2 + \Lambda^{\bar{2}}_{\ 3}\, V^3 \tag{13.51b}$$

$$V^{\bar{3}} = V^\phi = \Lambda^{\bar{3}}_{\ 1}\, V^1 + \Lambda^{\bar{3}}_{\ 2}\, V^2 + \Lambda^{\bar{3}}_{\ 3}\, V^3, \tag{13.51c}$$

where the Cartesian components are

$$V^1 = \dot{x} - \Omega\, y = \dot{r}\cos\phi\cos\lambda - r\,\dot{\phi}\sin\phi\cos\lambda - r\,(\dot{\lambda} + \Omega)\cos\phi\sin\lambda \tag{13.52a}$$

$$V^2 = \dot{y} + \Omega\, x = \dot{r}\cos\phi\sin\lambda - r\,\dot{\phi}\sin\phi\sin\lambda + r\,(\dot{\lambda} + \Omega)\cos\phi\cos\lambda \tag{13.52b}$$

$$V^3 = \dot{z} = \dot{r}\sin\phi + r\,\dot{\phi}\cos\phi. \tag{13.52c}$$

Making use of the inverse transformation matrix components $\Lambda^{\bar{a}}_{\ b}$ given by equation (13.27), as well as the relation (13.24) between the coordinate basis vectors, leads to

$$\vec{V} = \boldsymbol{V} = V^{\bar{a}}\,\vec{e}_{\bar{a}} = r_\perp\,(\dot{\lambda} + \Omega)\,\hat{\boldsymbol{\lambda}} + r\,\dot{\phi}\,\hat{\boldsymbol{\phi}} + \dot{r}\,\hat{\boldsymbol{r}}, \tag{13.53}$$

which is the same as equation (13.46f) determined without the formalism of tensor algebra.

13.7.4 Axial angular momentum

As seen in Section 14.6, the zonal component of the inertial frame velocity, times the *moment arm* (distance from the rotation axis), equals to the axial angular momentum per unit mass

$$L^z = m\,r_\perp\,\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{V} = m\,r_\perp\,(u + r_\perp\,\Omega). \tag{13.54}$$

The distance to the rotational axis is given by $r_\perp$, and this is the moment arm for the axial angular momentum. For cases with rotational symmetry around polar axis, as for motion of a particle around a smooth sphere, the axial angular momentum is a constant of the motion. As discussed in Section 14.6, this conservation law provides a constraint on the particle trajectory and it plays a role in the motion of geophysical fluids (Section 25.7).

13.8 Planetary Cartesian representation of acceleration

The acceleration measured in an inertial reference frame is given by the second time derivative of the position vector

$$\boldsymbol{A} = \frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = \frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2}. \tag{13.55}$$

We here consider its representation using planetary Cartesian coordinates (x, y, z) and the Cartesian basis $(\vec{e}_1, \vec{e}_2, \vec{e}_3) = (\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}})$. The results here were anticipated by the discussion in Section 11.4.3. We find it useful to go through the derivation again, here with more focus on the geophysical applications of this book.

13.8.1 Planetary Cartesian representation

For our study of geophysical fluid motion, we assume the planetary angular velocity, $\boldsymbol{\Omega}$, is a constant in time

$$\frac{\mathrm{d}\boldsymbol{\Omega}}{\mathrm{d}t} = 0. \tag{13.56}$$

Making use of the results from Section 13.2.1 leads to

$$\frac{\mathrm{d}\vec{e}_a}{\mathrm{d}t} = \boldsymbol{\Omega} \times \vec{e}_a \tag{13.57}$$

and

$$\frac{\mathrm{d}^2\vec{e}_a}{\mathrm{d}t^2} = \frac{\mathrm{d}}{\mathrm{d}t}\left(\boldsymbol{\Omega} \times \vec{e}_a\right) = \boldsymbol{\Omega} \times \frac{\mathrm{d}\vec{e}_a}{\mathrm{d}t} = \boldsymbol{\Omega} \times \left(\boldsymbol{\Omega} \times \vec{e}_a\right), \tag{13.58}$$

which yields the acceleration

$$\begin{aligned}
\boldsymbol{A} &= \frac{\mathrm{d}}{\mathrm{d}t}\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} && (13.59\text{a})\\
&= \frac{\mathrm{d}^2\xi^a}{\mathrm{d}t^2}\,\vec{e}_a + 2\,\frac{\mathrm{d}\xi^a}{\mathrm{d}t}\left(\boldsymbol{\Omega} \times \vec{e}_a\right) + \xi^a\,\boldsymbol{\Omega} \times \left(\boldsymbol{\Omega} \times \vec{e}_a\right) && (13.59\text{b})\\
&= \hat{\boldsymbol{x}}\left[\ddot{x} - 2\,\Omega\,\dot{y} - \Omega^2 x\right] + \hat{\boldsymbol{y}}\left[\ddot{y} + 2\,\Omega\,\dot{x} - \Omega^2 y\right] + \hat{\boldsymbol{z}}\,\ddot{z} && (13.59\text{c})\\
&= \ddot{x}\,\hat{\boldsymbol{x}} + \ddot{y}\,\hat{\boldsymbol{y}} + \ddot{z}\,\hat{\boldsymbol{z}} + 2\,\Omega\left(-\dot{y}\,\hat{\boldsymbol{x}} + \dot{x}\,\hat{\boldsymbol{y}}\right) - \Omega^2\left(x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}\right) && (13.59\text{d})\\
&= \boldsymbol{A}_{\text{Cartesian}} + 2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{\Omega} \times \left(\boldsymbol{\Omega} \times \boldsymbol{X}\right) && (13.59\text{e})\\
&= \boldsymbol{A}_{\text{Cartesian}} - \boldsymbol{A}_{\text{Coriolis}} - \boldsymbol{A}_{\text{centrifugal}}. && (13.59\text{f})
\end{aligned}$$

The acceleration is thus decomposed into three terms that we now discuss.

Coordinate acceleration in the rotating reference frame

The first acceleration on the right hand side of equation (13.59f) is

$$\boldsymbol{A}_{\text{Cartesian}} = \frac{\mathrm{d}^2 x}{\mathrm{d}t^2}\,\hat{\boldsymbol{x}} + \frac{\mathrm{d}^2 y}{\mathrm{d}t^2}\,\hat{\boldsymbol{y}} + \frac{\mathrm{d}^2 z}{\mathrm{d}t^2}\,\hat{\boldsymbol{z}} = \ddot{x}\,\hat{\boldsymbol{x}} + \ddot{y}\,\hat{\boldsymbol{y}} + \ddot{z}\,\hat{\boldsymbol{z}}, \tag{13.60}$$

which is the coordinate acceleration measured in the rotating frame using planetary Cartesian coordinates.

Planetary Coriolis acceleration

The second term on the right hand side of equation (13.59f) is the planetary Coriolis acceleration

$$\boldsymbol{A}_{\text{Coriolis}} = -2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}}. \tag{13.61}$$

One key feature of the Coriolis acceleration is that it vanishes when there is no motion relative to the rotating reference frame. The Coriolis acceleration plays a fundamental role in geophysical fluid mechanics and is central to our studies in this book.

Planetary centrifugal/centripetal acceleration

The third contribution to acceleration in equation (13.59f) is the planetary *centrifugal acceleration*, which is also minus the planetary *centripetal acceleration*

$$\boldsymbol{A}_{\text{centrifugal}} = -\boldsymbol{A}_{\text{centripetal}} = -\boldsymbol{\Omega} \times \left(\boldsymbol{\Omega} \times \boldsymbol{X}\right) = \Omega^2\,\boldsymbol{X}. \tag{13.62}$$

The planetary centrifugal acceleration points outward from (perpendicular to) the polar axis of rotation whereas the planetary centripetal acceleration points inward; they are action/reaction

pairs. They can be written as the gradient of a scalar potential

$$\boldsymbol{A}_{\text{centrifugal}} = -\nabla\Phi_{\text{centrifugal}} \tag{13.63}$$

with

$$-\Phi_{\text{centrifugal}} \equiv \frac{(\boldsymbol{\Omega}\times\boldsymbol{x})\cdot(\boldsymbol{\Omega}\times\boldsymbol{x})}{2} = \frac{\Omega^2\, r_\perp^2}{2} = \frac{(\Omega\, r\cos\phi)^2}{2} = \frac{\Omega^2\,(x^2+y^2)}{2}. \tag{13.64}$$

The planetary centripetal acceleration (pointing towards the rotational axis) keeps the rotating particle from flying outward away from the rotational axis. On a massive rotating sphere, the planetary centripetal acceleration acting on the moving particle is provided by that component of the gravitational acceleration (Section 13.10) that is directed towards the rotation axis. The planetary centripetal acceleration's opposing partner, the planetary centrifugal acceleration, arises from the rotating planet and it accounts for the slight equatorial bulge of the earth. For a human scale example, note that the centrifugal acceleration pulls a person outward from the center of a rotating merry-go-round, whereas the person's arms provide the opposing centripetal acceleration to keep from from flying outward. In summary, the centrifugal acceleration arises from rotation of the non-inertial reference frame, and as such is a non-inertial acceleration, whereas the centripetal acceleration arises from a "real" force that balances the centrifugal acceleration.

13.8.2 Summary

For the purpose of formulating the equation of motion in the rotating terrestrial frame, we write the rigid-body rotating frame acceleration as

$$\boldsymbol{A}_{\text{Cartesian}} = \boldsymbol{A} + \boldsymbol{A}_{\text{Coriolis}} + \boldsymbol{A}_{\text{centrifugal}} \tag{13.65a}$$

$$= \boldsymbol{A} - 2\,\boldsymbol{\Omega}\times\boldsymbol{V}_{\text{Cartesian}} - \nabla\Phi_{\text{centrifugal}} \tag{13.65b}$$

and summarize the following accelerations (force per unit mass).

- INERTIAL: Newton's law of motion is formulated within an inertial reference frame making use of the acceleration, $\boldsymbol{A}$, that is directly affected by forces such as gravitation.

- PLANETARY CORIOLIS: The planetary Coriolis acceleration

$$\boldsymbol{A}_{\text{Coriolis}} = -2\,\boldsymbol{\Omega}\times\boldsymbol{V}_{\text{Cartesian}} = -2\,\Omega\,\hat{\boldsymbol{z}}\times\boldsymbol{V}_{\text{Cartesian}} = -2\,\Omega\left[-\frac{\mathrm{d}y}{\mathrm{d}t}\,\hat{\boldsymbol{x}} + \frac{\mathrm{d}x}{\mathrm{d}t}\,\hat{\boldsymbol{y}}\right], \tag{13.66}$$

  arises from our choice to describe motion within the rotating terrestrial reference frame. The Coriolis acceleration gives rise to a rich suite of fundamentally new phenomena relative to non-rotating motion, with much of this book focused in describing such phenomena. It has components only in the horizontal planetary Cartesian plane spanned by the unit vectors $(\hat{\boldsymbol{x}},\hat{\boldsymbol{y}})$. That is, the Coriolis acceleration occurs in a plane parallel to the equatorial plane. We expect this orientation of the Coriolis acceleration since it arises from rotation about the $\hat{\boldsymbol{z}}$ axis, so that there can be no component of the Coriolis acceleration aligned with $\hat{\boldsymbol{z}}$.

- PLANETARY CENTRIFUGAL: The planetary centrifugal acceleration

$$\boldsymbol{A}_{\text{centrifugal}} = -\nabla\Phi_{\text{centrifugal}} = \Omega^2\,\boldsymbol{r}_\perp = \Omega^2\,(x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}) \tag{13.67}$$

  is another term arising from the rotating reference frame. As for the Coriolis acceleration, the planetary centrifugal acceleration has components only in the horizontal planetary

Cartesian plane spanned by the unit vectors $(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}})$; i.e., the planetary centrifugal acceleration occurs in a plane parallel to the equatorial plane, which is again expected since the planetary centrifugal pacceleration arises from rotation of the planet about the polar axis. The planetary centrifugal acceleration is directed outward from (perpendicular to) to the polar axis of rotation. We see this orientation in Figure 13.4 to be ldiscussed later. Furthermore, the planetary centrifugal acceleration is nonzero even when the particle is fixed relative to the rotating planet, whereas the Coriolis acceleration is zero when the particle has zero motion relative to the planet.

The planetary centrifugal acceleration can be written as the gradient of a scalar potential, $\boldsymbol{A}_{\text{centrifugal}} = -\nabla\Phi_{\text{centrifugal}}$ where $\Phi_{\text{centrifugal}} = -\Omega^2\,(x^2+y^2)/2$ (equation (13.64)). Hence, the planetary centrifugal acceleration can be combined with the gravitational acceleration in the equation of motion (see Section 13.10). The resulting "effective gravity" leads to a conservative force field that is modified relative to the central gravitational field of the non-rotating spherical planet. We detail these points in Section 13.10.4.

13.8.3 Further study

We build up our understanding of the Coriolis acceleration as the book develops, such as in Section 14.7 where we offer a thorough examination of its facets. Further related study can be found in Section 3.5 of *Apel* (1987). Visualizations from rotating tank experiments are useful to garner an experiential understanding of the Coriolis acceleration. The first few minutes of this video from Prof. Fultz of the University of Chicago is particularly insightful.

13.9 Spherical representation of acceleration

The spherical representation of the velocity viewed in an inertial reference frame is given by equation (13.46f)

$$\boldsymbol{V} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = (u + r_\perp\,\Omega)\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}} = \boldsymbol{V}_{\text{sphere}} + r_\perp\,\Omega\,\hat{\boldsymbol{\lambda}}, \tag{13.68}$$

where we introduced the spherical velocity from equation (13.48)

$$\boldsymbol{V}_{\text{sphere}} \equiv u\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}. \tag{13.69}$$

We also make use of the notation for the zonal component of the velocity as measured in the inertial reference frame,

$$u_{\text{I}} = u + r_\perp\,\Omega. \tag{13.70}$$

Just as for computing the velocity vector, the corresponding acceleration measured in the inertial reference frame must take into account changes in both the spherical coordinates and spherical basis vectors

$$\boldsymbol{A} = \frac{\mathrm{d}}{\mathrm{d}t}\left(u_{\text{I}}\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}\right) \tag{13.71a}$$

$$= \frac{\mathrm{d}u_{\text{I}}}{\mathrm{d}t}\,\hat{\boldsymbol{\lambda}} + \frac{\mathrm{d}v}{\mathrm{d}t}\,\hat{\boldsymbol{\phi}} + \frac{\mathrm{d}w}{\mathrm{d}t}\,\hat{\boldsymbol{r}} + u_{\text{I}}\,\frac{\mathrm{d}\hat{\boldsymbol{\lambda}}}{\mathrm{d}t} + v\,\frac{\mathrm{d}\hat{\boldsymbol{\phi}}}{\mathrm{d}t} + w\,\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t}. \tag{13.71b}$$

The spherical unit vectors change due to both the rigid-body rotation of the rotating reference frame, plus motion of the particle relative to the rotating frame. Making use of the expressions

given in Section (10.2.2), a bit of algebra yields the time derivatives

$$\frac{\mathrm{d}\hat{\boldsymbol{\lambda}}}{\mathrm{d}t} = \left[\Omega + \frac{\mathrm{d}\lambda}{\mathrm{d}t}\right] (\hat{\boldsymbol{\phi}} \sin\phi - \hat{\boldsymbol{r}} \cos\phi) \tag{13.72}$$

$$\frac{\mathrm{d}\hat{\boldsymbol{\phi}}}{\mathrm{d}t} = -\hat{\boldsymbol{\lambda}} \left[\Omega + \frac{\mathrm{d}\lambda}{\mathrm{d}t}\right] \sin\phi - \hat{\boldsymbol{r}}\, \dot{\phi} \tag{13.73}$$

$$\frac{\mathrm{d}\hat{\boldsymbol{r}}}{\mathrm{d}t} = \hat{\boldsymbol{\lambda}} \left[\frac{\mathrm{d}\lambda}{\mathrm{d}t} + \Omega\right] \cos\phi + \frac{\mathrm{d}\phi}{\mathrm{d}t}\, \hat{\boldsymbol{\phi}}. \tag{13.74}$$

We are thus led to the decomposition of the acceleration viewed from the inertial frame

$$\boldsymbol{A} \cdot \hat{\boldsymbol{\lambda}} = \frac{\mathrm{d}u_{\mathrm{I}}}{\mathrm{d}t} + \left[\frac{\mathrm{d}\lambda}{\mathrm{d}t} + \Omega\right] (w \cos\phi - v \sin\phi) \tag{13.75a}$$

$$\boldsymbol{A} \cdot \hat{\boldsymbol{\phi}} = \frac{\mathrm{d}v}{\mathrm{d}t} + \left[\frac{\mathrm{d}\lambda}{\mathrm{d}t} + \Omega\right] u_{\mathrm{I}} \sin\phi + w\, \frac{\mathrm{d}\phi}{\mathrm{d}t} \tag{13.75b}$$

$$\boldsymbol{A} \cdot \hat{\boldsymbol{r}} = \frac{\mathrm{d}w}{\mathrm{d}t} - \left[\frac{\mathrm{d}\lambda}{\mathrm{d}t} + \Omega\right] u_{\mathrm{I}} \cos\phi - v\, \frac{\mathrm{d}\phi}{\mathrm{d}t}. \tag{13.75c}$$

Use of the identities

$$u = r_\perp \frac{\mathrm{d}\lambda}{\mathrm{d}t} \qquad \text{and} \qquad u_{\mathrm{I}} = u + r_\perp\, \Omega \qquad \text{and} \qquad \frac{\mathrm{d}u_{\mathrm{I}}}{\mathrm{d}t} = \frac{\mathrm{d}u}{\mathrm{d}t} + \Omega\, (w \cos\phi - v \sin\phi) \tag{13.76}$$

and some reorganization leads to the spherical coordinate representation of the inertial frame acceleration

$$\begin{aligned} \boldsymbol{A} = \hat{\boldsymbol{\lambda}} &\left[\frac{\mathrm{d}u}{\mathrm{d}t} + \frac{u\,(w - v \tan\phi)}{r} + 2\,\Omega\,(w \cos\phi - v \sin\phi)\right] \\ &+ \hat{\boldsymbol{\phi}} \left[\frac{\mathrm{d}v}{\mathrm{d}t} + \frac{v\,w + u^2 \tan\phi}{r} + 2\,\Omega\, u \sin\phi + r_\perp\, \Omega^2 \sin\phi\right] \\ &+ \hat{\boldsymbol{r}} \left[\frac{\mathrm{d}w}{\mathrm{d}t} - \frac{u^2 + v^2}{r} - 2\,\Omega\, u \cos\phi - r_\perp\, \Omega^2 \cos\phi\right]. \end{aligned} \tag{13.77}$$

13.9.1 Transforming from Cartesian to spherical

As in Section 13.7.3, we can make use of the tensor algebra from Section 13.3 to transform from the Cartesian representation of the acceleration vector to the spherical representation. Following the same steps as for the velocity leads to

$$A^{\overline{a}} = \Lambda^{\overline{a}}{}_{a}\, A^a \tag{13.78}$$

where the Cartesian components to the acceleration are

$$A^1 = \ddot{x} - 2\,\Omega\, \dot{y} - \Omega^2\, x \tag{13.79a}$$

$$A^2 = \ddot{y} + 2\,\Omega\, \dot{x} - \Omega^2\, y \tag{13.79b}$$

$$A^3 = \ddot{z}. \tag{13.79c}$$

Making use of the coordinate transformation (13.22) allows us to express these Cartesian components of the acceleration in terms of spherical coordinates. Then we make use of the inverse transformation matrix components $\Lambda^{\overline{a}}{}_{b}$ given by equation (13.27), as well as the relation (13.24)

between the coordinate basis vectors, which leads to

$$\vec{A} = \boldsymbol{A} = A^a \, \vec{e}_a = A^{\overline{a}} \, \vec{e}_{\overline{a}} \tag{13.80}$$

with the spherical coordinate representation given by equation (13.77) as derived without the formalism of tensor algebra. Both approaches require algebraic manipulations, so that it is useful to have two approaches to double-check results.

13.9.2 Decomposing the acceleration

We decompose the inertial frame acceleration (13.77) into the following terms

$$\boldsymbol{A} = \boldsymbol{A}_{\text{sphere}} + \boldsymbol{A}_{\text{metric}} - \boldsymbol{A}_{\text{Coriolis}} - \boldsymbol{A}_{\text{centrifugal}}, \tag{13.81}$$

with signs chosen so that in the rigid-body rotating frame the acceleration is written

$$\underbrace{\boldsymbol{A}_{\text{sphere}} + \boldsymbol{A}_{\text{metric}}}_{\text{net spherical acceleration}} = \boldsymbol{A} + \boldsymbol{A}_{\text{Coriolis}} + \boldsymbol{A}_{\text{centrifugal}}. \tag{13.82}$$

We identify the net spherical acceleration as the sum of the coordinate acceleration and metric acceleration. In the absence of reference frame rotation, this sum provides an expression for the acceleration as represented by spherical coordinates. For example, if we are describing the motion of a satellite from an inertial reference frame using spherical coordinates, then we would use $\boldsymbol{A}_{\text{sphere}} + \boldsymbol{A}_{\text{metric}}$. The Coriolis and planetary centrifugal terms arise from the rigid-body rotation of the planet.

13.9.3 Spherical coordinate acceleration

The spherical coordinate acceleration is given by the time change in the spherical velocity components

$$\boldsymbol{A}_{\text{sphere}} = \frac{\mathrm{d}u}{\mathrm{d}t} \, \hat{\boldsymbol{\lambda}} + \frac{\mathrm{d}v}{\mathrm{d}t} \, \hat{\boldsymbol{\phi}} + \frac{\mathrm{d}w}{\mathrm{d}t} \, \hat{\boldsymbol{r}}. \tag{13.83}$$

This term has no contribution from changes to the spherical unit vectors.

13.9.4 Metric acceleration

We define the *metric acceleration* as that contribution to the acceleration arising from the time dependence of the spherical unit vectors that appears when taking the time derivative of the velocity vector. For spherical coordinates we have

$$\boldsymbol{A}_{\text{metric}} = \hat{\boldsymbol{\lambda}} \left[\frac{u \, (w - v \tan \phi)}{r} \right] + \hat{\boldsymbol{\phi}} \left[\frac{v \, w + u^2 \tan \phi}{r} \right] - \hat{\boldsymbol{r}} \left[\frac{u^2 + v^2}{r} \right] \tag{13.84a}$$

$$= \hat{\boldsymbol{\lambda}} \left[\frac{u \, (w \cos \phi - v \sin \phi)}{r \cos \phi} \right] + \hat{\boldsymbol{\phi}} \left[\frac{v \, w \cos \phi + u^2 \sin \phi}{r \cos \phi} \right] - \hat{\boldsymbol{r}} \left[\frac{u^2 + v^2}{r} \right] \tag{13.84b}$$

$$= \frac{1}{r} \left[u \tan \phi \, (\hat{\boldsymbol{r}} \times \boldsymbol{V}_{\text{sphere}}) + w \, \boldsymbol{U}_{\text{sphere}} - \hat{\boldsymbol{r}} \, \boldsymbol{U}_{\text{sphere}} \cdot \boldsymbol{U}_{\text{sphere}} \right], \tag{13.84c}$$

where we wrote the horizontal (angular) and vertical (radial) components of the spherical velocity according to

$$\boldsymbol{V}_{\text{sphere}} = \boldsymbol{U}_{\text{sphere}} + \hat{\boldsymbol{r}} \, w = \hat{\boldsymbol{\lambda}} \, u + \hat{\boldsymbol{\phi}} \, v + \hat{\boldsymbol{r}} \, w. \tag{13.85}$$

Note that

$$\boldsymbol{V}_{\text{sphere}} \cdot \boldsymbol{A}_{\text{metric}} = 0, \tag{13.86}$$

so that the metric acceleration is orthogonal to the spherical velocity, in which case with (see equation (13.46f)) $\boldsymbol{V} = \boldsymbol{V}_{\text{sphere}} + r_\perp \, \Omega \, \hat{\boldsymbol{\lambda}}$ we have

$$\boldsymbol{V} \cdot \boldsymbol{A}_{\text{metric}} = \Omega \, u \, (-v \sin\phi + w \cos\phi). \tag{13.87}$$

Furthermore, the metric acceleration vanishes when the curvature of the sphere vanishes (i.e., $r \to \infty$), as per a flat plane.

13.9.5 Planetary centrifugal acceleration

The spherical coordinate representation of the planetary centrifugal acceleration is given by

$$\boldsymbol{A}_{\text{centrifugal}} = -\nabla \Phi_{\text{centrifugal}} = \Omega^2 \, (x \, \hat{\boldsymbol{x}} + y \, \hat{\boldsymbol{y}}) = r_\perp \, \Omega^2 \, (-\hat{\boldsymbol{\phi}} \sin\phi + \hat{\boldsymbol{r}} \cos\phi). \tag{13.88}$$

The planetary centrifugal acceleration points outward from the axis of rotation (see Figure 13.4 to be discussed later), so that it has no component in the longitudinal direction. Furthermore, note that

$$\boldsymbol{V} \cdot \boldsymbol{A}_{\text{centrifugal}} = \boldsymbol{V}_{\text{sphere}} \cdot \boldsymbol{A}_{\text{centrifugal}} = r_\perp \, \Omega^2 \, (-v \sin\phi + w \cos\phi). \tag{13.89}$$

13.9.6 Planetary Coriolis acceleration

The spherical coordinate representation of the Coriolis acceleration makes use of the spherical representation of the earth's angular velocity

$$\boldsymbol{\Omega} = \Omega \, \hat{\boldsymbol{z}} = \Omega \, (\hat{\boldsymbol{\phi}} \, \cos\phi + \hat{\boldsymbol{r}} \, \sin\phi). \tag{13.90}$$

Although $\boldsymbol{\Omega} = \Omega \, \hat{\boldsymbol{z}}$ is fixed in absolute space, its representation using spherical coordinates is a function of latitudinal position on the sphere, with components in the local radial and local meridional directions. This spatial dependence gives rise to much of the characteristic features of geophysical flows associated with the *beta*-effect studied in Section 41.6.2.

We use the representation (13.90) to write the spherical coordinate representation of the Coriolis acceleration

$$\begin{aligned}
\boldsymbol{A}_{\text{Coriolis}} &= -2 \, \boldsymbol{\Omega} \times \boldsymbol{V}_{\text{sphere}} && \text{(13.91a)} \\
&= -2 \, \Omega \, (\hat{\boldsymbol{\phi}} \, \cos\phi + \hat{\boldsymbol{r}} \, \sin\phi) \times (u \, \hat{\boldsymbol{\lambda}} + v \, \hat{\boldsymbol{\phi}} + w \, \hat{\boldsymbol{r}}) && \text{(13.91b)} \\
&= -2 \, \Omega \left[\hat{\boldsymbol{\lambda}} \, (w \cos\phi - v \sin\phi) + \hat{\boldsymbol{\phi}} \, u \sin\phi - \hat{\boldsymbol{r}} \, u \cos\phi \right]. && \text{(13.91c)}
\end{aligned}$$

As a check on this result, note that

$$\boldsymbol{A}_{\text{Coriolis}} \cdot \hat{\boldsymbol{z}} = 0, \tag{13.92}$$

as it must since there is no component of the Coriolis acceleration that is parallel to the rotation axis. Furthermore, as for the metric acceleration, we see that the Coriolis acceleration is orthogonal to the spherical velocity

$$\boldsymbol{V}_{\text{sphere}} \cdot \boldsymbol{A}_{\text{Coriolis}} = 0, \tag{13.93}$$

so that

$$\boldsymbol{V} \cdot \boldsymbol{A}_{\text{Coriolis}} = 2 \, r_\perp \, \Omega^2 \, (v \sin\phi - w \cos\phi). \tag{13.94}$$

We commonly find it convenient to introduce a shorthand notation

$$\boldsymbol{f} = (2\,\Omega\,\sin\phi)\,\hat{\boldsymbol{r}} \qquad \text{and} \qquad \boldsymbol{f}^* = (2\,\Omega\,\cos\phi)\,\hat{\boldsymbol{\phi}}, \tag{13.95}$$

so that the Coriolis acceleration is decomposed into two terms

$$\boldsymbol{A}_{\text{Coriolis}} = -(\boldsymbol{f} + \boldsymbol{f}^*) \times \boldsymbol{V}_{\text{sphere}}. \tag{13.96}$$

These two terms take on the form

$$\boldsymbol{A}^{\boldsymbol{f}}_{\text{Coriolis}} = -(2\,\Omega\,\sin\phi)\,\hat{\boldsymbol{r}} \times (u\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}) = 2\,\Omega \sin\phi\,(v\,\hat{\boldsymbol{\lambda}} - u\,\hat{\boldsymbol{\phi}}), \tag{13.97}$$

which is purely in the spherical angular directions, and

$$\boldsymbol{A}^{\boldsymbol{f}^*}_{\text{Coriolis}} = -(2\,\Omega\,\cos\phi)\,\hat{\boldsymbol{\phi}} \times (u\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}) = 2\,\Omega \cos\phi\,(u\,\hat{\boldsymbol{r}} - w\,\hat{\boldsymbol{\lambda}}), \tag{13.98}$$

which has a zonal and radial component.

13.9.7 Centrifugal acceleration from particle plus planetary motion

The radial component to the inertial frame acceleration (13.77) can be written in the form

$$\boldsymbol{A} \cdot \hat{\boldsymbol{r}} = \frac{\mathrm{d}w}{\mathrm{d}t} - (u_{\mathrm{I}}^2 + v^2)/r. \tag{13.99}$$

Evidently, the contribution from $(u_{\mathrm{I}}^2 + v^2)/r$ term leads to a vertical (radially outward) acceleration in the radial equation of motion (13.136) discussed in Section 13.11.2. We identify it as the radial acceleration arising from the particle's centrifugal acceleration due to angular motion of the particle around the sphere, combined with the local vertical contribution from the planetary centrifugal acceleration of Section 13.9.5.

13.9.8 Coriolis acceleration for large-scale motions

Let us again write the Coriolis acceleration in equation (13.91c), now underlining two terms

$$\boldsymbol{A}_{\text{Coriolis}} = -2\,\Omega \left[\hat{\boldsymbol{\lambda}}\,(\underline{w\cos\phi} - v\sin\phi) + \hat{\boldsymbol{\phi}}\,u\sin\phi - \hat{\boldsymbol{r}}\,\underline{u\cos\phi}\right]. \tag{13.100}$$

For many applications in geophysical fluid mechanics, the term $\hat{\boldsymbol{r}}\,(2\,\Omega\,u\cos\phi)$ is much smaller than the competing gravitational acceleration that also contributes to the radial acceleration, thus prompting $\hat{\boldsymbol{r}}\,(2\,\Omega\,u\cos\phi)$ to be dropped from the $\hat{\boldsymbol{r}}$ equation of motion.[3] Furthermore, the vertical velocity term is often much smaller than the horizontal velocity term appearing in the $\hat{\boldsymbol{\lambda}}$ component. Dropping these two terms results in the Coriolis acceleration used for large-scale dynamics, such as when considering the hydrostatic primitive equations for geophysical fluids (Section 28.1)

$$\boldsymbol{A}^{\text{large-scale}}_{\text{Coriolis}} \equiv -2\,\Omega \sin\phi\,(-\hat{\boldsymbol{\lambda}}\,v + \hat{\boldsymbol{\phi}}\,u) \equiv -f\,\hat{\boldsymbol{r}} \times \boldsymbol{V}_{\text{sphere}}. \tag{13.101}$$

For the last equality we introduced the Coriolis parameter

$$f \equiv 2\,\Omega \sin\phi. \tag{13.102}$$

[3] The term $\hat{\boldsymbol{r}}\,(2\,\Omega\,u\cos\phi)$ is called the Eötvös correction in the study of marine gravity.

As illustrated in Figure 13.3, we see that it is the radial (i.e., the local vertical) component of the earth's angular rotation that plays the most important role in large-scale geophysical fluid mechanics

$$\boldsymbol{\Omega} \cdot \hat{\boldsymbol{r}} = \Omega\, \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{r}} = \Omega\, (\hat{\boldsymbol{\phi}}\, \cos\phi + \hat{\boldsymbol{r}}\, \sin\phi) \cdot \hat{\boldsymbol{r}} = \Omega \sin\phi = f/2. \tag{13.103}$$

FIGURE 13.3: This figure illustrates the two components of the earth's rigid-body rotational velocity, $\boldsymbol{\Omega} = \Omega\, \hat{\boldsymbol{z}} = \Omega\, (\hat{\boldsymbol{\phi}} \cos\phi + \hat{\boldsymbol{r}} \sin\phi)$. The radial component (also known as the local vertical component), $\Omega^r = \Omega \sin\phi$, is generally more important for large scale geophysical fluid motions than the meridional component, $\Omega^\phi = \Omega \cos\phi$.

13.10 Newtonian gravity

Thus far we have focused on the kinematics of a particle moving around a rotating sphere. We now acknowledge that the particle is moving in the gravitational field of the massive sphere. The gravitational force acting on the particle is the only force felt by the point particle when viewed in an inertial reference frame. Since the point particle contains no internal structure and it has no surface area, the total energy for the particle equals to the mechanical energy (Chapter 14). We here discuss the gravitational potential energy and the associated gravitational force, all within the context of Newtonian mechanics.

13.10.1 Newtonian gravity from Poisson's equation

The Newtonian gravitational potential, $\Phi_{\rm N}$, in the presence of a mass distribution with density, ρ, satisfies Poisson's equation (see Section 3.4)

$$\nabla^2 \Phi_{\rm N} = 4\, \pi\, G\, \rho, \tag{13.104}$$

where

$$G = 6.674 \times 10^{-11}\ {\rm N\ m^2\ kg^{-2}} = 6.674 \times 10^{-11}\ {\rm m^3\ kg^{-1}\ s^{-2}} \tag{13.105}$$

is Newton's gravitational constant. Gravity is a conservative force, so that the gradient of the gravitational potential gives the gravitational acceleration

$$\boldsymbol{g} = -\nabla \Phi_{\rm N}. \tag{13.106}$$

The gravitational potential has dimensions of $\rm L^2\ T^{-2}$ so that its gradient indeed has the dimensions of acceleration, $\rm L\ T^{-2}$. Note that the gravitational potential responds instantaneously to any

changes in the mass distribution. It took a few centuries, and the genius of Einstein, to provide a local connection between mass and gravity as rendered by space-time curvature and gravitational waves.

A volume integral of Poisson's equation (13.104), computed over a region in space, leads to

$$\int_{\mathcal{R}} \nabla^2 \Phi_{\mathrm{N}} \, \mathrm{d}V = 4\,\pi\,G \int_{\mathcal{R}} \rho \, \mathrm{d}V. \tag{13.107}$$

The integral on the right hand side is the mass contained in the region,

$$M = \int_{\mathcal{R}} \rho \, \mathrm{d}V, \tag{13.108}$$

whereas the divergence theorem (Section 2.7) allows us to write the left hand side as a surface integral

$$\int_{\partial\mathcal{R}} \nabla \Phi_{\mathrm{N}} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = 4\,\pi\,G\,M. \tag{13.109}$$

We now consider the special case of a spherical mass distribution as viewed from a point outside of the mass.

13.10.2 Gravitational field for a spherical earth

In this book we assume the mass density of the planet to be spherically symmetric, in which case the gravitational potential is a function only of the radial distance from the center of the mass distribution, $\Phi_{\mathrm{e}} = \Phi_{\mathrm{e}}(r)$. Letting the integration region, $\mathcal{R}$, be a sphere of radius $r > R_{\mathrm{e}}$, where R_{e} is the radius of the planet, and making use of spherical coordinates from Section 10.2.8, brings equation (13.109) to

$$4\,\pi\,r^2 \, \frac{\partial \Phi_{\mathrm{e}}}{\partial r} = 4\,\pi\,G\,M. \tag{13.110}$$

Integration leads to the gravitational potential for an arbitrary point outside the spherically symmetric mass distribution

$$\Phi_{\mathrm{e}} = -\frac{G\,M}{r}, \tag{13.111}$$

where we set the integration constant to zero. We see that when sampling the gravity field at a radius equal to or larger than the spherical planet radius, the gravitational potential is identical to that of a point mass at the origin. The gradient of the gravitational potential (13.111) yields the inverse-squared dependence of the gravitational acceleration

$$\boldsymbol{g}_{\mathrm{e}} = -\nabla \Phi_{\mathrm{e}} = -\frac{G\,M}{r^2}\,\hat{\boldsymbol{r}} = -\frac{G\,M}{r^3}\,\boldsymbol{r}, \tag{13.112}$$

along with the gravitational force acting on a point particle of mass m

$$\boldsymbol{F}_{\mathrm{gravity}} = m\,\boldsymbol{g}_{\mathrm{e}} = -m\,\nabla \Phi_{\mathrm{e}}. \tag{13.113}$$

Furthermore, the gravitational potential energy of the particle (dimensions M L^2 T^{-2}) is given by

$$P = m\,\Phi_{\mathrm{e}}. \tag{13.114}$$

13.10.3 Approximate gravitational acceleration

For most applications of atmospheric and oceanic fluid dynamics, it is sufficient to assume the gravitational acceleration is constant and equal to its value at the earth's surface. This assumption holds so long as the radial position of the particle is a distance from the earth surface that is small relative to the earth radius. We generally make this assumption throughout this book, with the exception of our treatment of tides in Chapter 35.[4] In this case we can assume the earth's gravitational acceleration, g_{e}, is a constant so that

$$\boldsymbol{g}_{\mathrm{e}} = -g_{\mathrm{e}}\,\hat{\boldsymbol{r}}, \tag{13.115}$$

where

$$g_{\mathrm{e}} = \frac{G\,M_{\mathrm{e}}}{R_{\mathrm{e}}^2} \approx 9.8 \text{ m s}^{-2}. \tag{13.116}$$

To reach this value, we assumed a sphere of mass equal to the earth mass

$$M_{\mathrm{e}} = 5.977 \times 10^{24} \text{ kg}, \tag{13.117}$$

and radius

$$R_{\mathrm{e}} = 6.371 \times 10^{6} \text{ m} \tag{13.118}$$

determined so that the sphere has the same volume as the earth.

The corresponding gravitational potential for the particle is given by

$$\Phi_{\mathrm{e}} = g_{\mathrm{e}}\,r, \tag{13.119}$$

with the gravitational acceleration

$$\boldsymbol{g}_{\mathrm{e}} = -\nabla\Phi_{\mathrm{e}} = -g_{\mathrm{e}}\,\hat{\boldsymbol{r}}, \tag{13.120}$$

and the gravitational potential energy

$$m\,\Phi_{\mathrm{e}} = m\,g_{\mathrm{e}}\,r. \tag{13.121}$$

We emphasize that the expression for the gravitational potential, (13.119), and potential energy, (13.121), are accurate only so long as the radial position of the particle is a distance from the earth surface that is small relative to the earth radius. Furthermore, note that the approximate gravitational potential (13.119) is positive whereas the unapproximated potential (13.111) is negative. However, the absolute zero of the potential has no physical significance. Instead, what is relevant is the change between two points in space. As defined, both of the geopotentials increase when moving away from the earth center.

13.10.4 Effective gravitational force from the geopotential

Combining the potential for the planetary centrifugal acceleration as given by equation (13.64) with the gravitational potential (13.111), leads to the *geopotential*

$$\Phi = r\,[g_{\mathrm{e}} - \boldsymbol{U}_{\mathrm{rigid}}^2/(2r)], \tag{13.122}$$

[4] The assumption of constant gravitational field is not appropriate when considering details of oceanic or atmospheric tidal motions or when aiming for precise measures of sea level. We consider more general gravitational fields in Chapter 35.

where $\boldsymbol{U}_{\text{rigid}} = r\cos\phi\,\Omega\,\hat{\boldsymbol{\lambda}}$ is the rigid body velocity of the planet, as per equation (13.50). The expression (13.122) for the geopotential is relevant for motion that is close enough to the earth surface that we can assume the earth's gravitational acceleration, g_{e}, is constant (see discussion in Section 13.10.3). In Exercise 13.7 we derive the geopotential for the more general case when this assumption is not made.

The contribution from the planetary centrifugal term in the geopotential (13.122) can be estimated by making use of terrestrial values, in which $R = R_{\text{e}} = 6.371 \times 10^6$ m (equation (13.118)), and $\Omega_{\text{e}} = 7.292 \times 10^{-5}$ s^{-1} (Section 13.1). The planetary centrifugal term is its largest at the equator, $\phi = 0$, where

$$\frac{\boldsymbol{U}_{\text{rigid}}^2}{2\,R_{\text{e}}} \approx 0.017 \text{ m s}^{-2}, \tag{13.123}$$

so that the ratio of the gravitational to planetary centrifugal accelerations is (at most)

$$\frac{g_{\text{e}}}{\boldsymbol{U}_{\text{rigid}}^2/(2R_{\text{e}})} = \frac{M_{\text{e}}\,G/R_{\text{e}}^2}{\Omega_{\text{e}}^2\,R_{\text{e}}/2} \approx 576. \tag{13.124}$$

The geopotential is thus dominated by the earth's gravitational potential. Even so, the planetary centrifugal acceleration leads to a slight equatorial bulge on the earth. To account for this slight non-sphericity, geophysical fluid models generally interpret the radial direction, $\hat{\boldsymbol{r}}$, as pointing parallel to $\nabla\Phi$ rather than parallel to $\nabla\Phi_{\text{e}}$. We have more to say on this topic in Section 13.11.3.

13.10.5 Further study

Newton's gravitational law is standard material from freshman physics. Some commonly used physical properties of the earth are summarized in Appendix Two of *Gill* (1982).

13.11 Newton's law of motion

As seen in Section 11.1, Newton's law of motion says that in an inertial reference frame, the time derivative of the linear momentum arises only from externally applied forces. In our study, we are only concerned with the gravitational force that the constant mass particle feels in an inertial frame. In this case, Newton's equation of motion says that

$$m\,\boldsymbol{A} = -m\,\nabla\Phi_{\text{e}}. \tag{13.125}$$

This is a relatively simple equation of motion. Its representation is somewhat complex, yet useful for practical purposes, when moving to the rigid-body rotating reference frame of terrestrial observers and when represented using spherical coordinates.

13.11.1 Cartesian coordinate representation

The inertial frame acceleration using planetary Cartesian coordinates is decomposed according to equation (13.65b)

$$\boldsymbol{A} = \boldsymbol{A}_{\text{Cartesian}} - \boldsymbol{A}_{\text{Coriolis}} - \boldsymbol{A}_{\text{centrifugal}} \tag{13.126a}$$

$$= \boldsymbol{A}_{\text{Cartesian}} + 2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}} + \nabla\Phi_{\text{centrifugal}}. \tag{13.126b}$$

We thus have the equation of motion as viewed within the rigid-body rotating frame and using Cartesian coordinates

$$\boldsymbol{A}_{\text{Cartesian}} = \boldsymbol{A} - 2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}} - \nabla\Phi_{\text{centrifugal}} \tag{13.127a}$$
$$= -\nabla\Phi_{\text{e}} - 2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}} - \nabla\Phi_{\text{centrifugal}} \tag{13.127b}$$
$$= -2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{Cartesian}} - \nabla\Phi, \tag{13.127c}$$

where the geopotential is the sum of the gravitational and planetary centrifugal potentials (equation (13.122))

$$\Phi = \Phi_{\text{e}} + \Phi_{\text{centrifugal}}. \tag{13.128}$$

We can write the equation of motion in component form by exposing indices (Cartesian tensors) and using a dot for time derivative

$$\ddot{X}_a + 2\,\epsilon_{abc}\,\boldsymbol{\Omega}_b\,\dot{X}_c = -\partial_a\Phi, \tag{13.129}$$

which takes on the vector form within the rotating reference frame

$$\frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2} + 2\,\boldsymbol{\Omega} \times \dot{\boldsymbol{X}} = -\nabla\Phi. \tag{13.130}$$

Note that the basis vectors need not be time differentiated again since their rigid-body rotation has already been taken care of when exposing the Coriolis and planetary centrifugal accelerations. That is, the time derivatives are all computed within the rigid-body rotating reference frame. This equation of motion is the standard form that occurs also for a fluid, though with the addition of contact forces from pressure and friction as studied in Chapter 25.

Since the rotation of the reference frame is assumed to be constant in time, the equation of motion (13.130) can be written

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}(\boldsymbol{V}_{\text{Cartesian}} + 2\,\boldsymbol{\Omega} \times \boldsymbol{X}) = -\nabla\Phi, \tag{13.131}$$

where we introduced the *potential momentum* per mass

$$\boldsymbol{M} = \boldsymbol{V}_{\text{Cartesian}} + 2\,\boldsymbol{\Omega} \times \boldsymbol{X}. \tag{13.132}$$

Evidently, the potential momentum is a constant of the motion for particles moving along directions parallel to the geopotential (so long as the geopotential is a constant). We emphasize that the potential momentum per mass is distinct from the inertial frame velocity (13.42e). Namely, the factor of 2 in the potential momentum arises from the Coriolis acceleration, whereas the inertial frame velocity has $\boldsymbol{\Omega} \times \boldsymbol{X}$ arising from the rigid-body rotation of the planet. We further discuss potential momentum in Section 14.4.

13.11.2 Spherical coordinate representation

We now follow the spherical coordinate discussion in Section 13.9 by writing the inertial frame acceleration using planetary spherical coordinates and decomposing this acceleration into terms that arise in a rigid-body rotating non-inertial frame

$$\boldsymbol{A}_{\text{sphere}} + \boldsymbol{A}_{\text{metric}} = \boldsymbol{A}_{\text{Coriolis}} + \boldsymbol{A} + \boldsymbol{A}_{\text{centrifugal}} = -2\,\boldsymbol{\Omega} \times \boldsymbol{V}_{\text{sphere}} - \nabla\Phi. \tag{13.133}$$

The effective gravitational force is not a central force due to the contribution from the planetary centrifugal acceleration. We see this fact more explicitly by using the equations in Section 13.9 to write the spherical equations of motion

$$\dot{u} + \frac{u\,(w - v\tan\phi)}{r} + 2\,\Omega\,(w\cos\phi - v\sin\phi) = 0 \tag{13.134}$$

$$\dot{v} + \frac{v\,w + u^2\tan\phi}{r} + 2\,\Omega\,u\sin\phi = -r_\perp\,\Omega^2\sin\phi \tag{13.135}$$

$$\dot{w} - \frac{u^2 + v^2}{r} - 2\,\Omega\,u\cos\phi = r_\perp\,\Omega^2\cos\phi - g_{\mathrm{e}}, \tag{13.136}$$

where, again, $r_\perp = r\cos\phi$.

The Ω^2 term in both the meridional equation, (13.135), and the radial equation, (13.136), are the two components of the planetary centrifugal acceleration, $\boldsymbol{A}_{\mathrm{centrifugal}} = r_\perp\,\Omega^2\,(-\hat{\boldsymbol{\phi}}\sin\phi + \hat{\boldsymbol{r}}\cos\phi)$. The planetary centrifugal acceleration is directed outward from the planetary axis of rotation, and it is balanced by an inward directed planetary centripetal acceleration provided by that portion of the gravitational acceleration directed oppositely to the planetary centrifugal. Notably, a particle initially at rest on a smooth spherical planet accelerates meridionally toward the equator due to the meridional component of the planetary centrifugal acceleration. The initial meridional acceleration for this particle is derived from equation (13.135), whereby $\dot{v} = -r_\perp\,\Omega^2\sin\phi$.

Imagine setting the planetary centripetal acceleration to zero, in which case the particle would still feel the central force from gravity but its trajectory would differ. As seen in Section 13.10.4, the earth's gravitational acceleration is much larger than the planetary centrifugal acceleration, so that in the absence of the planetary centrifugal acceleration the particle would still be bound to the planet. But in more extreme conditions where the rotational rate is much higher (e.g., a rotating neutron star), removing the centripetal acceleration causes a huge modification to the particle trajectory.

13.11.3 Geopotential coordinate representation

As we saw in Section 13.10.2, the radius of a sphere that best fits the volume of the earth is given by $R_{\mathrm{e}} = 6.371 \times 10^6\,\mathrm{m}$. The non-central nature of the effective gravitational force (arising from central gravity plus planetary centrifugal) leads to an oblate spheroidal shape for planets such as the earth. The result is a distinction between the earth's equatorial and polar radii (Appendix Two of *Gill* (1982))

$$R_{\mathrm{equator}} = 6.378 \times 10^6\,\mathrm{m} \qquad \text{and} \qquad R_{\mathrm{pole}} = 6.357 \times 10^6\,\mathrm{m}, \tag{13.137}$$

with a corresponding ratio

$$1 - \frac{R_{\mathrm{pole}}}{R_{\mathrm{equator}}} \approx 3 \times 10^{-3}. \tag{13.138}$$

An oblate spheroid shape does a better job fitting the actual earth shape than a sphere, thus motivating the use of oblate spheroid coordinates for describing planetary scale mechanics. In this case, the radial coordinate is constant on the oblate spheroid shaped geopotential, and the effective gravitational acceleration is precisely aligned with the geopotential direction.

Even though oblate spheroidal coordinates are better than spherical for describing geopotentials, it is possible, to a high degree of accuracy, to describe the earth's geometry as spherical (*Veronis*, 1973). Doing so simplifies the mathematics since oblate spheroidal coordinates are less convenient and less familiar than standard spherical coordinates. We are thus led to assume that

the radial coordinate measures distances perpendicular to the geopotential, yet to use geometric/metric functions based on spherical coordinates. The error in this approach is small for the earth, and well worth the price since there is no component to the effective gravitational force that is within the geopotential surface.

We illustrate the change in coordinates in Figure 13.4, with the figure caption also explaining how the force balances are reorganized. Absorbing the planetary centrifugal term into an effective gravitational potential then leads to the effective gravitational acceleration vector

$$-\nabla\Phi = -g\,\hat{\boldsymbol{r}}, \tag{13.139}$$

with g the effective gravitational acceleration. Using this convention, the particle equations of motion take the following form

$$\dot{u} + \frac{u\,(w - v\tan\phi)}{r} + 2\,\Omega\,(w\cos\phi - v\sin\phi) = 0 \tag{13.140a}$$

$$\dot{v} + \frac{v\,w + u^2\tan\phi}{r} + 2\,\Omega\,u\sin\phi = 0 \tag{13.140b}$$

$$\dot{w} - \frac{u^2 + v^2}{r} - 2\,\Omega\,u\cos\phi = -g. \tag{13.140c}$$

Notably, in geopotential vertical coordinates the effective gravitational acceleration only impacts the radial equation of motion. There is no longer a component of the effective gravity pointing meridionally.

We emphasize the relevance of the non-spherical geopotential for the earth by again referring to the spherical equations (13.134)-(13.136), whereby a particle on a smooth and rotating spherical earth would be attracted to the equator through the effects from centrifugal accelerations. Such motion is unobserved, thus offering evidence for the non-spherical nature of the earth surface. Stated otherwise, if we consider an ocean covered spherical planet, then at static equilibrium the sea surface corresponds to a geopotential.

13.11.4 Comments

Figure 13.4, including its caption, offers a view on the transition from spherical coordinates to geopotential coordinates. The use of geopotential coordinates is rather accurate and extremely convenient for most purposes of geophysical fluid mechanics, with a notable exception being the study of tides and sea level, in which detailed models of the earth's mass distribution and gravity field are used (see *Gregory et al.* (2019) for a review).

Although precise, the transition to geopotential coordinates is somewhat subtle in principle since we are reorganizing how the planetary centrifugal acceleration appears. It is through this reorganization that we can largely ignore the planetary centrifugal acceleration in our studies of geophysical motions since it is absorbed by the geopotential. The single exception for our studies concerns the rotating laboratory tank experiments in Section 28.4, where we find it more convenient to expose the centrifugal acceleration.

13.11.5 Further study

Section 4.12 of *Gill* (1982) and section 2.2.1 of *Vallis* (2017) present the terrestrial scaling needed to justify spherical coordinates with a radial effective gravitational potential. *Morse and Feshbach* (1953) and *Veronis* (1973) present details of oblate spheroidal coordinates. See also the textbook from *Staniforth* (2022) for a careful presentation of the equations for earth's gravity.

FIGURE 13.4: This figure illustrates the spherical (left panel) versus geopotential (right panel) coordinate systems used to study geophysical motions. The left panel shows the non-central nature of the effective gravitational acceleration, $\boldsymbol{g}$, on a rotating spherical planet, with the effective gravity given by the sum of the gravitational acceleration, $-g_{\text{e}}\,\hat{\boldsymbol{r}}$, plus planetary centrifugal acceleration (equation (13.88)), $\boldsymbol{A}_{\text{centrifugal}} = r_\perp\,\Omega^2\,(-\hat{\boldsymbol{\phi}}\sin\phi + \hat{\boldsymbol{r}}\cos\phi)$. The gravitational acceleration points radially to the center of the earth whereas the planetary centrifugal acceleration points outward away from the polar axis of rotation, thus leading to an effective gravitational acceleration $\boldsymbol{g} = \hat{\boldsymbol{r}}\,(-g_{\text{e}} + r_\perp\,\Omega^2\cos\phi) - \hat{\boldsymbol{\phi}}\,r_\perp\,\Omega^2\sin\phi = \hat{\boldsymbol{r}}\,g^r + \hat{\boldsymbol{\phi}}\,g^\phi$. The angle between the radial gravity and the effective gravity, α, is determined by a *plumb line* and is a function of the rotation rate, earth radius, gravitational acceleration, and latitude. The expression for α is determined in Exercise 13.5. A particle initially at rest on a smooth spherical planet accelerates meridionally toward the equator due to the meridional component of the planetary centrifugal acceleration (from equation (13.135) we have $\dot{v} = -r_\perp\,\Omega^2\sin\phi$). The right panel shows a *geopotential vertical coordinate*, $r = R + z$, that measures the distance perpendicular to the oblate spheroid shaped geopotential surface (dotted surface). The geopotential vertical coordinate precisely aligns the effective gravitational force with the vertical coordinate, so that there is no component of the effective gravity along the surface directions ($g_\phi = 0$). Equivalently, the central gravitational acceleration now has a meridional component on the oblate spheroid that exactly balances the meridional component to the planetary centrifugal acceleration, leaving an effective gravity that is only vertical. Hence, a frictionless oblate spheroidal planet allows for a particle at rest on the planet's surface to remain at rest (see equation (13.140b)). Note that this figure is not drawn to scale, with the oblate nature highly exaggerated compared to the real earth system (see equation (13.138)), and the planetary centrifugal acceleration much smaller than the gravitational (see equation (13.124)). This figure is taken after Figure 2.2 of *Vallis* (2017) and Figure 2.8 of *Olbers et al.* (2012).

The transition from spherical to geopotential coordinates for geophysical fluid mechanics has been the topic of some confusion, as evidenced by the papers from *Stewart and McWilliams* (2022), *Chang and Wolfe* (2022), and *Chang et al.* (2023). For the purposes of this book, the key point is that gravity is directed vertically and thus provides no acceleration in the local horizontal directions.

13.12 Exercises

EXERCISE 13.1: WORKING THROUGH THE SPHERICAL ACCELERATION

Convince yourself that the spherical form of the acceleration given by equation (13.77) is indeed correct.

EXERCISE 13.2: DERIVING THE SPHERICAL UNIT VECTOR TIME DERIVATIVES

In this exercise we work through details for deriving the time derivative of the spherical coordinate unit vector from Section 13.2.3.

(A) Fill in the details for deriving equation (13.13)

(B) Fill in the details for deriving equation (13.14a)

(C) Fill in the details for deriving equation (13.14b)

EXERCISE 13.3: VELOCITY AND ACCELERATION IN CYLINDRICAL-POLAR COORDINATES
In Section 10.3 we worked through the transformation from Cartesian coordinates to cylindrical-polar coordinates for describing motion in a rotating reference frame. We also made use of polar coordinates in Section 13.2.2 to illustrate how polar unit vectors change under rotations. The cylindrical-polar coordinates are useful when describing physical systems such as rotating fluid columns (e.g., fluids in a rotating circular tank as in Section 37.8) or when studying cyclostrophically balanced flow (Section 33.5). Here we work through the details using a cylindrical-polar coordinate system in the rigid-body rotating reference frame.

In particular, we here derive the cylindrical-polar coordinate representation of the velocity and acceleration vectors for a particle moving in a reference frame rigid-body rotating with a constant rate about the vertical axis ($\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$). The derivation is directly analogous to the spherical coordinate representation presented in the chapter. Specifically, in Section 13.7.2 we determined a spherical coordinate representation of the velocity vector, and then in Section 13.9 we found the spherical coordinate representation of the acceleration vector.

(A) Determine the representation of the inertial frame velocity vector, $\boldsymbol{V} = \mathrm{d}\boldsymbol{X}/\mathrm{d}t$, in terms of cylindrical-polar coordinates. Hint: do not forget to include the solid body motion of the rotating reference frame, which was discussed in Section 13.2.2.

(B) Determine the representation of the inertial frame acceleration vector, $\boldsymbol{A} = \mathrm{d}\boldsymbol{V}/\mathrm{d}t$, in terms of cylindrical-polar coordinates.

(C) Writing the inertial frame acceleration in the form

$$\boldsymbol{A} = \boldsymbol{A}_{\text{cylindrical-polar}} + \boldsymbol{A}_{\text{metric}} - \boldsymbol{A}_{\text{centrifugal}} - \boldsymbol{A}_{\text{Coriolis}}, \tag{13.141}$$

give the mathematical expressions for these terms:

- $\boldsymbol{A}_{\text{cylindrical-polar}}$ = acceleration in the rotating reference frame using cylindrical-polar coordinates;
- $\boldsymbol{A}_{\text{metric}}$ = acceleration due to motion of the cylindrical-polar unit vectors relative to the rotating reference frame;
- $\boldsymbol{A}_{\text{centrifugal}}$ = centrifugal acceleration;
- $\boldsymbol{A}_{\text{Coriolis}}$ = Coriolis acceleration.

EXERCISE 13.4: VELOCITY PROJECTED ONTO ACCELERATION
The kinetic energy per mass of a particle is given by

$$\mathcal{K} = \boldsymbol{V} \cdot \boldsymbol{V}/2, \tag{13.142}$$

where $\boldsymbol{V}$ is the velocity of the particle viewed in the inertial reference frame. Hence, in an inertial reference frame it is trivial to show that

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \boldsymbol{V} \cdot \boldsymbol{A} \tag{13.143}$$

through use of the chain rule, where $\boldsymbol{A} = \mathrm{d}\boldsymbol{V}/\mathrm{d}t$ is the inertial frame acceleration. Verify that this identity also holds when viewing the motion in the rigid-body rotating reference frame. For simplicity make use of planetary Cartesian coordinates.

EXERCISE 13.5: ANGLE OF A PLUMB LINE

A *plumb line* defines the local vertical direction, which is parallel to the effective gravity. As illustrated in Figure 13.4, the planetary centrifugal acceleration causes the plumb line to not extend through the earth center.

(A) What is the angle that the plumb line makes with a line that does extend through the earth center? Hint: read the caption to Figure 13.4, and orient your thinking according to the left panel of this figure. Make use of the spherical coordinate version of the equations of motion (13.134)–(13.136).

(B) Explain why the plumb line angle, α, vanishes at both the equator and the poles.

EXERCISE 13.6: GEOMETRY OF CONSTANT GEOPOTENTIAL SURFACES

Here we examine some properties of the geopotential given by equation (13.122), where the squared rigid-body speed is $\boldsymbol{U}^2_{\text{rigid}} = (\Omega\, r \cos\phi)^2$. We only consider geopotentials that are close to the radius of the planet, so that we can assume the gravitational acceleration, g_{e}, is constant and takes on its value at R_{e} as in Sections 13.10.2 and 13.10.4.

(A) Sketch surfaces of constant geopotential according to equation (13.122).

(B) By equating the geopotential going around the pole to that going around the equator, show that the polar radius is less than the equatorial radius when $\Omega > 0$.

(C) Taking the terrestrial values of g_{e}, R_{equator}, and Ω, what is the polar radius R_{pole}? Compare to the measured value of the polar radius given by equation (13.137).

EXERCISE 13.7: GENERAL FORM OF THE GEOPOTENTIAL

In Exercise 13.6, as in Sections 13.10.3 and 13.10.4, we only considered geopotentials that are close to the radius of the planet. Show that geopotentials have larger radius at the equator than at the poles even when not making this assumption. Hint: maintain the general form of the gravitational potential as given by equation (13.111), then add to the potential for the planetary centrifugal acceleration (13.64). Evaluate the geopotential at the pole and then show that this same geopotential has a larger radial position anywhere equatorward of the pole.

EXERCISE 13.8: SCALING TO JUSTIFY USE OF GEOPOTENTIAL COORDINATES

Summarize the argument that justifies the use of geopotential coordinates while retaining the spherical geometry. Make use of your favorite textbook discussion such that given in Chapter 2 of *Vallis* (2017).

EXERCISE 13.9: ACCELERATIONS ACTING ON A RESTING PARTICLE

In this exercise we consider the accelerations acting on a particle at rest (in the rotating frame) on a smooth/frictionless rotating spherical planet and a rotating oblate spheroidal planet. We also consider similar questions in Section 14.9.

(A) Motion of a particle on a rotating spherical planet is described using the spherical coordinates from Section 13.11.2 with the corresponding equations of motion (13.134)-(13.136). Suppose that we drop a particle on a rotating sphere and that we describe its motion using the spherical coordinates. Discuss the initial acceleration of the particle that is released from rest.

(B) Motion of a particle on a rotating oblate spheroid planet is described using the geopotential coordinates from Section 13.11.3 with the corresponding equations of motion (13.140a)-(13.140c). Suppose that we drop a particle on a rotating oblate spheroid and that we describe its motion using the geopotential coordinates. Discuss the initial acceleration of the particle that is released from rest. Note that we return to this freely falling particle in Section 14.9.3.

EXERCISE 13.10: GRAVITATIONAL POTENTIAL INSIDE A SPHERE

In Section 13.10.1 we found the gravitational, Φ, for a point outside of the spherical earth. Here we find the gravitational potential inside of the earth. That is, solve the Poisson equation

$$\nabla^2 \Phi = 4\,\pi\,G\,\rho, \tag{13.144}$$

for a radial position $r < R_{\text{e}}$. Hint: follow the approach in Section 13.10.1 and then match the potential at $r = R_{\text{e}}$. Note: the solution can be found in many undergraduate physics texts.

Chapter 14

Symmetries and conservation laws

Symmetries are discrete or continuous operations that leave a physical system unchanged. For example, let $\boldsymbol{X}$ be a trajectory satisfying Newton's equation of motion and $\mathcal{A}$ be an operation. If $\mathcal{A}[\boldsymbol{X}]$ also satisfies Newton's equation of motion then $\mathcal{A}$ is a symmetry of the physical system. As studied in Section 12.9, *Noether's theorem* provides a connection between symmetries and *conservation laws*, with conservation laws providing *dynamical constraints* on the motion. In this chapter we study a variety of dynamical constraints respected by particle motion. We then use these dynamical constraints as a means to study the nature of the motion and, in turn, to further our understanding. We are particularly interested here in delving further into a study of motion as observed in a rigid-body rotating reference frame.

One of the key reasons to make use of conserved quantities concerns their additive nature. Namely, a conserved quantity for a system composed of several weakly interacting parts is given by the sum of the conserved quantity for the individual parts. As a result, symmetries and conservation laws are fundamental to how we garner a qualitative and quantitative understanding of motion in which, for many purposes, it is more useful to know the dynamically conserved properties of any realized motion rather than details of any particular trajectory.

CHAPTER GUIDE

This chapter relies on our study of particle mechanics in Chapter 13. In Section 12.9 we provide the mathematical basis for Noether's theorem through the study of Lagrangian mechanics and Hamilton's principle. However, full reading of that material is not necessary for the present chapter.

- Design and exercise that computes the angular momentum in the $\hat{\boldsymbol{\phi}}$ and $\hat{\boldsymbol{r}}$ directions, showing that these components are not conserved for the rotating sphere.

14.2 Trajectories and dynamical constraints

Time integration (twice) of the equation of motion provides an expression for the trajectory of a particle. To assist in this integration we find it very useful to make use of *dynamical constraints* respected by the motion. Dynamical constraints manifest as conservation laws and thus can be an essential part of how we determine the trajectory in practice. Dynamical constraints also provide predictive statements of value when studying the stability of motion and for developing numerical methods for simulations.

Knowledge of the trajectory is important if we are interested in details of a particular realization of the motion. For example, the particle might be an idealization of a satellite orbiting the planet, with an accurate trajectory needed to predict its location at a future time. However, for other purposes we might wish to know that all particles, no matter what trajectory, conserve *angular momentum* and mechanical energy. This information about the dynamical constraints satisfied by the motion offers the ability to understand basic properties of the motion and to predict its response to perturbations, even without determining trajectories. Dynamical constraints

imposed by conservation laws are especially relevant for fluids since it is rare to determine the analytical expression for the motion of fluid particles, making the knowledge of constraints incredibly valuable.

14.2.1 Connecting symmetries to conservation laws

The discovery of conservation laws often comes from inspired manipulations of the equations of motion. However, there is a more robust and fundamental means to deduce conservation laws through their connection to symmetries, with a symmetry manifesting as an operation that leaves the physical system unchanged. For example, does the physical system remain unchanged when shifting the origin of time? If so, then mechanical energy is a constant of the motion. Likewise, if there is rotational symmetry around an axis, then the associated angular momentum is a constant of the motion.

The connection between symmetries (kinematics) and conservation laws (dynamics) was made by *Noether* (1918) (see *Noether and Tavel* (2018) for an English translation). We provide the mathematical expression of Noether's theorem in Section 12.9 as part of our study of Hamilton's principle. It is sufficient for this chapter to make use of this theorem as a conceptual framework for understanding conservation laws and their connections to symmetries. Quite simply, if there is a symmetry then there is a corresponding conservation law, and vice versa.

It is very useful to identify conserved quantities as a means to understand and to dynamically constrain the motion. This perspective holds even when the symmetries giving rise to conserved quantities are broken through the introduction of non-conservative forces such as friction. For example, as seen in Section 11.1.6, friction breaks time translation symmetry and so leads to the dissipation of mechanical energy. Nonetheless, understanding the conservative motion, and the associated energy conservation law, offers insights for the case with friction. Indeed, for many purposes, knowledge of the trajectory is less important than knowledge of conserved, or partially conserved, dynamical quantities. In this chapter, we offer two examples to support this point: mechanical energy conservation and axial angular momentum conservation. These conservation laws also hold in a modified form for the continuum fluid (e.g., Chapter 25). Additional conservation properties also arise that are unique to the continuum, with conservation of potential vorticity the most notable one for geophysical fluids (Chapter 42).

14.2.2 Further study

Conservation laws and symmetries in classical mechanics are lucidly discussed in Chapters 1 and 2 of *Landau and Lifshitz* (1976). Pedagogical presentations on these topics can be found in this online lecture from the Space Time series and this online lecture from Physics with Elliot. This essay about Emmy Noether provides insights into this mathematician whose work, conducted under some very unfortunate circumstances, forever connected symmetry and conservation laws, with this connection providing the basis for nearly all modern theories of physics.

14.3 Time reversal symmetry

As a warm-up to the ideas of symmetry, consider here the question about time reversibility. A deterministic process is time-reversible if the time-reversed process satisfies the same dynamic equations as the forward-time process. That is, the dynamical equations are symmetric under a change in the sign of time so that the time-reversed evolution of one state is equivalent to the forward-time evolution of a corresponding state. We here discuss time reversal symmetry in the context of the point particle with trajectory, $\boldsymbol{X}(t)$, and velocity, $\boldsymbol{V}(t) = \mathrm{d}\boldsymbol{X}(t)/\mathrm{d}t$.

If $\boldsymbol{X}(t)$ is a solution to the equations of motion, then what is needed for

$$\boldsymbol{X}^*(t^*) = \boldsymbol{X}(-t) \quad \text{and} \quad \boldsymbol{V}^*(t^*) = \mathrm{d}\boldsymbol{X}^*(t^*)/\mathrm{d}t^* = -\mathrm{d}\boldsymbol{X}(-t)/\mathrm{d}t \tag{14.1}$$

to define the same trajectory traversed backwards in time, where $t^* = -t$? We answer this question by recalling from Section 13.11.1 that with planetary rotation a constant in time then the Cartesian coordinate equation of motion is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\mathrm{d}\boldsymbol{X}(t)}{\mathrm{d}t} + 2\,\boldsymbol{\Omega}\times\boldsymbol{X}(t)\right] = -\nabla\Phi(t). \tag{14.2}$$

We are interested in the constraints that ensure the following equation is satisfied

$$\frac{\mathrm{d}}{\mathrm{d}t^*}\left[\frac{\mathrm{d}\boldsymbol{X}^*(t^*)}{\mathrm{d}t^*} + 2\,\boldsymbol{\Omega}^*\times\boldsymbol{X}^*(t^*)\right] = -\nabla\Phi(t^*). \tag{14.3}$$

The effective gravitational acceleration remains time reversible if

$$\Phi^*(t^*) = \Phi(t), \tag{14.4}$$

which is trivially satisfied for $\Phi = g\,z$. The Coriolis acceleration is velocity dependent so that it generally breaks time reversal symmetry. However, we can recover time symmetry by assuming that the rotation direction switches when time reverses so that

$$\boldsymbol{\Omega}^* = -\boldsymbol{\Omega}. \tag{14.5}$$

With this transformation, a trajectory, $\boldsymbol{X}(t)$, that solves the forward equation (14.2) yields a trajectory $\boldsymbol{X}(-t)$ that solves the same equation but with time reversed. We return to this question of time reversal symmetry for the Euler equations of perfect fluid mechanics in Section 26.8.11.

14.4 Potential momentum

In Section 13.11.1 we introduced the *potential momentum*, and we here further study its conservation properties. Recall that it is a constant of the motion when a particle moves on a time independent geopotential in a direction where the geopotential does not change. That is, the conservation of potential momentum arises from a spatial symmetry of the geopotential.

14.4.1 Basics

Start with the planetary Cartesian coordinate equation of motion

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\dot{\boldsymbol{X}} + 2\,\boldsymbol{\Omega}\times\boldsymbol{X}\right] = -\nabla\Phi. \tag{14.6}$$

Now introduce the *potential momentum* per mass

$$\boldsymbol{M} \equiv \dot{\boldsymbol{X}} + 2\,\boldsymbol{\Omega}\times\boldsymbol{X} = \hat{\boldsymbol{x}}\,(u - 2\,\Omega\,y) + \hat{\boldsymbol{y}}\,(v + 2\,\Omega\,x) + \hat{\boldsymbol{z}}\,w, \tag{14.7}$$

in which case the equation of motion takes the form

$$\dot{\boldsymbol{M}} = -\nabla\Phi. \tag{14.8}$$

Now let $\hat{\boldsymbol{s}}$ be a unit vector tangent to the geopotential surface so that $\hat{\boldsymbol{s}} \cdot \nabla\Phi = 0$. Assuming the geopotential surface is time independent so that $\hat{\boldsymbol{s}}$ is also time independent, then the equation of motion (14.8) leads to

$$\frac{\mathrm{d}(\hat{\boldsymbol{s}} \cdot \boldsymbol{M})}{\mathrm{d}t} = 0. \tag{14.9}$$

That is, the projection of the potential momentum onto a static geopotential surface is a constant of motion. This dynamical constraint arises since we cannot distinguish one point on the geopotential from another; i.e., there is a symmetry associated with motion along the static geopotential. Noether's theorem (Section 14.2.1) then says that this geometric symmetry leads to a constant of the motion, here given by that component of potential momentum within the geopotential surface. We illustrate this situation in Figure 14.1 with a horizontal geopotential surface.

FIGURE 14.1: The projection of the potential momentum onto the geopotential surface is a constant of the motion, $\mathrm{d}(\hat{\boldsymbol{s}} \cdot \boldsymbol{M})/\mathrm{d}t = 0$. Here the geopotential surface is the x-y-plane so that $\hat{\boldsymbol{x}} \cdot \boldsymbol{M} = u - 2\,\Omega\, y$ and $\hat{\boldsymbol{y}} \cdot \boldsymbol{M} = v + 2\,\Omega\, x$ are the two conserved components of potential momentum.

Consider a particle with potential momentum $\boldsymbol{M}$ and move it from an arbitrary point to a reference position with $\boldsymbol{X} = 0$. Upon reaching the reference position, the horizontal velocity of the particle must equal to $\boldsymbol{M}$ in order to maintain the same potential momentum. This example motivates the name "potential momentum", since $\boldsymbol{M}$ measures the potential for relative motion contained in the particle as it moves along a geopotential.

14.4.2 Comment about terminology

As noted on page 51 of *Markowski and Richardson* (2010), one might see potential momentum referred to as *pseudo angular momentum*, with some dropping the "pseudo" portion to the name. In either case, it is important to note that potential momentum is distinct from angular momentum. In particular, there is no moment-arm as part of the potential momentum, nor is there any axial symmetry corresponding to the conservation law.

Many authors use the term *absolute momentum* rather than potential momentum, perhaps in reference to the momentum measured in the absolute or inertial reference frame. However, that connection is incorrect since the inertial frame velocity is (Section 13.7.1)

$$\boldsymbol{V} = \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{U}_{\text{rigid-body}} = \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{\Omega} \times \boldsymbol{X}. \tag{14.10}$$

The factor of two multiplying the rotation rate in the potential momentum arises from the Coriolis acceleration. In contrast, the rigid-body rotation velocity contributes to the inertial frame velocity and it has a factor of unity multiplying the rotation rate.

14.5 Free particle motion on the f-plane

In Section 25.5 we introduce the tangent plane approximation for motion on a rotating sphere. In this approximation, motion occurs on a geopotential surface with the surface approximated as a

horizontal flat plane. Furthermore, we use local tangent plane Cartesian coordinates (which are distinct from the planetary Cartesian coordinates used in Chapter 13 and illustrated in Figure 10.1). The $f-$plane approximation furthermore sets the Coriolis parameter to a constant,

$$f = 2\,\Omega \sin\phi_0, \tag{14.11}$$

where ϕ_0 is a chosen latitude. Consequently, a *free particle* constrained to move on a constant geopotential under the f-plane approximation maintains a constant horizontal potential momentum

$$\frac{\mathrm{d}M_x}{\mathrm{d}t} = \frac{\mathrm{d}(u - f\,y)}{\mathrm{d}t} = 0 \tag{14.12a}$$

$$\frac{\mathrm{d}M_y}{\mathrm{d}t} = \frac{\mathrm{d}(v + f\,x)}{\mathrm{d}t} = 0, \tag{14.12b}$$

where we introduced the horizontal velocity components $(u, v) = (\dot{x}, \dot{y})$. These two conservation laws provide dynamical constraints on the free particle motion on a constant geopotential surface.[1]

14.5.1 Oscillator equation

Taking the time derivative of the zonal equation (14.12a) and using the meridional equation (14.12b) leads to

$$\ddot{u} - f\,\dot{v} = \ddot{u} + f^2 u = 0. \tag{14.13}$$

Similar manipulations for the meridional velocity equation render the free oscillator equation for each component of the horizontal velocity

$$\frac{\mathrm{d}^2 u}{\mathrm{d}t^2} + f^2 u = 0 \qquad \text{and} \qquad \frac{\mathrm{d}^2 v}{\mathrm{d}t^2} + f^2 v = 0. \tag{14.14}$$

Motions that satisfy this equation are termed *inertial oscillations*.

14.5.2 Particle trajectory and velocity

Time integrating the equation of motion (14.14) renders the particle trajectory and its velocity

$$\boldsymbol{X}(t) = (U/f)\,[\hat{\boldsymbol{x}}\sin(ft) + \hat{\boldsymbol{y}}\cos(ft)] \tag{14.15a}$$

$$\boldsymbol{U}(t) = U\,[\hat{\boldsymbol{x}}\cos(ft) - \hat{\boldsymbol{y}}\sin(ft)], \tag{14.15b}$$

where $U > 0$ is the particle speed, which is a constant, and we assumed the initial conditions

$$\boldsymbol{X}(0) = (U/f)\,\hat{\boldsymbol{y}} \qquad \text{and} \qquad \boldsymbol{U}(0) = U\,\hat{\boldsymbol{x}}. \tag{14.16}$$

From the particle trajectory equation (14.15a), we see that the free particle motion is circular with a radius

$$R = U/|f|. \tag{14.17}$$

As depicted in Figure 14.2, northern hemisphere ($f > 0$) free particle motion occurs in the clockwise direction whereas southern hemisphere motion is counter-clockwise. This motion arises from the rightward deflection by the Coriolis in the northern hemisphere and leftward in the

[1] It is important to recall from Section 13.10.4 that motion on a geopotential incorporates the acceleration from both the central gravitational field and the planetary centrifugal acceleration. Hence, there is no planetary centifugal term when studying free particle motion on the f-plane.

FIGURE 14.2: Free particle motion on a horizontal f-plane occurs when the particle's centrifugal acceleration balances its planetary Coriolis acceleration. Left panel: $f > 0$ for the northern hemisphere, revealing that the motion is an anti-cyclonic (clockwise) circular motion with radius $|R| = U/|f|$. The Coriolis acceleration is to the right, pointing into the center of the inertial circle, whereas the centrifugal acceleration points away from the center. Right panel: Counterclockwise motion in the southern hemisphere with the same balance between Coriolis and centrifugal accelerations.

southern. Consequently, particle motion occurs in an anti-cyclonic sense (opposite to the sense of the rotating reference frame). As studied in Section 33.4, this motion arises from a balance between the Coriolis acceleration of the rotating frame and the centrifugal acceleration arising from the particle's circular motion.[2] The only way to realize this balance is for the particle to move anti-cyclonically, with the Coriolis acceleration pointing towards the inside of the circle and the centrifugal acceleration pointing outside. Finally, note that the potential momentum vanishes since

$$\boldsymbol{M}(t) = \boldsymbol{U}(t) + f\,\hat{\boldsymbol{z}} \times \boldsymbol{X}(t) = 0. \tag{14.18}$$

Adding an arbitrary constant to the initial position makes the potential momentum equal to a nonzero constant.

14.5.3 Period of the circular motion

The circular motion of the free particle possesses a constant speed and moves around a circle with a period

$$T_{\text{inertial}} = \frac{2\,\pi}{f} = \frac{11.97}{|\sin\phi_0|}\,\text{hour}, \tag{14.19}$$

where we set $\Omega = 7.292 \times 10^{-5}\text{s}^{-1}$ (equation (13.1)). This period is the time it takes to go around the circle. It is smallest at the poles, where the latitude $\phi_0 = \pm\pi/2$ and $T_{\text{smallest}} \approx 12\,\text{hour}$. At the equator, $\phi_0 = 0$, so that the radius of the inertial circle is infinite and inertial oscillations are unavailable. Furthermore, T_{inertial} is the time for a Foucault pendulum to turn through π radians, so that T_{inertial} is sometimes referred to as one-half a pendulum day.

14.5.4 Inertial oscillations

The circular free particle motion studied in this section is sometimes referred to as an *inertial oscillation*. Again, this circular motion occurs on a constant geopotential and on the f-plane when there is a balance between the Coriolis acceleration from planetary rotation and centrifugal acceleration due to the curved motion of a particle on a constant geopotential. Importantly, the centrifugal acceleration here is not the planetary centrifugal acceleration, with the planetary centrifugal acceleration absorbed into the effective gravity that is a fixed constant along a geopotential.

[2]This centrifugal acceleration is distinct from the planetary centrifugal acceleration, which has been absorbed into the geopotential (Section 13.10.4).

Furthermore, the name "inertial" does not refer to motion as observed in an inertial reference frame. Instead, it is used as a synonym for free particle motion, with the free motion here in the directions along a constant geopotential.[3] More generally, there has been some confusion in the literature concerning the forces acting in inertial oscillations, particularly when not making a tangent plane approximation. *Early* (2012) clarifies the fundamental physics. We return to these matters in Section 15.4, there making use of the methods of Lagrangian mechanics.

14.5.5 Comments and further study

Inertial oscillations of fluid elements are described by the above constant potential momentum equation of motion. Such oscillations are commonly measured by ocean current meters, especially in higher latitude regions where diurnal (day-night) variations in wind forcing have a strong projection onto the inertial period. This resonant forcing puts energy into inertial or near-inertial motions. It is quite amazing that such oscillations are indeed found in the ocean, given that we have ignored pressure and friction, which are two forces that impact on fluid motion (whereas pressure and friction do not affect point particles). A key reason we can observe such motion is that upper ocean currents are often generated by winds even in the absence of horizontal pressure gradients. Hence, there are occasions when the motion is not strongly affected by pressure gradients or friction, thus allowing for the inertial oscillations to manifest.

We study inertial waves in Chapter 51 as part of our study of rapidly rotating fluid motion. We also encounter inertial motions in Section 33.4 as part of our characterization of horizontal fluid motion according to the balance between forces. A rotating tank fluid experiment offers a useful controlled setting to observe inertial waves in a fluid, such as shown near the 18 minute mark in this video from Prof. Fultz.

14.6 Angular momentum

We introduced the concept of angular momentum in Section 11.2.4, which is written

$$\boldsymbol{L} = m\,\boldsymbol{X} \times \boldsymbol{V}. \tag{14.20}$$

In this section we study the angular momentum computed relative to the center of the sphere; i.e., where $\boldsymbol{X}$ is the position of the particle with respect to the sphere's center. For a non-rotating sphere, there is spherical symmetry, meaning that rotations around any axis extending out from the sphere's center represent symmetry operations. Noether's theorem then says that the angular momentum projected onto any of these axes is a constant of the motion for a particle moving around the non-rotating sphere. For a rotating spherical planet, the polar rotational axis is distinguished from all other axes, so that the spherical symmetry of the non-rotating planet is broken down to symmetry around just the rotational axis. Noether's theorem then says that it is only the axial component of angular momentum that is conserved for the rotating sphere.

To be more specific, we ask whether a point particle knows anything about the longitudinal angle, λ, on the rotating sphere (Figure 14.3)? Assuming the sphere is smooth (i.e., no mountains), and the sphere rotates around the polar axis (along the planetary $\hat{\boldsymbol{z}}$ direction), then there is an arbitrariness in the value of the longitude. That is, the physical system remains unchanged if we shift the longitudinal angle by a constant. Noether's theorem then says that this symmetry leads to a corresponding conservation of angular momentum around the polar axis.

[3] See Section 11.3.2 for comments on the somewhat confusing terminology used to refer to the Coriolis acceleration and centrifugal acceleration as "inertial" accelerations.

We here display the manipulations that show axial angular momentum, $L^z = \hat{\boldsymbol{z}} \cdot \boldsymbol{L}$, is a constant of the motion for motion around the rotating sphere, and furthermore show that the other components to angular momentum, $L^x = \hat{\boldsymbol{x}} \cdot \boldsymbol{L}$ and $L^y = \hat{\boldsymbol{y}} \cdot \boldsymbol{L}$, are not constant. Many of the same concepts and mathematical manipulations occur when considering angular conservation for a fluid in Section 25.7.

FIGURE 14.3: Axial angular momentum is the component of the angular momentum through the polar axis, $L^z = \hat{\boldsymbol{z}} \cdot \boldsymbol{L}$. It is the moment of the zonal momentum around the polar axis, with the moment-arm, $r_\perp = r\,\cos\phi = \sqrt{x^2+y^2}$, the distance to the axis of rotation, whereas $r^2 = \sqrt{x^2+y^2+z^2}$ is the radial distance to the center of the sphere. It can be written in the equivalent manners $L^z = m\,r_\perp\,(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{V}) = m\,r_\perp^2\,(\dot{\lambda} + \Omega) = m\,r_\perp\,(u + r_\perp\,\Omega)$. The axial angular momentum is a constant of the motion for the particle moving on a smooth rotating sphere in the absence of friction.

14.6.1 Axial angular momentum

The axial angular momentum is the component of the angular momentum through the polar axis, and it can be written in the following manners

$$L^z = \boldsymbol{L} \cdot \hat{\boldsymbol{z}} = m\,(\boldsymbol{X} \times \boldsymbol{V}) \cdot \hat{\boldsymbol{z}} = m\,(\hat{\boldsymbol{z}} \times \boldsymbol{X}) \cdot \boldsymbol{V} = m\,r\cos\phi\,(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{V}) = m\,r_\perp\,(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{V}). \tag{14.21}$$

Evidently, the component of angular momentum along the polar axis equals to the component of the linear momentum in the longitudinal direction, multiplied by the distance to the polar rotational axis (the moment-arm)

$$r_\perp = r\cos\phi. \tag{14.22}$$

In deriving equation (14.21), we made use of the identity (see equation (10.44))

$$\hat{\boldsymbol{z}} \times \boldsymbol{X} = r\,\hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}} = r_\perp\,\hat{\boldsymbol{\lambda}}, \tag{14.23}$$

which we use below for proving that axial angular momentum is a constant of the motion.

We can write the axial angular momentum from equation (14.21) in terms of the rotating frame quantities. To do so, decompose the inertial frame velocity written using spherical coordinates according to equation (13.46f), which yields

$$L^z = m\,r_\perp\,(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{V}) = m\,r_\perp^2\,(\dot{\lambda} + \Omega) = m\,r_\perp\,(u + r_\perp\,\Omega). \tag{14.24}$$

Evidently, when measured from the rotating terrestrial frame, the axial angular momentum consists of two terms: one from the zonal velocity of the particle relative to the rotating planet and

another from the rigid-body motion of the planet.

14.6.2 Axial angular momentum is a constant of the motion

The time derivative of the axial angular momentum is given by

$$
\begin{aligned}
m^{-1}\,\mathrm{d}L^z/\mathrm{d}t &= \mathrm{d}/\mathrm{d}t\,[(\boldsymbol{X}\times\boldsymbol{V})\cdot\hat{\boldsymbol{z}}] && \text{definition of axial angular momentum} && (14.25a)\\
&= \mathrm{d}/\mathrm{d}t\,[(\hat{\boldsymbol{z}}\times\boldsymbol{X})\cdot\boldsymbol{V}] && \text{cyclic permutation from equation (1.34j)} && (14.25b)\\
&= (\hat{\boldsymbol{z}}\times\boldsymbol{V})\cdot\boldsymbol{V}+(\hat{\boldsymbol{z}}\times\boldsymbol{X})\cdot\boldsymbol{A} && \mathrm{d}\boldsymbol{X}/\mathrm{d}t=\boldsymbol{V},\ \mathrm{d}\boldsymbol{V}/\mathrm{d}t=\boldsymbol{A},\ \text{and}\ \mathrm{d}\hat{\boldsymbol{z}}/\mathrm{d}t=0 && (14.25c)\\
&= (\hat{\boldsymbol{z}}\times\boldsymbol{X})\cdot\boldsymbol{A} && (\hat{\boldsymbol{z}}\times\boldsymbol{V})\cdot\boldsymbol{V}=0 && (14.25d)\\
&= r_\perp\,\hat{\boldsymbol{\lambda}}\cdot\boldsymbol{A}. && \hat{\boldsymbol{z}}\times\boldsymbol{X}=r_\perp\,\hat{\boldsymbol{\lambda}}\ \text{from equation (14.23).} && (14.25e)
\end{aligned}
$$

The inertial frame acceleration arises just from the central-force gravitational field (equation (13.125))

$$\boldsymbol{A}=-\nabla\Phi_{\mathrm{e}}=-g_{\mathrm{e}}\,\hat{\boldsymbol{r}}. \tag{14.26}$$

Evidently, the central gravity force has no affect on the axial angular momentum since $\hat{\boldsymbol{\lambda}}\cdot\hat{\boldsymbol{r}}=0$. We are thus led to axial angular momentum conservation

$$\frac{\mathrm{d}L^z}{\mathrm{d}t}=0. \tag{14.27}$$

Conservation of axial angular momentum plays an important role in constraining the particle motion, and we explore those constraints in Section 14.7.

14.6.3 L^x and L^y are not constants of the motion

To display the symmetry breaking nature of rotation around the polar axis, we here show that the angular momentum components, $\hat{\boldsymbol{x}}\cdot\boldsymbol{L}$ and $\hat{\boldsymbol{y}}\cdot\boldsymbol{L}$, are not constants of the motion. For $L^x=\hat{\boldsymbol{x}}\cdot\boldsymbol{L}$ we write

$$m^{-1}\,L^x=(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{X}})\cdot\boldsymbol{V}=r\,(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{r}})\cdot\boldsymbol{V}, \tag{14.28}$$

so that its time derivative is

$$
\begin{aligned}
m^{-1}\,\mathrm{d}L^x/\mathrm{d}t &= (\mathrm{d}\hat{\boldsymbol{x}}/\mathrm{d}t\times\boldsymbol{X})\cdot\boldsymbol{V}+(\hat{\boldsymbol{x}}\times\dot{\boldsymbol{X}})\cdot\boldsymbol{V}+r\,(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{r}})\cdot\boldsymbol{A} && (14.29a)\\
&= r\,\Omega\,(\hat{\boldsymbol{y}}\times\hat{\boldsymbol{r}})\cdot\boldsymbol{V}, && (14.29b)
\end{aligned}
$$

where we used equation (13.7) to write $\mathrm{d}\hat{\boldsymbol{x}}/\mathrm{d}t=\Omega\,\hat{\boldsymbol{y}}$. Similarly, we have

$$m^{-1}\,L^y=(\hat{\boldsymbol{y}}\times\hat{\boldsymbol{X}})\cdot\boldsymbol{V}=r\,(\hat{\boldsymbol{y}}\times\hat{\boldsymbol{r}})\cdot\boldsymbol{V}, \tag{14.30}$$

so that its time derivative is

$$m^{-1}\,\mathrm{d}L^y/\mathrm{d}t=(\mathrm{d}\hat{\boldsymbol{y}}/\mathrm{d}t\times\boldsymbol{X})\cdot\boldsymbol{V}=-r\,\Omega\,(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{r}})\cdot\boldsymbol{V}, \tag{14.31}$$

where $\mathrm{d}\hat{\boldsymbol{y}}/\mathrm{d}t=-\Omega\,\hat{\boldsymbol{x}}$ from equation (13.7). Evidently, both $\mathrm{d}L^x/\mathrm{d}t$ and $\mathrm{d}L^y/\mathrm{d}t$ vanish when $\Omega=0$. Otherwise, when $\Omega\neq 0$ then both L^x and L^y are not constant, leaving just L^z as a constant of the motion.

14.7 Facets of the Coriolis acceleration

The Coriolis acceleration is a primary feature of motion in the ocean and atmosphere, and for any motion that spans large distances over the planet (e.g., projectiles, satellites). There are a variety of methods available to lend understanding to facets of Coriolis, though few can replace time pondering its implications. In this section we offer a few thought experiments to help build understanding. As part of those thought experiments, we show that acceleration induced by axial angular momentum conserving motion connects to the Coriolis acceleration appearing in the zonal momentum equation. This connection offers a clear example of how conservation principles, which lead to constraints, directly affect motion.

14.7.1 Two pictures to help frame the discussion

Before working through the mathematical analysis needed to quantitatively understand the Coriolis acceleration, we consider two depictions of the Coriolis acceleration as it acts on a moving particle whose motion is viewed in a rotating reference frame. These pictures capture essential features of the Coriolis acceleration for studies of geophysical fluid motion.

Figure 14.4 shows the motion of a particle on a rotating and frictionless table. We can choose to observe this motion from the comfort of the laboratory frame, which we assume approximates an inertial frame, or we can view the motion from the rotating table (preferably viewed by a camera on the table so as to avoid becoming too dizzy). The figure caption details the motion from the two reference frames. Evidently, the rotating reference frame observer sees the particle motion deflected to the right, regardless the direction that the particle moves on the table. In contrast, the inertial reference frame observer views the table moving to the left according to the counter-clockwise motion of the table, whereas the particle moves along a straight line. We emphasize that the motion is objectively the same; it is the same particle moving through space along the same single trajectory. However, the perspectives of observers in the two reference frames clearly differ.

FIGURE 14.4: Illustrating the motion of a particle on a frictionless table (e.g., a perfectly slick ice rink), with the table rotating in the counter-clockwise sense around its center. The particle (red dot) moves outward from the center of the table at time t_0 to the edge at time t_2, with an intermediate position at time t_1. The left panel shows the motion viewed from an inertial (non-rotating) reference frame, whereby the particle moves along a straight line from the center to the edge. During this transit, the table moves underneath the particle. Stars designate points painted on the table, with the stars moving to the left as the table rotates. The right panel depicts the motion viewed within the frame at rest with the rotating table (rigid-body rotating non-inertial reference frame). Here, the positions on the table remain fixed (the stars do not move), whereas the particle moves along a rightward curved trajectory as it reaches the edge. The rotating frame observer interprets the rightward deflection as due to the Coriolis acceleration.

The rotating table example in Figure 14.4 captures the essence of how the Coriolis acceleration deflects particles moving along horizontal trajectories around the rotating planet. Namely, each point on the planet is akin to a rotating table. Importantly, the rotation rate (and sign) is a function of latitude since the imprint of the planetary rotation depends on the latitude. So although the planet rotates at a constant angular velocity, the imprint of that rotation has a latitudinal dependence due to the spherical geometry of the planet. This added feature of planetary Coriolis acceleration is referred to as the *beta effect*, and it is is a fundamental distinction from the rotating flat table of Figure 14.4 where each point on the table feels the same angular rotation vector. Facets of the beta effect are uncovered through the course of this book.

Figure 14.5 summarizes features of the Coriolis acceleration seen for motion on a rotating planet. Here, the particle trajectories are deflected to the right in the northern hemisphere, where the planetary rotation is counter-clockwise just as in the rotating table example. However, for the southern hemisphere the planetary rotation is clockwise, so that the Coriolis deflection is to the left. To help understand the sign switch, imagine viewing the planet from above the north pole, whereby the rotation of the planet is counter-clockwise. Now view the planet from below the south pole, in which case the earth is seen to rotate clockwise.[4] This sign swap reflects the *axial vector* nature of the angular velocity vector, with axial vectors discussed in Section 1.4.2.

FIGURE 14.5: For a particle moving at constant radial distance from the planet center, the Coriolis acceleration deflects to the right in the northern hemisphere and to the left in the southern hemisphere. This figure summarizes key features of the Coriolis acceleration for large-scale geophysical motions. The one exception is the missing vertical acceleration induced by Coriolis as discussed in Section 14.7.8, though this acceleration is tiny compared to that from gravity.

14.7.2 Constraints from axial angular momentum conservation

There are various ways to express the constraints resulting from conservation of axial angular momentum, most notably whether we describe the motion from the inertial frame or rotating frame. Here we explore the constraints viewed by the rotating terrestrial observer. Since the mass, m, of the particle is constant, we find it a bit more convenient to work with the axial angular momentum per mass, which from Section 14.6.1 takes on the form

$$l^z = L^z/m = r_\perp \, \hat{\boldsymbol{\lambda}} \cdot \boldsymbol{V} = r_\perp^2 \, (\dot{\lambda} + \Omega) = r_\perp \, (u + r_\perp \, \Omega), \tag{14.32}$$

[4]Those who do not trust their mind's eye are encouraged to perform the thought experiment with a globe.

where the zonal velocity component is given by equation (13.48)

$$u = r_\perp \, \dot{\lambda} = r \cos\phi \, \dot{\lambda}. \tag{14.33}$$

Note that for most geophysical applications, $l^z > 0$ since rigid-body motion dominates over the relative zonal velocity:

$$r_\perp \, \Omega > |u| \qquad \text{for most terrestrial motions,} \tag{14.34}$$

with $r_\perp \, \Omega = 465$ m s^{-1} at the equator (see Figure 13.2). In Exercise 14.1 we consider the interesting, but geophysically uncommon, case where $l^z \leq 0$.

Constraints on δu and $\delta\dot{\lambda}$ in terms of $\delta r_\perp$

To determine the constraints, we set $\delta l^z = 0$, where δ refers to any small change brought about by some perturbation whose origins are not of concern. When writing $l^z = r_\perp^2 \, (\dot{\lambda} + \Omega)$ we have

$$\delta l^z = 2 \, r_\perp \, \delta r_\perp \, (\dot{\lambda} + \Omega) + r_\perp^2 \, \delta\dot{\lambda} = 2 \, l^z \, \frac{\delta r_\perp}{r_\perp} + r_\perp^2 \, \delta\dot{\lambda}, \tag{14.35}$$

where we set $\delta\Omega = 0$ since the earth's rotation rate is assumed to be fixed. Furthermore, we find it useful to express the perturbations in terms of l^z since it is a constant of the motion. Likewise, when writing $l^z = r_\perp \, (u + r_\perp \, \Omega)$ we have

$$\delta l^z = \delta r_\perp \, (u + r_\perp \, \Omega) + r_\perp \, (\delta u + \Omega \, \delta r_\perp) = \Omega \, r_\perp \, \delta r_\perp \left[1 + \frac{l^z}{\Omega \, r_\perp^2} \right] + r_\perp \, \delta u. \tag{14.36}$$

Setting $\delta l^z = 0$ then leads to the expressions for the constraints

$$\delta\dot{\lambda} = -\frac{2 \, l^z}{r_\perp^2} \, \frac{\delta r_\perp}{r_\perp} \Longleftrightarrow \delta u = -\Omega \, \delta r_\perp \left[1 + \frac{l^z}{\Omega \, r_\perp^2} \right]. \tag{14.37}$$

As noted above, $l^z > 0$ is generally the case for geophysical fluid motion. Consequently, axial angular momentum conserving motion that brings the particle closer to the rotation axis ($\delta r_\perp < 0$) leads to an eastward velocity change (angular velocity $\delta\dot{\lambda} > 0$ and zonal velocity $\delta u > 0$). The opposite occurs for motion with $\delta r_\perp > 0$. These results hold in both the northern and southern hemispheres.

Unpacking $\delta r_\perp$ in terms of δr and $\delta\phi$

Since $r_\perp = r \cos\phi$, the distance to the rotational axis can be perturbed through changing either the radial position or the meridional position

$$\delta r_\perp = (\cos\phi) \, \delta r - (r \sin\phi) \, \delta\phi. \tag{14.38}$$

Assuming these perturbations occur over a small time increment δt allows us to write

$$\delta r_\perp / \delta t = w \cos\phi - v \sin\phi, \tag{14.39}$$

where we made use of equation (13.48) to introduce the meridional and vertical velocity components

$$v = r \, \delta\phi / \delta t = r \, \dot{\phi} \quad \text{and} \quad w = \delta r / \delta t = \dot{r}. \tag{14.40}$$

For motion in the earth's atmosphere and ocean, perturbations to vertical distance, δr, are far smaller than the distance to the earth's center, $\delta r \ll r$, since the thickness of the ocean and atmosphere are very small compared to the earth's radius. In this case, when $\phi \neq 0$, then $\delta r_\perp$ is affected much more by meridional motion at constant radial position (second term on right hand side of equation (14.39)) than by vertical motion at constant latitude (first term on right hand side of equation (14.39)). We return to this observation in Section 14.7.9 when discussing the shallow fluid approximation used to develop the primitive equations for the atmosphere and ocean (Section 28.1.2).

14.7.3 Axial angular momentum conservation and Coriolis acceleration

Consider a particle at rest in the rotating frame so that its axial angular momentum equals to that arising from the rigid-body motion of the planet, $l^z = r_\perp^2\,\Omega$. If we perturb this initial state while conserving axial angular momentum, equation (14.37) says there must be an associated change in the zonal velocity given by

$$\delta\dot{\lambda} = -2\,\Omega\,\frac{\delta r_\perp}{r_\perp} \quad \text{and} \quad \delta u = -2\,\Omega\,\delta r_\perp. \tag{14.41}$$

If the perturbation occurs over a time increment, δt, then we have

$$\delta\dot{\lambda}/\delta t = \ddot{\lambda} = -2\,\Omega\,\frac{\delta r_\perp/\delta t}{r_\perp} = -2\,\Omega\,(w\cos\phi - v\sin\phi)/r_\perp \tag{14.42a}$$

$$\delta u/\delta t = \dot{u} = -2\,\Omega\,(\delta r_\perp/\delta t) = -2\,\Omega\,(w\cos\phi - v\sin\phi), \tag{14.42b}$$

where we used equation (14.39) for $\delta r_\perp/\delta t$. The expression for $\dot{u}$ is precisely the same as the Coriolis acceleration appearing in the zonal momentum equation (13.140a)

$$\dot{u} + \frac{u\,(w - v\tan\phi)}{r} = \underbrace{-2\,\Omega\,(w\cos\phi - v\sin\phi)}_{\text{Coriolis acceleration}}. \tag{14.43}$$

We thus find that the Coriolis acceleration appearing in the zonal momentum equation is identical to the zonal acceleration induced by constraining the motion to conserve axial angular momentum. That is, by unpacking the constraint of axial angular momentum conservation to reveal the zonal momentum equation, the Coriolis acceleration is revealed to be part of the package. Furthermore, we see that both vertical and meridional motion lead to zonal accelerations through the Coriolis acceleration or, equivalently, through axial angular momentum conservation.

14.7.4 Deriving $\dot{u}$ from $\mathrm{d}L^z/\mathrm{d}t = 0$

The discussion in Section 14.7.3 can be formalized by analyzing how the conservation of axial angular momentum leads to an expression for the zonal acceleration, $\dot{u}$. For this purpose, compute the time derivative of the first form of the axial angular momentum in equation (14.32), in which case

$$\frac{\mathrm{d}l^z}{\mathrm{d}t} = \frac{\mathrm{d}[(r\cos\phi)^2\,(\dot{\lambda} + \Omega)]}{\mathrm{d}t} \tag{14.44a}$$

$$= 2\,(\dot{r}\cos\phi - r\,\dot{\phi}\sin\phi)\,(\dot{\lambda}\,r\cos\phi + r\,\Omega\cos\phi) + (r\cos\phi)^2\,\ddot{\lambda} \tag{14.44b}$$

$$= 2\,(w\cos\phi - v\sin\phi)\,(u + r\,\Omega\cos\phi) + (r\cos\phi)^2\,\ddot{\lambda}, \tag{14.44c}$$

where we introduced the (u, v, w) velocity components according to equation (13.48). With the zonal velocity $u = \dot{\lambda}\, r_\perp = \dot{\lambda}\, r \cos\phi$, we have

$$r \cos\phi\, \ddot{\lambda} = \dot{u} + \frac{u}{r\cos\phi}\left(v \sin\phi - w\cos\phi\right), \tag{14.45}$$

so that equation (14.44c) takes the form

$$\frac{\mathrm{d}l^z}{\mathrm{d}t} = 2\left(w\cos\phi - v\sin\phi\right)\left(u + r\,\Omega\cos\phi\right) + \left(r\cos\phi\right)^2 \ddot{\lambda} \tag{14.46a}$$

$$= \left(w\cos\phi - v\sin\phi\right)\left(u + 2\,r\,\Omega\cos\phi\right) + \dot{u}\, r\cos\phi. \tag{14.46b}$$

Setting $\mathrm{d}l^z/\mathrm{d}t = 0$ and rearranging then leads to a prognostic equation for the zonal velocity

$$\frac{\mathrm{d}u}{\mathrm{d}t} = \left[\frac{u}{r\cos\phi} + 2\,\Omega\right]\left(v\sin\phi - w\cos\phi\right). \tag{14.47}$$

The first term in the bracket arises from curvature of the sphere (the "metric acceleration") whereas the second term is the Coriolis acceleration.

The same result can be obtained by performing the time derivative on the second form of the axial angular momentum in equation (14.32), in which case

$$\frac{\mathrm{d}l^z}{\mathrm{d}t} = \frac{\mathrm{d}\left[u\,r\,\cos\phi + \Omega\left(r\,\cos\phi\right)^2\right]}{\mathrm{d}t} \tag{14.48a}$$

$$= \dot{u}\,r\,\cos\phi + u\,\dot{r}\,\cos\phi - u\,r\,\dot{\phi}\,\sin\phi + 2\,\Omega\,r\,\cos\phi\left(\dot{r}\,\cos\phi - r\,\dot{\phi}\,\sin\phi\right). \tag{14.48b}$$

Again, setting $\mathrm{d}l^z/\mathrm{d}t = 0$ and rearranging leads to the zonal acceleration (14.47).

14.7.5 Zonal acceleration induced by meridional motion

We now consider a few thought experiments to help understand how axial angular momentum conservation gives rise to the Coriolis acceleration appearing in the zonal momentum equation. Start by considering a particle moving meridionally ($\delta\phi \neq 0$) while maintaining a constant radial position ($\delta r = 0$). The axial angular momentum constraint (14.42b) induces a zonal acceleration

$$\dot{u} = 2\,\Omega\, v \sin\phi, \tag{14.49}$$

which, as seen by equation (14.43), is the Coriolis acceleration appearing in the zonal momentum equation arising from the meridional motion. For poleward motion in either hemisphere, the product $v\sin\phi$ is always positive.[5] Hence, axial angular momentum conserving motion towards either pole induces an eastward acceleration, whereas a westward acceleration is induced for equatorward motion. For the northern hemisphere, the induced acceleration deflects the particle to the right when looking downstream whereas in the southern hemisphere the induced acceleration deflects the particle to the left. These deflections are illustrated in Figure 14.5.

A rudimentary means to understand the deflections arising from meridional motion is to view a particle trajectory from an inertial reference frame off the planet. For a meridional trajectory, the spinning earth causes the trajectory to pick up zonal motion relative to the earth surface, zonally to the right in the northern hemisphere and zonally to the left in the southern hemisphere. Equivalently, consider a projectile starting from rest on the planet and shot poleward. Since the projectile started closer to the equator, it has a zonal velocity component that is larger than

[5] Recall from Figure 10.1 that $\sin\phi \leq 0$ in the Southern Hemisphere, where $-\pi/2 \leq \phi \leq 0$. In contrast, $\sin\phi \geq 0$ in the Northern Hemisphere, where $0 \leq \phi \leq \pi/2$.

the more poleward ground underneath it as it flies away from the equator. Hence, as it moves poleward it also picks up an eastward velocity component, which is to the right of the poleward motion in the northern hemisphere and to the left in the southern.

14.7.6 Zonal acceleration induced by radial (vertical) motion

Now consider a particle moving radially while holding the latitude fixed ($\delta r \neq 0$ and $\delta\phi = 0$). The axial angular momentum constraint (14.42b) induces a zonal acceleration

$$\dot{u} = -2\,\Omega\, w \cos\phi, \tag{14.50}$$

which, as seen by equation (14.43), is the Coriolis acceleration appearing in the zonal momentum equation arising from the vertical motion. Hence, for vertically downward motion ($w < 0$), axial angular momentum conservation induces a positive zonal acceleration, $\dot{u} > 0$, which we expect from axial angular momentum conservation since the particle is moving closer to the rotation axis.

14.7.7 Meridional acceleration from Coriolis

We showed in Section 14.7.4 that the zonal equation of motion determining $\dot{u}$ is another way of writing the conservation of axial angular momentum. The same, however, cannot be said for the meridional equation of motion, which is given by equation (13.140b)

$$\dot{v} + \frac{v\,w + u^2 \tan\phi}{r} = -2\,\Omega\, u \sin\phi. \tag{14.51}$$

The Coriolis acceleration is on the right hand side. In the northern hemisphere ($\sin\phi > 0$), the Coriolis acceleration gives rise to a rightward (equatorward) acceleration, $-2\,\Omega\, u \sin\phi < 0$, when the particle is moving eastward, $u > 0$, thus inducing a negative meridional acceleration, $\dot{v} < 0$. Conversely, if the particle is moving to the west so that $u < 0$, then the Coriolis acceleration is again to the right, only this time it provides a poleward acceleration, $\dot{v} > 0$. The analogous considerations hold in the southern hemisphere where the particle is deflected to the left by the Coriolis acceleration. These motions are reflected in Figure 14.5. Once the particle picks up a meridional component to the motion, then we return to the axial angular momentum constraint (14.42b) to see how zonal flow is affected.

14.7.8 Vertical acceleration from Coriolis

As for the meridional Coriolis acceleration in Section 14.7.7 there is no angular momentum constraint that connects to the Coriolis acceleration appearing in the vertical velocity equation (13.140c)

$$\dot{w} - \frac{u^2 + v^2}{r} = 2\,\Omega\, u \cos\phi - g. \tag{14.52}$$

In both hemispheres the cosine factor is positive, $\cos\phi > 0$. Hence, the Coriolis acceleration is positive (upward) for eastward motion and negative (downward) for westward motion. Note that for typical geophysical motion, the Coriolis acceleration is tiny compared to that arising from gravity.

14.7.9 When lateral motions dominate vertical motions

We here consider two approximations relevant to large scale geophysical fluid motions.

1. The particle kinetic energy is dominated by lateral motions on the sphere (i.e., motion at constant radial position).

2. Vertical (radial) excursions are much smaller than the earth radius.

When applied to a fluid, the first assumption leads to the hydrostatic approximation (Section 28.2), and the second assumption leads to the shallow fluid approximation (Section 28.1.2). Self-consistency of the equations of motion means that these two assumptions must be applied together.

Dropping the vertical velocity component to the kinetic energy leads to

$$K \approx \frac{m}{2}\left[(u + r_\perp\,\Omega)^2 + v^2\right]. \tag{14.53}$$

The second assumption means that the axial angular momentum takes the approximate form

$$L^z \approx m\,R_\perp\,(u + \Omega\,R_\perp) = m\,R_\perp^2\,(\dot{\lambda} + \Omega), \tag{14.54}$$

where

$$r = R + z \approx R \qquad \text{and} \qquad R_\perp = R\cos\phi. \tag{14.55}$$

The approximate angular momentum (14.54) ignores contributions from vertical motion in changing the moment-arm. Indeed, as noted in Section 14.7.2, vertical movements within the atmosphere and ocean (relatively thin fluid layers over the earth's surface) lead to a relatively small modification to the moment-arm, so the assumption that $r_\perp \approx R\cos\phi$ is reasonable. With $r \approx R$, the zonal acceleration (14.47) is modified to the form

$$\frac{\mathrm{d}u}{\mathrm{d}t} = v\left[\frac{u\tan\phi}{R} + f\right] \qquad \text{where} \qquad f = 2\,\Omega\,\sin\phi. \tag{14.56}$$

That is, we dropped the vertical velocity component, w, from the general form of the acceleration (14.47). Correspondingly, the meridional momentum equation takes the form

$$\frac{\mathrm{d}v}{\mathrm{d}t} = -u\left[\frac{u\tan\phi}{R} + f\right]. \tag{14.57}$$

These approximate forms for the zonal and meridional accelerations appear in the primitive equations developed in Section 28.1.

14.7.10 Comments

A concise summary of many features of rotating physics is provided by this video from SciencePrimer.

14.8 Mechanical energy conservation

Does the particle know anything about the origin of time? Since the angular velocity of the planet and the gravitational acceleration are both assumed constant in time, then shifting the time by an arbitrary constant will leave the physical system unaltered. That is, the physical system remains unchanged if we shift all clocks by a constant amount. Through Noether's theorem, this symmetry in time leads to mechanical energy conservation, which means that the particle's mechanical energy is a fixed constant. We here prove that mechanical energy is constant in time by manipulating the equations of motion. Many of the manipulations also occur when considering the mechanical energy conservation laws for a continuum fluid discussed in Chapter 25.

14.8.1 Some properties of kinetic energy

In this subsection we establish some basic properties of kinetic energy for a particle. As we saw in Section 11.1.4, changes in the kinetic energy of a particle equal to the *mechanical work* done on the particle as it moves along its trajectory

$$K(t_2) - K(t_1) = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{x} = \int_{t_1}^{t_2} \boldsymbol{F} \cdot \boldsymbol{V}\, \mathrm{d}t, \tag{14.58}$$

where $\boldsymbol{V}\,\mathrm{d}t = \mathrm{d}\boldsymbol{x}$ defines the vector increment along the trajectory, and $\boldsymbol{x}_{1,2}$ are the endpoints of the trajectory at times $t_{1,2}$. The integrand, $\boldsymbol{F} \cdot \boldsymbol{V}$, is known as the *power*. Hence, equation (14.58) says that the time integral of the power equals to the difference in kinetic energy between the final and initial times.

The kinetic energy is *not* Galilean invariant since movement to another inertial reference frame leads to the kinetic energy change

$$\overline{\boldsymbol{V}} = \boldsymbol{V} + \boldsymbol{U} \Longrightarrow \overline{K} = K + \frac{m}{2}\,(2\,\boldsymbol{V} \cdot \boldsymbol{U} + \boldsymbol{U} \cdot \boldsymbol{U}), \tag{14.59}$$

where $\boldsymbol{U}$ is a constant boost velocity so that $\mathrm{d}\boldsymbol{U}/\mathrm{d}t = 0$. We do not expect kinetic energy to be Galilean invariant since kinetic energy measures energy of motion relative to a chosen reference frame. Even so, the time change of the kinetic energy in a different inertial frame is given by the power in the new frame

$$\frac{\mathrm{d}\overline{K}}{\mathrm{d}t} = \frac{\mathrm{d}K}{\mathrm{d}t} + m\,\boldsymbol{A} \cdot \boldsymbol{U} = \boldsymbol{F} \cdot \boldsymbol{V} + \boldsymbol{F} \cdot \boldsymbol{U} = \boldsymbol{F} \cdot \overline{\boldsymbol{V}}. \tag{14.60}$$

Hence, we can directly connect kinetic energy changes to forces within an arbitrary inertial reference frame.

Cartesian expression for kinetic energy

Consider the expression for kinetic energy when introducing the velocity of the rotating reference frame. Writing the inertial frame velocity in the planetary Cartesian form

$$\boldsymbol{V} = \boldsymbol{V}_{\text{Cartesian}} + \boldsymbol{U}_{\text{rigid}}, \tag{14.61}$$

leads to

$$K = \frac{m}{2}\,[\boldsymbol{V}_{\text{Cartesian}} \cdot \boldsymbol{V}_{\text{Cartesian}} + 2\,\boldsymbol{V}_{\text{Cartesian}} \cdot \boldsymbol{U}_{\text{rigid}} + \boldsymbol{U}_{\text{rigid}} \cdot \boldsymbol{U}_{\text{rigid}}] \tag{14.62}$$

The first term arises from motion of the particle relative to the rotating sphere; the second arises from coupling between relative velocity and rigid-body velocity; and the third arises from rigid-body motion of the sphere.

Spherical expression for kinetic energy: Part I

To expose spherical symmetry of the physical system, we express the kinetic energy in terms of the planetary spherical coordinates defined in Figure 10.1. Doing so for the rigid-body velocity leads to equation (13.50)

$$\boldsymbol{U}_{\text{rigid}} = \Omega\, r \cos\phi\, (-\sin\lambda\, \hat{\boldsymbol{x}} + \cos\lambda\, \hat{\boldsymbol{y}})\,. \tag{14.63}$$

Likewise, the velocity components measured in the rotating frame are given by

$$\dot{X} = \frac{\mathrm{d}\,(r\cos\phi\cos\lambda)}{\mathrm{d}t} = \dot{r}\,\cos\phi\,\cos\lambda - r\dot{\phi}\,\sin\phi\,\cos\lambda - r\dot{\lambda}\,\cos\phi\,\sin\lambda \tag{14.64a}$$

$$\dot{Y} = \frac{\mathrm{d}\,(r\cos\phi\sin\lambda)}{\mathrm{d}t} = \dot{r}\,\cos\phi\,\sin\lambda - r\dot{\phi}\,\sin\phi\,\sin\lambda + r\dot{\lambda}\,\cos\phi\,\cos\lambda \tag{14.64b}$$

$$\dot{Z} = \frac{\mathrm{d}\,(r\sin\phi)}{\mathrm{d}t} = \dot{r}\,\sin\phi + r\dot{\phi}\,\cos\phi. \tag{14.64c}$$

Bringing terms together then leads to the kinetic energy in terms of spherical coordinates

$$K = \frac{m}{2}\left[(\dot{r}^2 + r^2\dot{\phi}^2 + \dot{\lambda}^2\,r^2\cos^2\phi) + (2\,\Omega\,r^2\dot{\lambda}\,\cos^2\phi) + (\Omega\,r\,\cos\phi)^2\right]. \tag{14.65}$$

Spherical expression for kinetic energy: Part II

An alternative means for deriving the kinetic energy in equation (14.65) makes use of the spherical coordinate form of the inertial frame velocity given by equation (13.46f), in which case

$$\boldsymbol{V} = (u + r_\perp\,\Omega)\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}}, \tag{14.66}$$

so that

$$K = \frac{m}{2}\left[(u + r_\perp\,\Omega)^2 + v^2 + w^2\right], \tag{14.67}$$

where $r_\perp = r\cos\phi$. Additionally, as discussed in Section 14.6, the axial angular momentum is given by

$$L^z = m\,r_\perp\,(u + r_\perp\,\Omega) \equiv m\,l^z, \tag{14.68}$$

and this property is a constant of the motion when there is azimuthal (zonal) symmetry. It is thus convenient to write the kinetic energy as

$$K = \frac{m}{2}\left[(l^z/r_\perp)^2 + v^2 + w^2\right]. \tag{14.69}$$

Geopotential expression for mechanical energy

As seen in Section 14.8.4 below, the mechanical energy using geopotential coordinates takes on the form

$$M_{\mathrm{geop}} = \frac{m}{2}\left[u^2 + v^2 + w^2 + 2\,g\,r\right], \tag{14.70}$$

where each of these symbols takes on their geopotential interpretation.

14.8.2 Planetary Cartesian mechanical energy

The time derivative of the kinetic energy is given by

$$\frac{\mathrm{d}K}{\mathrm{d}t} = m\,\boldsymbol{V}\cdot\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} = m\,\boldsymbol{V}\cdot\boldsymbol{A} = -m\,\boldsymbol{V}\cdot\nabla\Phi_{\mathrm{e}}. \tag{14.71}$$

For the final equality we introduced the gravitational potential given that the particle only feels an external force from gravity as per equation (13.125). The gravitational potential is given by (see equation (13.119))

$$\Phi_{\mathrm{e}} = g_{\mathrm{e}}\,r, \tag{14.72}$$

so that

$$\frac{\mathrm{d}K}{\mathrm{d}t} = -m\,\boldsymbol{V}\cdot\nabla\Phi_{\mathrm{e}} = -m\,g_{\mathrm{e}}\,\dot{r}. \tag{14.73}$$

This result means that kinetic energy is reduced when moving the particle away from the earth center ($\dot{r} > 0$). Moving away from the earth requires work to overcome the gravitational acceleration pointing towards the earth. This work to overcome the gravitational attraction is taken away from the kinetic energy of the particle. Furthermore, the work is added to the gravitational potential energy, whose evolution is given by (see equation (13.121))

$$\frac{\mathrm{d}P_{\mathrm{e}}}{\mathrm{d}t} = m\,g_{\mathrm{e}}\,\dot{r}, \tag{14.74}$$

where we assumed a constant gravitational acceleration g_{e}. Consequently, as the particle moves away from the earth center, its reduction in kinetic energy is exactly compensated by an increase in potential energy. Hence, the mechanical energy for the particle remains constant throughout the motion

$$\frac{\mathrm{d}(K+P_{\mathrm{e}})}{\mathrm{d}t} = 0, \tag{14.75}$$

where the mechanical energy is the sum of the inertial frame kinetic energy plus the gravitational potential energy

$$M = K + P_{\mathrm{e}} \tag{14.76a}$$

$$= \frac{m}{2}\,\boldsymbol{V}\cdot\boldsymbol{V} + m\,\Phi_{\mathrm{e}} \tag{14.76b}$$

$$= \frac{m}{2}\left[(u + r_{\perp}\,\Omega)^2 + v^2 + w^2\right] + m\,g_{\mathrm{e}}\,r \tag{14.76c}$$

$$= \frac{m}{2}\left[(l^z/r_{\perp})^2 + v^2 + w^2\right] + m\,g_{\mathrm{e}}\,r. \tag{14.76d}$$

14.8.3 Planetary spherical mechanical energy

It is physically revealing to expose the exchange of mechanical energy between kinetic and gravitational potential energies. Furthermore, knowledge of the total mechanical energy at any time affords knowledge for all time since the mechanical energy (in the absence of dissipation) remains constant. Following from the discussion in Section 14.7, where we examined the constraints on particle motion due to conservation of axial angular momentum, we here ask similar questions about mechanical energy conservation. We make use of the spherical form of the equations of motion, equations (13.134)-(13.136), which expose the planetary centrifugal and Coriolis accelerations, and pursue the calculation for geopotential coordinates in Section 14.8.4.

We find it convenient to write the momentum equations (13.134)-(13.136) in terms of the distance to the polar axis, $r_{\perp} = r\cos\phi$, and its time derivative, $\dot{r}_{\perp} = w\cos\phi - v\sin\phi$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[r_{\perp}\,u + \Omega\,r_{\perp}^2\right] = 0 \tag{14.77a}$$

$$\dot{v} = -\frac{v\,w}{r} - \frac{u\tan\phi}{r}\,(u + 2\,\Omega\,r_{\perp}) - r_{\perp}\,\Omega^2\sin\phi \tag{14.77b}$$

$$\dot{w} = \frac{u^2+v^2}{r} + 2\,\Omega\,u\,\cos\phi + r_{\perp}\,\Omega^2\cos\phi - g_{\mathrm{e}}. \tag{14.77c}$$

Equation (14.77a) expresses the conservation of axial angular momentum, $\dot{l}^z = 0$, where the axial angular momentum per mass is $l^z = r_{\perp}\,(u + r_{\perp}\,\Omega)$ (Section 14.6). For the mechanical energy, we

have

$$\dot{M} = 0 \qquad \text{with} \qquad M = \frac{m}{2}\left[(l^z/r_\perp)^2 + v^2 + w^2\right] + m\, g_{\rm e}\, r, \tag{14.78}$$

where $l^z/r_\perp = u + r_\perp\,\Omega$ is the zonal component to the inertial frame velocity (equation (13.46f)). We now show that $\dot{M} = 0$ arises from the momentum equations. Performing the time derivative, and setting $\mathrm{d}l^z/\mathrm{d}t = 0$, leads to

$$\frac{1}{m}\,\dot{M} = \frac{1}{2}\,\frac{\mathrm{d}}{\mathrm{d}t}\left[(l^z/r_\perp)^2 + v^2 + w^2 + 2\,g_{\rm e}\,r\right] = -\frac{(l^z)^2\,\dot{r}_\perp}{(r_\perp)^3} + v\,\dot{v} + w\,(\dot{w} + g_{\rm e}). \tag{14.79}$$

Use of the meridional momentum equation (14.77b) renders

$$v\,\dot{v} = -v\left[\frac{v\,w}{r} + \frac{u\tan\phi}{r}\,(u + 2\,\Omega\,r_\perp) + r_\perp\,\Omega^2\sin\phi\right] \tag{14.80a}$$

$$= -\frac{v^2\,w}{r} - \frac{v\tan\phi}{r}\,(u + r_\perp\,\Omega)^2. \tag{14.80b}$$

Likewise, the vertical momentum equation (14.77c) renders

$$w\,(\dot{w} + g_{\rm e}) = \frac{v^2\,w}{r} + \frac{w}{r}\left[u^2 + 2\,\Omega\,u\,r_\perp + (r_\perp\,\Omega)^2\right] \tag{14.81a}$$

$$= \frac{v^2\,w}{r} + \frac{w}{r}\,(u + r_\perp\,\Omega)^2, \tag{14.81b}$$

so that

$$v\,\dot{v} + w\,(\dot{w} + g_{\rm e}) = r^{-1}\,(-v\tan\phi + w)\,(u + r_\perp\,\Omega)^2 = \frac{(l^z)^2\,\dot{r}_\perp}{(r_\perp)^3}. \tag{14.82}$$

Combining this result with equation (14.79) leads to the expected $\dot{M} = 0$, so that angular momentum conservation combined with the meridional and vertical momentum equations is equivalent to mechanical energy conservation.

14.8.4 Geopotential mechanical energy

Now consider the mechanical energy conservation when using geopotential coordinates with the equations of motion (13.140a)-(13.140c)

$$\dot{u} + \frac{u\,(w - v\tan\phi)}{r} + 2\,\Omega\,(w\cos\phi - v\sin\phi) = 0 \tag{14.83a}$$

$$\dot{v} + \frac{v\,w + u^2\tan\phi}{r} + 2\,\Omega\,u\sin\phi = 0 \tag{14.83b}$$

$$\dot{w} - \frac{u^2 + v^2}{r} - 2\,\Omega\,u\cos\phi = -g. \tag{14.83c}$$

Multiplying each equation by its respective velocity component and summing yields

$$\frac{1}{m}\,\dot{M}_{\rm geop} = \frac{1}{2}\,\frac{\mathrm{d}}{\mathrm{d}t}\left[u^2 + v^2 + w^2 + 2\,g\,r\right] = 0. \tag{14.84}$$

The conserved mechanical energy for the particle written in geopotential coordinates

$$M_{\rm geop} = m\,(u^2 + v^2 + w^2)/2 + m\,g\,r \tag{14.85}$$

is compared to that written using spherical coordinates in equation (14.78). We note that since the coordinates are different (spherical versus geopotential), the velocity components (u, v, w) are slightly different in the two coordinate systems, as is the radial position. So care is needed when comparing the two expressions.

14.9 Sample particle trajectories

Here we examine some trajectories to illustrate how the dynamical properties discussed in this chapter, particularly angular momentum conservation, help to determine trajectories. The discussion complements that considered in Exercise 13.9.

14.9.1 Free fall starting from rest in the inertial reference frame

Consider a particle freely falling to the center of the sphere starting with zero axial angular momentum. Although the trajectory from an inertial reference frame is rather trivial, we need to do a bit more work in the non-inertial rotating frame, where we make use of the spherical coordinate equations to write

$$\dot{\lambda} = -\Omega \quad \text{and} \quad u = -r_\perp\,\Omega \quad \text{and} \quad v = 0 \quad \text{and} \quad \dot{w} = -g_{\rm e}. \tag{14.86}$$

Evidently, the longitude, latitude, and vertical position are given by

$$(\lambda - \lambda_0) = -\Omega\, t \quad \text{and} \quad \phi = \phi_0 \quad \text{and} \quad (w - w_0) = -g_{\rm e}\, t, \tag{14.87}$$

where λ_0 is the initial longitude, ϕ_0 is the initial latitude, and w_0 the initial vertical velocity. So the position with respect to the earth's longitude adjusts westward according to $(\lambda - \lambda_0) = -\Omega\, t$, which is needed to maintain a fixed absolute longitude. Likewise, the vertical free fall with $(w - w_0) = -g_{\rm e}\, t$ accords with the free fall seen in the inertial reference frame. Integrating the vertical equation leads to the radial position

$$r - r_0 = w_0\, t - g_{\rm e}\, t^2/2. \tag{14.88}$$

If we drop the particle from rest, so that $w_0 = 0$, then the particle falls a distance H within a time

$$T = (2\, H/g_{\rm e})^{1/2}. \tag{14.89}$$

During this time the particle deflects its longitude to the west by an amount

$$\lambda - \lambda_0 = -\Omega\, T = -\Omega\, (2\, H/g_{\rm e})^{1/2}. \tag{14.90}$$

It is useful to check self-consistency by verifying that the rotating reference frame description measures a zero axial angular momentum throughout the free fall. We first do so by noting that $l^z = r_\perp^2\, (\dot{\lambda} + \Omega) = 0$ since $\dot{\lambda} = -\Omega$. Taking the time derivative leads to

$$\dot{l}^z = r\, r_\perp\, \dot{r}_\perp\, (\Omega + \dot{\lambda}) + r_\perp^2\, \ddot{\lambda} = 0, \tag{14.91}$$

since $\dot{\lambda} = -\Omega$ and so $\ddot{\lambda} = 0$. Furthermore, we can write $l^z = r_\perp\, (u + r_\perp\, \Omega) = 0$, which also means that

$$\dot{l}^z = \dot{r}_\perp\, (u + r_\perp\, \Omega) + r_\perp\, (\dot{u} + \dot{r}_\perp\, \Omega) = 0, \tag{14.92}$$

where we noted that $u = -r_\perp\, \Omega$ means that $\dot{u} = -\dot{r}_\perp\, \Omega$.

14.9.2 Falling with $\dot{u} = 0$

Now consider a trajectory that maintains a constant zonal velocity, $\dot{u} = 0$, which, with $u = r_\perp \dot{\lambda}$, means that

$$\dot{u} = \dot{r}_\perp \dot{\lambda} + r_\perp \ddot{\lambda} = 0. \tag{14.93}$$

To maintain a constant axial angular momentum means

$$\dot{l}^z = 2\, r_\perp \dot{r}_\perp (\dot{\lambda} + \Omega) + r_\perp^2 \ddot{\lambda} = r_\perp \dot{r}_\perp (\dot{\lambda} + 2\,\Omega), \tag{14.94}$$

where the second step made use of the assumed $\dot{u} = 0$ condition from equation (14.93). Equation (14.94) can be satisfied by either $\dot{r}_\perp = 0$ or $\dot{\lambda} = -2\,\Omega$. Yet setting one of these conditions means that the other must also hold in order to maintain $\dot{u} = 0$ from equation (14.93). We are thus led to

$$\dot{u} = 0 \quad \text{and} \quad \dot{l}^z = 0 \Longleftrightarrow \dot{\lambda} = -2\,\Omega \quad \text{and} \quad \dot{r}_\perp = 0 \quad \text{and} \quad l^z = -\Omega\, r_\perp^2. \tag{14.95}$$

Evidently, a particle moving westward with $\dot{\lambda} = -2\,\Omega$, and maintaining a fixed distance from the polar rotation axis, maintains both constant axial angular momentum and a constant zonal velocity

$$u = -2\,\Omega\, r_\perp. \tag{14.96}$$

Furthermore, observe that a constant distance from the rotation axis, $\dot{r}_\perp = 0$, means that

$$\dot{r}_\perp = 0 \Longrightarrow w \cos\phi = v \sin\phi. \tag{14.97}$$

This relation couples vertical and meridional motion in the rotating reference frame in a manner that keeps the distance to the rotational axis fixed. For example, the vertical velocity vanishes at the equator. Additionally, if the particle is falling so that $w \cos\phi < 0$, then there is an equatorward meridional velocity to keep the distance from the rotational axis fixed. In this manner, the particle is falling not towards the earth center but instead towards the equatorial plane, all while maintaining a fixed zonal velocity with $\dot{u} = 0$.

To garner further insight into the trajectory, we examine the meridional and vertical accelerations. For this purpose, recall the meridional equation of motion (13.135), written as

$$r\, \dot{v} + v\, w + u^2 \tan\phi + \Omega\, r \sin\phi\, (2\, u + r_\perp\, \Omega) = 0. \tag{14.98}$$

Now multiply by $\cos\phi$ and set $w \cos\phi = v \sin\phi$ to reach

$$r_\perp\, \dot{v} + (u^2 + v^2) \sin\phi + \Omega\, r_\perp \sin\phi\, (2\, u + r_\perp\, \Omega) = 0. \tag{14.99}$$

Next set $u = -2\, r_\perp\, \Omega$ to have

$$r_\perp\, \dot{v} + [(\Omega\, r_\perp)^2 + v^2] \sin\phi = 0, \tag{14.100}$$

which, when setting $l^z / r_\perp = -\Omega\, r_\perp$, leads to the meridional acceleration

$$r_\perp\, \dot{v} = -[(l^z / r_\perp)^2 + v^2] \sin\phi. \tag{14.101}$$

Evidently, the meridional acceleration is negative in the northern hemisphere (where $\sin\phi > 0$) and positive in the southern, so that the particle always accelerates toward the equator. Similarly, use of the vertical acceleration from equation (13.136) leads to

$$r\, (\dot{w} + g_{\mathrm{e}}) = u^2 + v^2 + r_\perp\, \Omega\, u + (r_\perp\, \Omega)^2 = v^2 + (r_\perp\, \Omega)^2 = v^2 + (l^z / r_\perp)^2 > 0. \tag{14.102}$$

Hence, the vertical acceleration ($\dot{w} < 0$) is always smaller in magnitude than the earth's gravitational acceleration. Finally, combining the conditions (14.101) and (14.102) means that the meridional and vertical accelerations are related by

$$\dot{v}\cos\phi + (\dot{w} + g_{\mathrm{e}})\sin\phi = 0. \tag{14.103}$$

So when the particle reaches the equator at $\phi = 0$, we know from equation (14.97) that the vertical velocity vanishes, and from equation (14.103) we see that the merdional acceleration also vanishes. In contrast, at the poles where $\phi = \pm\pi/2$, the vertical acceleration is $\dot{w} = -g_{\mathrm{e}}$ whereas equation (14.97) says that the meridional velocity vanishes.

14.9.3 Free fall from rest in the rotating frame

We here consider the case of a particle initially at rest in the rotating reference frame that is allowed to freely fall. As in Exercise 13.9b, we make use of geopotential coordinates since the particle will initially fall parallel to the effective gravity direction; i.e., the *plumb line*. We consider the trajectory just in the zonal and vertical plane, assuming $v = 0$ throughout the free fall. Setting $v = \dot{v} = 0$ in the geopotential coordinate equations of motion (13.140a) and (13.140c) yields

$$\dot{u} + \frac{u\,w}{r} + 2\,\Omega\,w\cos\phi = 0 \tag{14.104a}$$

$$\dot{w} - \frac{u^2}{r} - 2\,\Omega\,u\cos\phi = -g. \tag{14.104b}$$

We now linearize by dropping the uw/r and u^2/r terms to render

$$\dot{u} = -2\,\Omega\,w\cos\phi \quad \text{and} \quad \dot{w} = 2\,\Omega\,u\cos\phi - g. \tag{14.105}$$

Now write $w = w_0 + w_1$, where

$$\dot{w}_0 = -g \quad \text{and} \quad \dot{w}_1 = 2\,\Omega\,u\cos\phi, \tag{14.106}$$

so that $w_0 = -g\,t$. To first order in Ω, the zonal velocity satisfies

$$\dot{u} = 2\,\Omega\,g\,t\,\cos\phi \Longrightarrow u = \Omega\,g\,t^2\cos\phi. \tag{14.107}$$

We are thus left with the free fall particle velocity that is valid to first order in Ω

$$\boldsymbol{V} = (\Omega\,g\,t^2\cos\phi)\,\hat{\boldsymbol{\lambda}} - g\,t\,\hat{\boldsymbol{r}}. \tag{14.108}$$

The eastward velocity component arises from the need for the particle to conserve axial angular momentum as it falls closer to the polar axis.

Time integrating the velocity equation (14.108) leads to the particle trajectory

$$\boldsymbol{X} = (1/3)\,(\Omega\,g\,t^3\cos\phi)\,\hat{\boldsymbol{\lambda}} - (g\,t^2/2)\,\hat{\boldsymbol{r}} + \boldsymbol{X}_0, \tag{14.109}$$

where $\boldsymbol{X}_0$ is an arbitrary initial position. The time it takes for the particle to fall a vertical distance H is given by

$$T = (2\,H/g)^{1/2}, \tag{14.110}$$

and within this time interval the particle is deflected eastward by a distance

$$D = (1/3)\,(\Omega\,g\,\cos\phi)\,(2\,H/g)^{3/2}. \tag{14.111}$$

14.10 Dynamical constraints from spatial symmetries

We close this chapter by summarizing the conservation laws that arise from spatial symmetries. These conservation laws complement the discussion in Section 14.8 for mechanical energy conservation arising from time symmetry.

14.10.1 Linear momentum conservation

As seen in Section 11.1.2, linear momentum remains constant for a particle moving without any forces acting on it; i.e., a *free particle*. This type of motion is not common for geophysical particles or fluids since they feel gravity and so are not free. Even so, we consider this limiting case as a point of comparison for the other conservation laws.

The conservation of linear momentum is simply viewed within the particle's inertial reference frame, where a vanishing inertial frame acceleration leads to a constant inertial frame velocity

$$\boldsymbol{A} = \mathrm{d}\boldsymbol{V}/\mathrm{d}t = 0. \tag{14.112}$$

In a Euclidean space, a vanishing acceleration means the particle is moving in a straight line with constant velocity.[6] When viewed from a rotating frame using Cartesian coordinates, a vanishing inertial frame acceleration means that the Cartesian acceleration balances Coriolis and centrifugal accelerations

$$\ddot{\boldsymbol{X}} = -2\,\boldsymbol{\Omega} \times \dot{\boldsymbol{X}} - \nabla\Phi_{\text{centrifugal}}. \tag{14.113}$$

This equation is clearly not a very useful means to describe unaccelerated free particle motion. We can provide a bit more compactness to this equation by introducing the potential momentum (14.7) so that

$$\mathrm{d}\boldsymbol{M}/\mathrm{d}t = -\nabla\Phi_{\text{centrifugal}}. \tag{14.114}$$

While the inertial frame acceleration vanishes ($\boldsymbol{A} = \mathrm{d}\boldsymbol{V}/\mathrm{d}t = 0$), time changes to the potential momentum are balanced by the gradient of the centrifugal potential.

14.10.2 Potential momentum conservation

Conservation of potential momentum arises from symmetry of particle motion on a constant geopotential surface. The conservation law is most readily viewed within the rotating frame, whereby equation (14.9) is given by

$$\frac{\mathrm{d}(\hat{\boldsymbol{s}} \cdot \boldsymbol{M})}{\mathrm{d}t} = 0. \tag{14.115}$$

A geopotential is a two-dimensional surface so that this conservation law corresponds to two dynamical constraints such as shown in Figure 14.1.

14.10.3 Angular momentum conservation

As detailed in Section 14.6, the angular momentum computed with respect to the axis of rotation is a constant of the motion (Figure 14.3). This conservation law arises from symmetry of the system about the rotational axis. Axial (z-axis) angular momentum conservation takes the form

$$\mathrm{d}L^z/\mathrm{d}t = 0, \tag{14.116}$$

[6] Recall that a zero acceleration as in equation (14.112) is an expression of Newton's first law, which was stated in the start of Chapter 11.

where the axial angular momentum is

$$L^z = m\, r_\perp^2\, (\dot{\lambda} + \Omega) \qquad \text{with} \qquad r_\perp = \sqrt{x^2 + y^2} = r \cos\phi. \tag{14.117}$$

The distance from the rotation axis, $r_\perp$, is the *moment arm* for the axial angular momentum. The longitude, λ, measures the angle in the counter-clockwise direction from the positive x-axis, and $\dot{\lambda}$ is the time change of the longitude.

14.11 Exercises

EXERCISE 14.1: NEGATIVE AXIAL ANGULAR MOMENTUM

In Section 14.7 we assume the axial angular momentum is positive, which is geophysically the common situation since axial angular momentum from the rigid-body motion is so large relative to motion of geophysical fluids. But let us consider the uncommon case where the particle moves zonally westward at a speed greater than the planetary rotation speed so that

$$\dot{\lambda} + \Omega < 0 \Longleftrightarrow u + \Omega\, r_\perp < 0, \tag{14.118}$$

which means the axial angular momentum per mass of the particle is negative

$$l^z = r_\perp\, (u + r_\perp\, \Omega) = -|l^z| < 0. \tag{14.119}$$

Throughout this exercise we seek answers based on conservation of axial angular momentum. When checking to see whether an answer agrees with common sense, be careful since motion of this sort is not commonly experienced by terrestrial observers. Correspondingly, it is useful to check answers by viewing the motion from the perspective of an inertial reference frame rather than the rotating terrestrial reference frame. For example, the particular case where $\dot{\lambda} = -\Omega$, in which case the particle has zero angular momentum, corresponds to a particle that is stationary in the inertial reference frame while the planet rotates underneath.

(A) Discuss what happens to $\delta\dot{\lambda}$ for the particle that is deflected poleward with constant radius while conserving axial angular momentum. Hint: consider the first form of equation (14.37).

(B) Discuss what happens to δu for the particle as it is deflected poleward with constant radius while conserving axial angular momentum. Separately discuss the three cases where

(i) $|l^z| = 0$
(ii) $|l^z| < \Omega\, r_\perp^2$.
(iii) $|l^z| > \Omega\, r_\perp^2$

Hint: consider the second form of equation (14.37).

(C) Is fluid particle motion with $u + \Omega\, r_\perp < 0$ relevant for the terrestrial atmosphere and ocean? Why? To help answer this question, what is $\Omega\, r_\perp$ for $\phi = \pi/4$ and $r = R_e$? Note, we already provided the result for the equator just after equation (14.34). Compare these speeds to that of a category 5 tropical cyclone (Google it).

EXERCISE 14.2: ANGULAR COMPONENTS TO ANGULAR MOMENTUM

In Section 14.6 we studied angular momentum relative to the center of the sphere, $\boldsymbol{L} = m\, \boldsymbol{X} \times \boldsymbol{V}$.

In particular, we considered the evolution equations for the planetary Cartesian compoents $\hat{\boldsymbol{x}} \cdot \boldsymbol{L}$, $\hat{\boldsymbol{y}} \cdot \boldsymbol{L}$, and $\hat{\boldsymbol{z}} \cdot \boldsymbol{L}$. Here we consider the projection of the angular momentum onto the planetary spherical directions $\hat{\boldsymbol{\lambda}}$ and $\hat{\boldsymbol{\phi}}$? For a space that is spherically symmetric around the center of the sphere, we do not expect $\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{L}$ or $\hat{\boldsymbol{\phi}} \cdot \boldsymbol{L}$ to be constants of the motion. The reason is that neither $\hat{\boldsymbol{\lambda}}$ nor $\hat{\boldsymbol{\phi}}$ extend outward from the center of the sphere, so that rotations around either of these axes do not manifest a symmetry operation. Nevertheless, it is interesting to explore properties of $\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{L}$ and $\hat{\boldsymbol{\phi}} \cdot \boldsymbol{L}$ as an exercise in the angular momentum formalism, and to display how their evolution relates to that of the linear momentum on the sphere.

(A) Write an expression for the zonal component to the angular momentum, $\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{L}$, in terms of $\dot{\phi}$ and r. Hint: check that the physical dimensions are correct, and that the sign accords with the right hand rule.

(B) Derive the time derivative, $\mathrm{d}(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{L})/\mathrm{d}t$, in terms of $\dot{\phi}$ and $\dot{r}$.

(C) Write an alternative expression for the time derivative, $\mathrm{d}(\hat{\boldsymbol{\lambda}} \cdot \boldsymbol{L})/\mathrm{d}t$, in terms $u = r_\perp \, \dot{\lambda}$ and Ω. Hint: recall the spherical coordinate version of the meridional momentum equation (13.135).

(D) Derive an expression for the meridional component to the angular momentum, $\hat{\boldsymbol{\phi}} \cdot \boldsymbol{L}$. Write the solution in terms of r, Ω, $\dot{\lambda}$, and ϕ.

(E) Derive an expression for the time derivative, $\mathrm{d}(\hat{\boldsymbol{\phi}} \cdot \boldsymbol{L})/\mathrm{d}t$.

Chapter 15

Case studies in analytical mechanics

The discussion in Chapter 12 certainly does support the name *analytical mechanics*, given that there is a nontrival degree of analysis needed to reformulate the laws of mechanics beyond their Newton's law expression. In this chapter, we work through some case studies for the purpose of illustrating the use of analytical mechanics for practical problems. These studies further exemplify and clarify the foundations of the theory while exploring geophysically interesting dynamical systems. It is through such examples that the power and elegance of analytical mechanics shines.

CHAPTER GUIDE

This chapter relies on the formulation of analytical mechanics from Chapter 12. We also make use of material from our study of particle mechanics around a rotating planet from Chapter 13.

15.1 Planar simple pendulum

Consider a planar simple pendulum as illustrated in Figure 15.1, where motion is restricted to the x-z plane. This pendulum consists of a point mass, m, attached to a massless string of fixed length, ℓ, oscillating around a fixed point within a constant gravity field with acceleration $-g\,\hat{\boldsymbol{z}}$. We derive the equations of motion for this system using both Newtonian mechanics and Lagrangian mechanics.

Before diving into the specifics of the simple pendulum, we note that it exemplifies the two key properties of any oscillatory system, including linear waves studied in Part IX of this book. The first property is a restoring force that kicks in when the system is displaced a small distance from its equilibrium. For the simple pendulum the restoring force is provided by the gravitational acceleration. The second property is inertia as that then allows the system to overshoot its equilibrium position, with mass providing the pendulum's inertia. The exchange between the restoring force and inertia lead to oscillations, and the natural oscillation frequencies are a function of the inertia and the restoring force.

15.1.1 Free particle motion using polar coordinates

Before addressing the simple pendulum, we find it useful to consider the equations for a free particle moving in the x-z plane without gravity and without any string. Cartesian coordinates provide the natural set of coordinates for describing this motion, in which the $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{z}}$ components to the Cartesian velocity velocity remain constant in space and time. We also consider polar coordinates, with the polar angle defined by φ as depicted in Figure 15.1, anticipating the motion of a simple pendulum using these coordinates. The coordinate transformation between Cartesian and polar is given by

$$x = r\sin\varphi \tag{15.1a}$$

$$z = -r\cos\varphi \tag{15.1b}$$

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}}\,\sin\varphi - \hat{\boldsymbol{z}}\cos\varphi \tag{15.1c}$$

$$\hat{\boldsymbol{\varphi}} = \hat{\boldsymbol{x}}\,\cos\varphi + \hat{\boldsymbol{z}}\sin\varphi. \tag{15.1d}$$

FIGURE 15.1: A simple pendulum is comprised of a point mass, m, attached to a massless string of fixed length, ℓ, with the string attached to a fixed point taken as the origin of a Cartesian coordinate system. The string makes an angle, φ, with respect to the vertical, and gravity points down with a constant acceleration, $-g\,\hat{\boldsymbol{z}}$. The force provided by the string on the particle, $\boldsymbol{T}$, points radially inward and balances the projection of the weight along the string plus the centrifugal acceleration due to motion of the particle. The point mass moves along the circumference of the circle. The string force is directed orthogonal to the motion so that it does no work on the point mass, and as such the string provides a force of constraint. The component of the weight directed along the circumference forces motion of the oscillator, with this force having magnitude $m\,g|\sin\varphi|$.

The Cartesian unit vectors are fixed in space, but the time derivatives of the polar unit vectors are

$$\dot{\hat{\boldsymbol{r}}} = \dot{\varphi}\,\hat{\boldsymbol{\varphi}} \quad \text{and} \quad \dot{\hat{\boldsymbol{\varphi}}} = -\dot{\varphi}\,\hat{\boldsymbol{r}}. \tag{15.2}$$

These results render the particle position, its velocity, and its acceleration

$$\boldsymbol{X} = r\,(\hat{\boldsymbol{x}}\,\sin\varphi - \hat{\boldsymbol{z}}\cos\varphi) = r\,\hat{\boldsymbol{r}} \tag{15.3a}$$

$$\dot{\boldsymbol{X}} = \dot{r}\,\hat{\boldsymbol{r}} + r\,\dot{\varphi}\,\hat{\boldsymbol{\varphi}} \tag{15.3b}$$

$$\ddot{\boldsymbol{X}} = (\ddot{r} - r\,\dot{\varphi}^2)\,\hat{\boldsymbol{r}} + (2\,\dot{r}\,\dot{\varphi} + r\,\ddot{\varphi})\,\hat{\boldsymbol{\varphi}}. \tag{15.3c}$$

Free particle motion has zero acceleration,

$$\ddot{x} = 0 \quad \text{and} \quad \ddot{z} = 0, \tag{15.4}$$

which means each Cartesian velocity component is a space and time constant. This trivial result has some nuance when written in polar coordinates

$$\ddot{r} - r\,\dot{\varphi}^2 = 0 \quad \text{and} \quad 2\,\dot{r}\,\dot{\varphi} + r\,\ddot{\varphi} = 0. \tag{15.5}$$

Of relevance to the pendulum, observe that forces are needed for both equations to maintain a fixed r.

Pursuing a Lagrangian mechanics approach, we compute the Euler-Lagrange equation (12.74) using (r, φ) as the two generalized coordinates. For the free particle, the Lagrangian equals to the kinetic energy

$$L = m\,(\dot{r}^2 + r^2\,\dot{\varphi}^2)/2, \tag{15.6}$$

so that the two Euler-Lagrange equations are

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{r}} = \frac{\partial L}{\partial r} \Longrightarrow \ddot{r} = r\,\dot{\varphi}^2 \tag{15.7a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{\varphi}} = \frac{\partial L}{\partial \varphi} \Longrightarrow \frac{\mathrm{d}\,(r^2\,\dot{\varphi})}{\mathrm{d}t} = 0. \tag{15.7b}$$

The radial equation says that the radial acceleration balances the centrifugal acceleration. The angular equation reflects the property of a Lagrangian that is independent of the generarlized coordinate, φ, so that its corresponding generalized momentum, the angular momentum computed relative to the origin, is a constant of the motion.

15.1.2 Newtonian mechanics of the simple pendulum

Now allow the particle to feel the constant gravitational field and the force by the string. Notably, the string force keeps the particle at a fixed distance, $r = \ell$, from the origin so that the particle motion only has a single degree of freedom. The position, velocity, and acceleration for the particle are thus given by

$$\boldsymbol{X} = \ell\,(\hat{\boldsymbol{x}}\sin\varphi - \hat{\boldsymbol{z}}\cos\varphi) = \ell\,\hat{\boldsymbol{r}} \tag{15.8a}$$

$$\dot{\boldsymbol{X}} = \ell\,\dot{\varphi}\,(\hat{\boldsymbol{x}}\cos\varphi + \hat{\boldsymbol{z}}\sin\varphi) = \ell\,\dot{\varphi}\,\hat{\boldsymbol{\varphi}} \tag{15.8b}$$

$$\ddot{\boldsymbol{X}} = \ell\,\ddot{\varphi}\,\hat{\boldsymbol{\varphi}} - \ell\,\dot{\varphi}^2\,\hat{\boldsymbol{r}}, \tag{15.8c}$$

with polar coordinates now ideally suited to the physical system. The force provided by the string points radially inward and it must be sufficient to exactly balance the projection of the particle weight along the string direction, plus the centrifugal acceleration of the particle as it oscillates along the circumference of the circle

$$\boldsymbol{T} = -m\,(g\cos\varphi + \ell\,\dot{\varphi}^2)\,\hat{\boldsymbol{r}}. \tag{15.9}$$

This string force constrains the particle to remain a fixed distance, $r = \ell$, from the center of the circle. Since the particle motion is directed along the circumference and the string force is radially directed, then the string force does no work on the particle. Evidently, the force provided by the string is a force of constraint. We reconsider this force of constraint from the Lagrangian perspective in Section 15.1.6.

Newton's equation of motion takes the form

$$m\,\ddot{\boldsymbol{X}} = -m\,g\,\hat{\boldsymbol{z}} + \boldsymbol{T}. \tag{15.10}$$

Projecting into the angular direction, $\hat{\boldsymbol{\varphi}}$, eliminates the string force and leads to the nonlinear oscillator equation

$$\ddot{\varphi} + (g/\ell)\sin\varphi = 0, \tag{15.11}$$

where we used

$$\hat{\boldsymbol{z}}\cdot\hat{\boldsymbol{\varphi}} = \sin\varphi. \tag{15.12}$$

When the angle is small we can approximate $\sin\varphi \approx \varphi$, in which case we have a linear oscillator equation

$$\ddot{\varphi} + (g/\ell)\,\varphi = 0, \tag{15.13}$$

with natural angular frequency, $\omega_0 = \sqrt{g/\ell}$ and period $2\,\pi/\omega_0 = 2\,\pi\,\sqrt{\ell/g}$.

15.1.3 Euler-Lagrange equation for the simple pendulum

With a single degree of freedom for the simple pendulum, we choose the angle, φ, as the generalized coordinate. The kinetic energy, potential energy (referenced to $z = 0$), and Lagrangian are thus given by

$$K = (m/2)\,(\dot{x}^2 + \dot{z}^2) = (m/2)\,\ell^2\,\dot{\varphi}^2 \tag{15.14a}$$

$$P = -m\,g\,\ell\cos\varphi \tag{15.14b}$$

$$L = m\,(\ell^2\,\dot{\varphi}^2/2 + g\,\ell\cos\varphi), \tag{15.14c}$$

with the corresponding Euler-Lagrange equation (12.74)

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\partial L}{\partial\dot{\varphi}}\right] = \frac{\partial L}{\partial\varphi} \Longrightarrow \ddot{\varphi} + (g/\ell)\sin\varphi = 0. \tag{15.15}$$

As expected, we derived the same oscillator equation (15.11) as when using Newtonian mechanics. However, the path to this equation is somewhat more streamlined since we had no need to consider forces.

15.1.4 The Hamiltonian is a constant of the motion

The coordinate transformation between the Cartesian coordinates and generalized coordinate does not depend explicitly on time, nor does the Lagrangian. Hence, from Section 12.9.4 we know that the Hamiltonian equals to the mechanical energy, and it is a constant of the motion

$$H = -L + \dot{\varphi}\,\frac{\partial L}{\partial\dot{\varphi}} = K + P. \tag{15.16}$$

We readily confirm that $\dot{H} = 0$ by computing

$$\dot{K} + \dot{P} = m\,\ell^2\,\dot{\varphi}\,[\ddot{\varphi} + (g/\ell)\sin\varphi] = 0, \tag{15.17}$$

where the second equality follows from the Euler-Lagrange equation of motion (15.15).

15.1.5 Hamilton's equations of motion

When proving that the Hamiltonian is a constant of the motion in Section 15.1.4, we did not first write the Hamiltonian in terms of the generalized coordinates and momenta. Instead, we directly computed the time derivative and used the Euler-Lagrange equation to show that $\dot{H} = 0$. However, as mentioned in Section 12.10.4, to derive Hamilton's equations of motion we must first write the Hamiltonian in terms of the generalized coordinates and generalized momenta. The generalized momenta for the pendulum is given by

$$\mathcal{P}_\varphi = \frac{\partial L}{\partial\dot{\varphi}} = m\,\ell^2\,\dot{\varphi}, \tag{15.18}$$

so that the Hamiltonian is

$$H(\varphi, \mathcal{P}_\varphi) = \frac{\mathcal{P}_\varphi^2}{2\,m\,\ell^2} - m\,g\,\ell\cos\varphi. \tag{15.19}$$

Hamilton's equations of motion (12.145a) and (12.145b) take on the general form

$$\dot{\mathcal{P}}_\sigma = -\frac{\partial H}{\partial\xi^\sigma} \quad \text{and} \quad \dot{\xi}^\sigma = \frac{\partial H}{\partial\mathcal{P}_\sigma}, \tag{15.20}$$

which for the pendulum are

$$\dot{\mathcal{P}}_\varphi = -m\,g\,\ell\sin\varphi \quad \text{and} \quad \dot{\varphi} = \frac{\mathcal{P}_\varphi}{m\,\ell^2}. \tag{15.21}$$

Reorganization of the $\dot{\mathcal{P}}_\varphi$ equation renders the Euler-Lagrange equation (15.15). In contrast, the $\dot{\varphi}$ equation is identical to the definition of the generalized momenta given by equation (15.18), so that this equation offers no new information.

15.1.6 Force of constraint provided by the string

Following the Lagrange multiplier method from Section 12.8, we here derive the force of constraint acting on the particle. As already noted, the force of constraint is provided by the string, and this force is always orthogonal to the particle motion. Indeed, we wrote this force by inspection in equation (15.9). Here we compute this force via the Lagrange multiplier. In particular, we follow the approach in Section 12.8 and identify the single constraint equation as

$$\Psi(r) = r = \ell, \tag{15.22}$$

so that $\partial\Psi/\partial r = 1$ and equation (12.109) then says that the Lagrange multiplier is the force of constraint corresponding to the radial coordinate

$$\Lambda = Q_r. \tag{15.23}$$

Following the procedure detailed in Section 12.8.3, we consider the extended Lagrangian (12.103) for the pendulum

$$L = m\,(\dot{r}^2 + r^2\,\dot{\varphi}^2)/2 + m\,g\,r\cos\varphi + \Lambda\,(r-\ell). \tag{15.24}$$

The corresponding Euler-Lagrange equations are

$$m\,\ddot{r} = m\,r\,\dot{\varphi}^2 + m\,g\cos\varphi + \Lambda \tag{15.25a}$$

$$m\,\frac{\mathrm{d}(r^2\,\dot{\varphi})}{\mathrm{d}t} = -m\,g\,r\sin\varphi \tag{15.25b}$$

$$r = \ell. \tag{15.25c}$$

The angular equation of motion (15.25a) remains unaffected by the Lagrange multiplier since there are no constraints on motion in the angular direction. So the set of three equations for the three unknowns, (r, φ, Λ), is given by

$$2\,\dot{r}\,\dot{\varphi} + r\,\ddot{\varphi} + g\sin\varphi = 0 \quad \text{and} \quad \Lambda = m\,(\ddot{r} - r\,\dot{\varphi}^2 - g\cos\varphi) \quad \text{and} \quad r = \ell. \tag{15.26}$$

Satisfying the constraint, $r = \ell$, means that $\dot{r} = 0$ and $\ddot{r} = 0$ so that the force of constraint is

$$Q_r = \Lambda = -m\,(\ell\,\dot{\varphi}^2 + g\cos\varphi) < 0, \tag{15.27}$$

where the inequality follows since $\ell\,\dot{\varphi}^2 + g\cos\varphi > 0$. This result agrees with equation (15.9) for the force provided by the string, $\boldsymbol{T}$, so that we identify

$$\boldsymbol{T} = Q_r\,\hat{\boldsymbol{r}} = -m\,(\ell\,\dot{\varphi}^2 + g\cos\varphi)\,\hat{\boldsymbol{r}}. \tag{15.28}$$

15.1.7 Comments

As anticipated, the Euler-Lagrange equation of motion is both equal to Newton's equation of motion and simple to derive. It is simpler to derive largely due to the scalar nature of the Lagrangian versus the vector nature of Newton's equation of motion. Namely, it is easier to derive the kinetic energy and potential energy than the acceleration and forces. Even though we do not need forces for analytical mechanics, the calculation of forces offers great physical insights into the nature of the physical system. Conservative forces are deduced as per Newtonian mechanics via the gradient of the force potential, and forces of constraint are inferred through the method of Lagrange multipliers.

15.2 Variable length pendulum

What if we let the length of the pendulum's string be a prescribed function of time? That is, we let the string length be a time dependent parameter of the physical system. In this case the Hamiltonian is an explicit function of time, through the string length, and so mechanical energy is not a constant of the motion. Correspondingly, the force of constraint acting along the string does work as the string changes, with this work the cause of the nonzero time derivative of the Hamiltonian. We are familiar with forces of constraint providing no work on a physical system, with this property enshrined in *d'Alembert's principle* studied in Section 12.3.1. Indeed, at any particular instance, the forces of constraint perform no work on a virtual displacement. However, when allowing time to evolve then the force of constraint acting along the string does work and that work results in an energy change.

Along with a time change in the pendulum's energy, there is a time change to the pendulum's angular frequency. Quite remarkably, the ratio of the energy to the angular frequency remains nearly constant for small amplitude oscillations, so long as changes to the string length are slow. The ratio of the energy to frequency is known as an *adiabatic invariant*. This adiabatic invariant arises when studying linear waves moving through a time dependent media. Additionally, adiabatic invariants played an important role in the development of quantum mechanics.

15.2.1 Work done by the force of constraint

Recall from Section 15.1.6 that we introduced the extended Lagrangian with a Lagrange multiplier, Λ, representing the force of constraint,

$$L = m\,(\dot{r}^2 + r^2\,\dot{\varphi}^2)/2 + m\,g\,r\cos\varphi + \Lambda\,(r-\ell), \tag{15.29}$$

where (r, φ, Λ) are three generalized coordinates, and the corresponding Hamiltonian is

$$H = -L + \dot{\varphi}\,\frac{\partial L}{\partial \dot{\varphi}} + \dot{r}\,\frac{\partial L}{\partial \dot{r}} = m\,(\dot{r}^2 + r^2\,\dot{\varphi}^2)/2 - m\,g\,r\cos\varphi - \Lambda\,(r-\ell). \tag{15.30}$$

The corresponding Euler-Lagrange equations (15.26) are here repeated for completeness

$$2\,\dot{r}\,\dot{\varphi} + r\,\ddot{\varphi} + g\sin\varphi = 0 \quad \text{and} \quad \Lambda = m\,(\ddot{r} - r\,\dot{\varphi}^2 - g\cos\varphi) \quad \text{and} \quad r(t) = \ell(t). \tag{15.31}$$

Evidently, the force of constraint, Λ, picks up a new contribution from the second time derivative, $\ddot{r}$, whereas this contribution vanished in Section 15.1.6 where we assumed ℓ has a fixed length.

Both the Lagrangian (15.29) and Hamiltonian (15.30) are explicit functions of time via the time dependent string length, $\ell(t)$. Hence, the Hamiltonian has a time derivative, which can be

evaluated in either of the following manners

$$\frac{\mathrm{d}H}{\mathrm{d}t} = \left[\frac{\partial H}{\partial t}\right]_{r,\varphi,\mathcal{P}_r,\mathcal{P}_\varphi} = \frac{\partial H}{\partial \ell}\,\frac{\mathrm{d}\ell}{\mathrm{d}t} = -\left[\frac{\partial L}{\partial t}\right]_{r,\varphi,r,\dot{r},\dot{\varphi}} = \dot{\ell}\,\Lambda, \tag{15.32}$$

so that the energy of the pendulum changes due to work done by the force of constraint acting in the presence of a changing string length. We can double-check the result (15.32) by making use of the equations of motion (15.31), which now requires us to set $r = \ell$ so that

$$\frac{\mathrm{d}H}{\mathrm{d}t} = \dot{H} = m\,\dot{l}\,(\ddot{l} + \ell\,\dot{\varphi}^2 - g\cos\varphi) + m\,\ell\,\dot{\varphi}\,(\ell\,\ddot{\varphi} + g\sin\varphi) = m\,\dot{\ell}\,(\ddot{\ell} - \ell\,\dot{\varphi}^2 - g\cos\varphi) = \dot{\ell}\,\Lambda. \tag{15.33}$$

15.2.2 Small amplitude oscillations

Assuming the angular displacements of the pendulum are small leads to the Lagrangian and Hamiltonian for a linear variable length pendulum

$$L = m\,\ell^2\,(\dot{\varphi}^2 - (g/\ell)\,\varphi^2)/2 + m\,g\,\ell + m\,\dot{\ell}^2/2, \tag{15.34a}$$

$$H = m\,\ell^2\,(\dot{\varphi}^2 + (g/\ell)\,\varphi^2)/2 - m\,g\,\ell - m\,\dot{\ell}^2/2, \tag{15.34b}$$

along with the corresponding Euler-Lagrange equation of motion

$$\frac{\mathrm{d}(\ell^2\,\dot{\varphi})}{\mathrm{d}t} + g\,\ell\,\varphi = 0. \tag{15.35}$$

Note that the term $m\,\ell^2\,(\dot{\varphi}^2 - (g/\ell)\,\varphi^2)/2$ appearing in the Lagrangian (15.34a) is the kinetic energy minus the potential energy for a simple harmonic oscillator, as studied in Section 15.6. We thus identify the angular frequency of the oscillator as

$$\omega^2(t) = g/\ell(t), \tag{15.36}$$

with $2\pi/\omega$ equal to the period of the oscillations.

15.2.3 Two time scales for the pendulum

For the linear pendulum with a fixed length, the angular displacement is given by $\varphi = A\cos(\omega\,t)$, where A is a constant amplitude and we set the initial conditions so that $\varphi(t=0) = A$. If the string length changes very slowly, then we expect the oscillations to continue yet with a time dependent frequency and amplitude. We are thus motivated to consider the ansatz

$$\varphi(t) = A(t)\cos\theta(t), \tag{15.37}$$

where the amplitude, $A(t)$, has a time dependence, as does the phase, $\theta(t)$. Furthermore, we note that the time scale for the phase derivative accords with the angular frequency

$$\dot{\theta} \approx \omega. \tag{15.38}$$

In Section 15.2.4 we find equality holds to leading order.

A string whose length slowly changes is one whose inverse time scale for changes, T^{-1}, is much smaller than the angular frequency for the pendulum, so that

$$\dot{\ell}/\ell = T^{-1} \ll \omega \approx \dot{\theta} \Longrightarrow \dot{\ell}^2 \ll \ell\,g \tag{15.39}$$

where the second inequality follows since $\omega^2 = g/\ell$. The inequality $T^{-1} \ll \dot{\theta}$ means that the phase of the oscillation varies rapidly relative to the string length. Another corresponding assumption concerns the amplitude of the oscillation, which we assume also slowly changes

$$\dot{A}/A = T^{-1} \ll \omega. \tag{15.40}$$

Finally, the relation $\omega^2 = g/\ell$, along with the inequality (15.39), shows that relative changes to the angular frequency are also small

$$2\,\dot{\omega}/\omega = -\dot{\ell}/\ell \Longrightarrow |\dot{\omega}| \ll \omega^2 = g/\ell. \tag{15.41}$$

These scaling relations can be summarized by stating that the phase of the oscillation changes rapidly whereas all other quantities change slowly.

In the Lagrangian (15.34a) and Hamiltonian (15.34b), we encounter the sum, $m\,g\,\ell + m\,\dot{\ell}^2/2$. The first term, $-m\,g\,\ell$, is the gravitational potential energy of a pendulum at zero angular displacement, $\varphi = 0$. Over the time scale of an oscillation, this term is roughly a constant and it can be ignored by merely readjusting the zero of the potential energy. Likewise, the term $m\,\dot{\ell}^2/2$ is the kinetic energy associated with changes to the string length. This term changes slowly and it is much smaller than the kinetic energy from angular motion, $m\,\ell^2\,\dot{\varphi}^2/2$. We thus ignore this term as well in the following analysis.

15.2.4 Adiabatic invariant

Making use of the ansatz (15.37) yields time changes to the pendulum's angle

$$\dot{\varphi} = \dot{A}\cos\theta - A\,\dot{\theta}\sin\theta \approx -A\,\dot{\theta}\sin\theta, \tag{15.42}$$

where we made use of the assumed scales in Section 15.2.3 to reach the approximation. We are thus led to the approximate form of the Lagrangian (15.34a) (recall we are ignoring the terms $m\,g\,\ell + m\,\dot{\ell}^2/2$)

$$L \approx m\,\ell^2\,A^2\,(\dot{\theta}^2\sin^2\theta - \omega^2\cos^2\theta)/2. \tag{15.43}$$

As part of the time scale separation in Section 15.2.3, we assume the phase of the oscillation changes rapidly relative to changes in the angular frequency as well as changes to $\dot{\theta}$ and ℓ. Hence, we are motivated to perform a phase average,[1] in which case $\sin^2\theta$ and $\cos^2\theta$ are replaced by $1/2$

$$\langle L\rangle = m\,\ell^2\,A^2\,(\dot{\theta}^2 - \omega^2)/4. \tag{15.44}$$

We treat the amplitude and phase as generalized coordinates that are connected to the angular displacement via the oscillator ansatz (15.37). Their respective phase averaged Euler-Lagrange equations are

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{A}} = \frac{\partial L}{\partial A} \Longrightarrow \dot{\theta}^2 = \omega^2 \tag{15.45a}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{\varphi}} = \frac{\partial L}{\partial \varphi} \Longrightarrow \frac{\mathrm{d}(\ell^2\,A^2\,\dot{\theta})}{\mathrm{d}t} = 0. \tag{15.45b}$$

Equation (15.45a) says that the phase has a time derivative equal to the instantaneous frequency. It also results in a zero phase averaged Lagrangian

$$\langle L\rangle = 0. \tag{15.46}$$

[1] We introduced phase averaging in Section 4.2.2 when studying Fourier analysis.

To interpret equation (15.45b) note that the phase averaged Hamiltonian (15.34b) is (recall we are ignoring the terms $m\,g\,\ell + m\,\dot{\ell}^2/2$)

$$\langle H \rangle = m\,\ell^2\,A^2\,(\dot{\theta}^2 + \omega^2)/4 = m\,\ell^2\,A^2\,\omega^2/2, \tag{15.47}$$

so that the Euler-Lagrange equation (15.45b) can be written

$$\frac{\mathrm{d}(H/\omega)}{\mathrm{d}t} = 0. \tag{15.48}$$

Evidently, although energy and angular frequency change due to the variable string length, their ratio is constant when the oscillations are small and the changes to the string length are slow. The ratio, H/ω, is known as the *phase averaged action*, and equation (15.48) says that it is an adiabatic invariant. Conservation of the phase averaged action results from symmetry of the phase in the phase averaged Lagrangian (15.44). That is, we can shift the phase by a constant and not alter the Lagrangian. This result exemplifies the importance of identifying any (sometimes quite innocent looking) symmetries of a dynamical system, as they inevitably lead to a conservation law.

15.2.5 Further study

A general discussion of adiabatic invariants is given in Section 49 of *Landau and Lifshitz* (1976), Section 11.7 of *Goldstein* (1980), and Section 6.4 of *José and Saletan* (1998). See also Section 7.1 of *Salmon* (1998) for a discussion of the adiabatic invariant for the harmonic oscillator. Furthermore, we encounter adiabatic invariants in Section 48.5 when studying waves in a media that changes in space and time, with the *wave action* the corresponding invariant.

Adiabatic invariants formed an important part in the foundations of quantum mechanics. For example, the energy of a photon is given by

$$E = \hbar\,\omega, \tag{15.49}$$

where $\hbar = h/2\pi$ is the reduced Planck's constant, thus revealing that E/ω is a constant.

15.3 The Foucault pendulum

In this section we use Lagrangian mechanics to study motion of the *Foucault pendulum*, which is a frictionless spherical pendulum in a gravity field on a rotating planet. To illustrate the rotation of the planet, we setup the pendulum to oscillate in a fixed plane as viewed in an inertial reference frame, and as such it precesses when viewed from the planetary rotating reference frame. In this manner, the Foucault pendulum provides a remarkable illustration of the planetary Coriolis acceleration, and hence of the planetary rotation.

15.3.1 Assumptions about the Coriolis acceleration

We illustrate the Foucault pendulum in Figure 15.2, which is a spherical pendulum that feels the effects of the earth's rotation. For any point on the earth, the planetary rotation has a projection in the local vertical and local meridional directions (see Figure 13.3). However, for our study of the Foucault pendulum we only consider the local vertical component to the planetary rotation. This approximate approach accords with our study of large-scale fluid flows in this book. Even though the Foucault pendulum is tiny compared to the planetary fluid flows, the motion of the

particle respects the same assumptions relevant for large-scale fluid motions. We detail these assumptions in the next paragraph.

As studied in Section 13.9.8, the meridional component to the planetary rotation leads to a Coriolis acceleration that has both a radial component and longitudinal component. The radial Coriolis acceleration is far smaller than the effective gravitational acceleration so that this contribution to the Coriolis acceleration can be ignored. The longitudinal Coriolis acceleration is determined by the vertical velocity of the particle. For the Foucault pendulum we assume the vertical motion is much smaller than the horizontal velocity. Hence, this piece of the longitudinal Coriolis acceleration is negligible compared to the other portion that arises from horizontal motion. For these two reasons, the most significant portion of the Coriolis acceleration acting on the pendulum arises just from the local vertical component to the planetary rotation. As such, the Coriolis acceleration acts just in the local horizontal tangent plane.

Furthermore, since the horizontal length scales of the pendulum are tiny relative to the earth's radius, we assume the Coriolis parameter (equation (13.102))

$$f = 2\,\Omega \sin\phi, \tag{15.50}$$

to be constant and evaluated at the fixed point of the pendulum, which we refer to as the *f-plane approximation* in Section 25.5. In equation (15.50), Ω is the angular frequency of the planetary rotation (Section 13.1), and ϕ is the planetary latitude (Figure 10.1).

FIGURE 15.2: A Foucault pendulum is a frictionless spherical pendulum on a rotating planet. Taking the f-plane approximation, we assume rotation of the reference frame occurs around the local vertical axis with angular frequency $(f/2)\,\hat{\boldsymbol{z}}$, with $f = 2\,\Omega \sin\phi$ the Coriolis parameter and ϕ the latitude of the fixed point of the pendulum. To avoid confusion with the planetary spherical angles (where we use ϕ for latitude and λ for longitude as in Figure 10.1), we here use the local spherical coordinates with $\psi \geq 0$ the angle the pendulum makes with the horizontal x-y plane, and $0 \leq \gamma \leq 2\pi$ the angle it makes with the x-axis in a counter-clockwise sense. The angle made by the string relative to the vertical axis is $\varphi \geq 0$, just as for the simple pendulum in Figure 15.1. The right panel shows a projection onto the y-z plane ($\gamma = \pi/2$), which clearly illustrates the relation $\psi = \varphi/2$. Furthermore, the law of cosines expresses the radial position as a function of the angle, φ, and the string length, $r^2 = 2\,\ell^2\,(1 - \cos\varphi) = 4\,\ell^2 \sin^2(\varphi/2)$.

15.3.2 Position vector for the point mass

To avoid confusion with the planetary spherical coordinates of Figure 10.1, we write the pendulum's spherical angles as ψ (angle relative to the horizontal plane with $\psi \geq 0$ for the pendulum) and γ (angle relative to $\hat{\boldsymbol{x}}$, with $0 \leq \gamma \leq 2\pi$). In this manner, the coordinates for the point mass

at the end of the string are given by

$$x = r\cos\psi\cos\gamma = 2\,\ell\sin(\varphi/2)\cos(\varphi/2)\cos\gamma = \ell\sin\varphi\cos\gamma \tag{15.51a}$$
$$y = r\cos\psi\sin\gamma = 2\,\ell\sin(\varphi/2)\cos(\varphi/2)\sin\gamma = \ell\sin\varphi\sin\gamma \tag{15.51b}$$
$$z = r\sin\psi = 2\,\ell\sin^2(\varphi/2) = \ell\,(1-\cos\varphi). \tag{15.51c}$$

For these equations we made use of the law of cosines to write the radial distance from the origin, r, in terms of the string length, ℓ, and the angle of the string from the vertical, φ,

$$r = \ell\sqrt{2\,(1-\cos\varphi)} = 2\,\ell\sin(\varphi/2). \tag{15.52}$$

Equations (15.51a)–(15.51c) provide an expression for the particle position

$$\boldsymbol{X}(t) = \ell\,[\hat{\boldsymbol{x}}\sin\varphi\cos\gamma + \hat{\boldsymbol{y}}\sin\varphi\sin\gamma + \hat{\boldsymbol{z}}\,(1-\cos\varphi)], \tag{15.53}$$

which is written in terms of just the two angles, φ and γ, which serve as our generalized coordinates.

15.3.3 Lagrangian for the Foucault pendulum

We are describing the motion of the particle within a rotating reference frame, with the horizontal axes rotating around the vertical as viewed in a local tangent plane on the planet. Hence, from the rigid-body rotation study in Section 11.2.2, we have (see equation (11.34)) the time change of the local horizontal Cartesian unit vectors

$$\dot{\hat{\boldsymbol{x}}} = (f/2)\,\hat{\boldsymbol{z}}\times\hat{\boldsymbol{x}} = (f/2)\,\hat{\boldsymbol{y}} \quad\text{and}\quad \dot{\hat{\boldsymbol{y}}} = (f/2)\,\hat{\boldsymbol{z}}\times\hat{\boldsymbol{y}} = -(f/2)\,\hat{\boldsymbol{x}}. \tag{15.54}$$

The corresponding velocity vector for the particle is

$$\dot{\boldsymbol{X}} = \ell\,\dot{\varphi}\cos\varphi\,(\hat{\boldsymbol{x}}\cos\gamma + \hat{\boldsymbol{y}}\sin\gamma) + \ell\,\dot{\gamma}\sin\varphi\,(-\hat{\boldsymbol{x}}\sin\gamma + \hat{\boldsymbol{y}}\cos\gamma) + \ell\,\hat{\boldsymbol{z}}\,\dot{\varphi}\sin\varphi + (f/2)\,\hat{\boldsymbol{z}}\times\boldsymbol{X}, \tag{15.55}$$

with rearrangement leading to

$$\dot{\boldsymbol{X}} = \ell\,\hat{\boldsymbol{x}}\,(\dot{\varphi}\cos\varphi\cos\gamma - (\dot{\gamma}+f/2)\sin\varphi\sin\gamma) + \ell\,\hat{\boldsymbol{y}}\,(\dot{\varphi}\cos\varphi\sin\gamma + (\dot{\gamma}+f/2)\sin\varphi\cos\gamma) + \ell\,\hat{\boldsymbol{z}}\,\dot{\varphi}\sin\varphi. \tag{15.56}$$

Notice the appearance of $\dot{\gamma}+f/2$, which is the net angular frequency for motion around the vertical axis.

Computing the squared velocity and rearranging then leads to the particle's kinetic energy

$$K = (m\,\ell^2/2)\,(\dot{\varphi}^2 + (\dot{\gamma}+f/2)^2\sin^2\varphi), \tag{15.57}$$

which arises from motion in the two angular directions plus the rigid-body motion of the rotating reference frame. The gravitational potential energy, referenced to the coordinate system origin, is given by

$$P = m\,g\,\ell\,(1-\cos\varphi), \tag{15.58}$$

so that the Lagrangian is

$$L = K - P = (m\,\ell^2/2)\,(\dot{\varphi}^2 + (\dot{\gamma}+f/2)^2\sin^2\varphi) + m\,g\,\ell\,(\cos\varphi - 1). \tag{15.59}$$

15.3.4 Euler-Lagrange equations of motion

The absence of an explicit appearance of γ in the Lagrangian (15.59) means that the γ component of the generalized momentum, $\mathscr{P}_\gamma$, is a constant of the motion

$$\frac{\mathrm{d}\mathscr{P}_\gamma}{\mathrm{d}t} = 0 \quad \text{with} \quad \mathscr{P}_\gamma = \frac{\partial L}{\partial \dot{\gamma}} = m\,\ell^2\,(\dot{\gamma} + f/2)\sin^2\varphi. \tag{15.60}$$

We interpret $\mathscr{P}_\gamma$ as the axial angular momentum for the unconstrained rotational motion around the local vertical axis, with $\ell \sin\varphi$ the distance of the particle from the vertical axis and $\dot{\gamma} + f/2$ the net angular frequency for motion around the axis.[2] The φ equation is derived from

$$\frac{\partial L}{\partial \dot{\varphi}} = m\,\ell^2\,\dot{\varphi} \quad \text{and} \quad \frac{\partial L}{\partial \varphi} = m\,\ell^2\,(\dot{\gamma} + f/2)^2 \sin\varphi\cos\varphi - m\,g\,\ell\sin\varphi, \tag{15.61}$$

which leads to

$$\ddot{\varphi} + (g/\ell)\sin\varphi = (\dot{\gamma} + f/2)^2 \sin\varphi\cos\varphi. \tag{15.62}$$

This equation reduces to the planar pendulum equation (15.15) for the special case of motion within a vertical plane so that $\dot{\gamma} = 0$, and in the absence of planetary rotation so that $f = 0$. It also reduces to the planar pendulum for the case where $\dot{\gamma} = -f/2$, in which the pendulum contains zero axial angular momentum. We return to the case of zero axial angular momentum in Section 15.3.6.

15.3.5 Mechanical energy conservation

Since the Cartesian expression (15.53) for the position vector has no explicit time dependence, and neither does the Lagrangian (15.53), we know that the Hamiltonian equals to the mechanical energy and it is a constant of the motion

$$H = K + P = (m\,\ell^2/2)\,(\dot{\varphi}^2 + (\dot{\gamma} + f/2)^2 \sin^2\varphi) + m\,g\,\ell\,(1 - \cos\varphi). \tag{15.63}$$

Using the Euler-Lagrange equations of motion (15.60) and (15.62), it is straightforward to show that (see Exercise 15.1)

$$\frac{\mathrm{d}H}{\mathrm{d}t} = 0. \tag{15.64}$$

15.3.6 The case of zero axial angular momentum

Let us view the Foucault pendulum from a non-rotating inertial frame off the planet. Upon release from a position of rest, the inertial observer sees a pendulum that oscillates in a plane that is fixed with respect to the non-rotating inertial frame. In contrast, the rotating reference frame sees the pendulum's oscillation plane rotate oppositvely to the planet. The situation is directly analogous to the frictionless motion of a particle on a rotating table as illustrated in Figure 14.4. For the Foucault pendulum, the particle is constrained to oscillate on the end of a string. However, its motion couples to the rotation and so the rotating reference frame experiences a Coriolis acceleration. In picturing the motion, it is important to remember the assumption of zero friction, so that the apparatus holding the pendulum can rotate with the planet and yet not impart any frictional force to cause the pendulum to also rotate with the planet. In this manner, the pendulum maintains a fixed planar motion as viewed in the inertial reference frame.

[2] Compare this result to our study in Section 14.6 of axial angular momentum for planetary motion. In that discussion we considered motion around the planetary rotational axis. Here, the rotational axis for the Foucault pendulum is approximated by the local vertical, as per our assumptions discussed in Section 15.3.1.

Our thought experiment focuses on the special case of zero axial angular momentum (where, again, the axis here refers to the local vertical axis of the pendulum). In this case, the Euler-Lagrange equations of motion reduce to the relatively simple set

$$(\dot{\gamma} + f/2)\sin^2\varphi = 0 \quad \text{and} \quad \ddot{\varphi} + (g/\ell)\sin\varphi = 0. \tag{15.65}$$

The first equation is generally satisfied with $\dot{\gamma} = -f/2$, whereas the second equation is that for the planar pendulum from Section 15.1. The zero axial angular momentum motion decouples the evolution equations for γ and φ.

Evidently, with $\dot{\gamma} = -f/2$ then γ evolves as $\gamma = -(f/2)\,t$. We refer to this motion as a *precession* of the pendulum motion around the vertical rotational axis. The precession of γ means that the Foucault pendulum is seen by a rotating frame observer to have its oscillation plane rotate opposite to the planetary rotation (anti-cyclonically). In the northern hemisphere the pendulum's rotational plane precesses clockwise, whereas it precesses counter-clockwise in the southern hemisphere. Again, as per the motion of a frictionless ball on a rotating table seen in Figure 14.4, the precession can be interpreted as the persistent effects of the rightward deflection by the Coriolis acceleration in the northern hemisphere and leftward deflction in the southern (see Section 14.7). The period of the precession is

$$T^{\text{precession}} = \frac{2\,\pi}{|f|/2} = \frac{2\,\pi}{\Omega|\sin\phi|}. \tag{15.66}$$

Hence, a Foucault pendulum positioned at either poles (where the latitude, $\phi = \pm\pi/2$) exhibits a complete precession once per day, whereas at the equator ($\phi = 0$) there is no precession (formally an infinite period). Observe that the precession period is twice the period of inertial oscillations studied in Section 14.5.

15.3.7 Comments

Our treatment of Foucault's pendulum is distinguished from certain standard treatments, such as Section 12 of *Fetter and Walecka* (2003) and Example 9-5 of *Marion and Thornton* (1988). First, we made use of Lagrangian mechanics whereas both of these alternative treatments used Newtonian mechanics. Consequently, we had no occasion to consider the forces acting within the string, as these forces of constraint are removed when using the angles φ and γ as generalized coordinates. Second, we made use of an approximate Coriolis acceleration as described in Section 15.3.1, where we only considered the local vertical component of the earth's rotation. The standard treatments reduce to this same approximate Coriolis acceleration, though they generally wait until later in the analysis to introduce the assumption. We found it useful to introduce the approximation earlier since it corresponds closely to how we treat the Coriolis acceleration for motion of the large-scale circulation in the ocean and atmosphere. It also simplifies the analysis. Third, we focused on the zero axial angular momentum case, which trivially yields the precession rate $\dot{\gamma} = -f/2$. Since the axial angular momentum is a constant of the motion, we can set it to a zero value initially and it will remain so throughout the experiment (ignoring friction). It is this situation that is realized by a careful initial release of the Foucault pendulum so as to not introduce any lateral bias to the motion. In this manner, the spherical pendulum oscillates in a fixed plane when viewed by an inertial observer, while the planetary rotation occurs underneath the oscillating pendulum so that the planetary observer sees a precession.

15.4 Motion on constant potential energy surfaces

In this section we study motion constrained to move on surfaces of constant potential energy. Since the potential energy is a function of the coordinates (and not the velocity), the constraint is holonomic thus enabling use of generalized coordinates and Lagrange multipliers.

15.4.1 Anticipating the results

Much can be anticipated before doing any analysis, and it is useful to do so. For each case gravity provides the external conservative force and we ignore friction as well as any other external forces. The first case considers motion in the presence of a horizontally symmetric gravitational potential, which leads to a vertically directed gravitational acceleration. Motion in the horizontal directions is free (again, we ignore friction and any other forces). Hence, linear momentum in the horizontal directions is a constant of the motion, as is angular momentum around the vertical axis centered anywhere in the field. Also, since the potential and the Lagrangian have no explicit time dependence, the Hamiltonian (mechanical energy) is a constant. Horizontal motion is maintained by a force of constraint, such as provided by a frictionless flat table, with this force exactly balancing the weight of the particle.

Next we study motion in the force field of a spherically symmetric gravitational potential such as generated by a spherical mass source. In this case the generalized coordinates are the two spherical angles (latitude and longitude), with the angular momentum around any axis a constant of the motion, as is the Hamiltonian. The force of constraint must counteract the gravitational force (pointing into the center) as well as the centrifugal force arising from the angular velocity (pointing away from the center). Indeed, particles with enough kinetic energy can have sufficient centrifugal acceleration to overcome the gravitational acceleration, in which case the force of constraint must keep the particle from flying outward.

15.4.2 Lagrangian using Cartesian coordinates

The unconstrained Lagrangian in Cartesian coordinates is given by

$$L = (m/2)\,(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) - P(x, y, z), \tag{15.67}$$

where we assume the potential energy has no explicit time dependence, in which case the Hamiltonian is a constant of the motion (see Section 12.9.4)

$$\dot{H} = 0 \quad \text{with} \quad H = (m/2)\,(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) + P. \tag{15.68}$$

Now introduce a Lagrange multiplier, Λ, to constrain the particle motion to a surface of constant potential energy, $P = \mathcal{C}$, so that the modified Lagrangian is

$$L^* = L + \Lambda\,(P - \mathcal{C}) = K - P\,(1 - \Lambda) - \Lambda\,\mathcal{C}. \tag{15.69}$$

The corresponding Euler-Lagrange equations of motion (12.106a) and (12.106b) are

$$m\,\ddot{\boldsymbol{X}} = -(1 - \Lambda)\,\nabla P \quad \text{and} \quad P = \mathcal{C}. \tag{15.70}$$

For particle motion along the $P = \mathcal{C}$ surface we know that the exact differential of the potential energy vanishes, which means that

$$\mathrm{d}P = \nabla P \cdot \mathrm{d}\boldsymbol{X} = 0 \Longrightarrow \nabla P \cdot \dot{\boldsymbol{X}} = 0. \tag{15.71}$$

This condition means that the velocity is parallel to constant potential energy surfaces, which it must be to maintain constant potential energy. Furthermore, taking the dot product of $\dot{\boldsymbol{X}}$ with the equation of motion (15.70), and using the constraint $\nabla P \cdot \dot{\boldsymbol{X}} = 0$, reveals that the kinetic energy is a constant of the motion

$$\dot{\boldsymbol{X}} \cdot \ddot{\boldsymbol{X}} = 0 \Longrightarrow \dot{K} = 0. \tag{15.72}$$

We can readily anticipate this result since with a constant potential energy and a constant Hamiltonian, then the kinetic energy is also a constant of the motion.

The Lagrange multiplier scales the force of constraint that counteracts the conservative force arising from the gradient of the potential energy. Making use of the general expression (12.109) yields the force of constraint

$$Q_\sigma^{\text{constraint}} = \Lambda \frac{\partial P}{\partial x^\sigma} = -\Lambda\, F_\sigma, \tag{15.73}$$

where F_σ is the conservative force arising from the potential energy. Setting $\Lambda = 1$ ensures that the force of constraint acts to exactly oppose the conservative force, thus rendering a zero acceleration along the σ direction. The case of $\Lambda = 1$ is encountered for the particle moving along a horizontal geopotential. However, when the particle experiences any acceleration due to curved motion (e.g., motion around the sphere), then $\Lambda \neq 1$. The reason is that in addition to the conservative force from gravity, the particle encounters the centrifugal acceleration due to its angular motion around the sphere. If the sphere is itself rotating, as considered in Section 15.5, then there are additional accelerations (planetary centrifugal and planetary Coriolis) that must be accounted for when determining the force of constraint. These points will become clearer as we work through the various examples.

15.4.3 Plane symmetric potential energy

If the potential energy arises from a gravitational force field in the $-\hat{\boldsymbol{z}}$ direction, then gravitational potential energy is given by

$$P = m\, g\, z, \tag{15.74}$$

and the corresponding force of constraint is

$$Q_z^{\text{constraint}} = m\, g. \tag{15.75}$$

Evidently, the force of constraint acts vertically upward to exactly balance the downward weight of the particle so that the particle remains on a fixed z surface. A particle moving on a flat frictionless table provides the canonical example of this situation, where the table provides the force of constraint that balances the particle weight.

With $\Lambda = 1$ the horizontal motion has no acceleration

$$\ddot{x} = \ddot{y} = 0. \tag{15.76}$$

It is notable that all three coordinate directions have zero acceleration. However, motion in the horizontal directions is unconstrained and so the horizontal motion is free, whereas motion in the vertical direction is constrained due to the force of constraint balancing the weight.

15.4.4 Spherically symmetric potential energy

Now consider motion in the presence of a spherically symmetric potential, such as for a particle moving around a non-rotating spherical earth. We make use of spherical coordinates, with the

transformation between planetary Cartesian coordinates and planetary spherical coordinates given by equations (10.18a)-(10.18c)

$$x = r\cos\phi\,\cos\lambda \quad \text{and} \quad y = r\cos\phi\,\sin\lambda \quad \text{and} \quad z = r\sin\phi, \tag{15.77}$$

where $0 \le \lambda \le 2\pi$ is the longitude, and $-\pi/2 \le \phi \le \pi/2$ is the latitude (see Figure 10.1). The velocity components are given by

$$\dot{x} = \dot{r}\cos\phi\cos\lambda - r\,\dot{\phi}\sin\phi\cos\lambda - r\,\dot{\lambda}\cos\phi\sin\lambda \tag{15.78a}$$

$$\dot{y} = \dot{r}\cos\phi\sin\lambda - r\,\dot{\phi}\sin\phi\sin\lambda + r\,\dot{\lambda}\cos\phi\cos\lambda \tag{15.78b}$$

$$\dot{z} = \dot{r}\sin\phi + r\,\dot{\phi}\cos\phi, \tag{15.78c}$$

which then leads (after a bit of algebra) to the kinetic energy

$$K = (m/2)\,(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) = (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}^2\cos^2\phi). \tag{15.79}$$

We could have written this expression down by inspection if using the spherical coordinate expression (13.46d). However, the approach shown here is useful in general. Namely, we first write the kinetic energy in Cartesian coordinates, and then transform to coordinates that respect the symmetry of the system and thus provide suitable generalized coordinates.

Assuming the particle motion moves at a radius close to that of the mean earth radius allows us to approximate the gravitational potential energy according to equation (13.121)

$$P = m\,\Phi_{\rm e} = m\,g_{\rm e}\,r, \tag{15.80}$$

where $g_{\rm e} \approx 9.8$ m s^{-2} (Section 13.10.3). We are thus led to the Lagrangian

$$L = (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}^2\cos^2\phi) - m\,g_{\rm e}\,r. \tag{15.81}$$

Since the Lagrangian and the potential energy are not explicit functions of time, then the Hamiltonian is a constant of the motion

$$\dot{H} = 0 \quad \text{with} \quad H = (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}^2\cos^2\phi) + m\,g_{\rm e}\,r. \tag{15.82}$$

We next modify the Lagrangian by adding a Lagrange multiplier to constrain the motion to remain on a constant potential energy surface, $P = P(R)$, in which case

$$L^* = L + \Lambda\,[P - P(R)] = (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}^2\cos^2\phi) - P\,(1-\Lambda) - \Lambda\,P(R). \tag{15.83}$$

The corresponding Euler-Lagrange equations are

$$\ddot{r} = r\,(\dot{\phi}^2 + \dot{\lambda}^2\cos^2\phi) - (1-\Lambda)\,g_{\rm e} \tag{15.84a}$$

$$\frac{{\rm d}(r^2\,\dot{\phi})}{{\rm d}t} = -r^2\,\dot{\lambda}^2\cos\phi\sin\phi \tag{15.84b}$$

$$\frac{{\rm d}(r^2\,\dot{\lambda}\cos^2\phi)}{{\rm d}t} = 0 \tag{15.84c}$$

$$r = R. \tag{15.84d}$$

The third equation corresponds to angular momentum conservation arising from the spherical symmetry. Satisfying the constraint, $r = R$, means that there is no radial acceleration, $\ddot{r} = 0$,

and that the potential energy is fixed at the constant

$$P = m\, g_{\rm e}\, R. \tag{15.85}$$

Equation (15.84a) thus leads to

$$m\, R^2\, (\dot{\phi}^2 + \dot{\lambda}^2 \cos^2 \phi) = (1 - \Lambda)\, P, \tag{15.86}$$

and the Hamiltonian (which is a constant of the motion) takes the form

$$H = m\, R^2\, (\dot{\phi}^2 + \dot{\lambda}^2 \cos^2 \phi)/2 + P. \tag{15.87}$$

Making use of this constant Hamiltonian in equation (15.86) gives us

$$\Lambda = 3 - 2\, H/P = 1 - 2\, K/P, \tag{15.88}$$

with the kinetic energy a constant of the motion since both H and P are also constants.[3] The radial force of constraint is thus given by

$$Q_r = \Lambda\, \frac{\partial P}{\partial r} = (1 - 2\, K/P)\, m\, g_{\rm e}. \tag{15.89}$$

To help interpret the force of constraint (15.89), write the kinetic energy in the form

$$2\, K = m\, R^2\, (\dot{\phi}^2 + \dot{\lambda}^2 \cos^2 \phi) = m\, (v^2 + u^2) = m\, R\, A^{\rm centrifugal}, \tag{15.90}$$

where we introduced the spherical velocity components according to equation (13.48), and defined the centrifugal acceleration arising from the angular motion of the particle around the sphere,

$$A^{\rm centrifugal} = R\, (\dot{\phi}^2 + \dot{\lambda}^2 \cos^2 \phi) = (u^2 + v^2)/R, \tag{15.91}$$

which is positive and points outward away from the axis of rotation. We can now write the force of constraint in the physically transparent manner

$$Q_r = m\, g_{\rm e}\, (1 - A^{\rm centrifugal}/g_{\rm e}). \tag{15.92}$$

Evidently, if the gravitational acceleration is greater than the centrifugal acceleration, then the force of constraint is directed radially outward with a magnitude less than the weight of the particle. In contrast, if the centrifugal acceleration is greater than the gravitational acceleration, then the force of constraint must point radially inward to keep the particle on a constant radius. If the centrifugal acceleration equals to the gravitational acceleration, then the particle remains at a fixed radius with a zero force of constraint.

15.5 Motion on geopotential surfaces

We extend the results from Section 15.4 to now consider motion on geopotential surfaces that arise from central gravity plus planetary centrifugal. For the rotating spherical planet, the geopotentials are oblate spheroidal shaped surfaces (Section 13.10.4), whereas they are parabolic for the case of a rotating plane (Section 15.5.3). The force of constraint accounts for the gravitational acceleration, the centrifugal acceleration from the particle motion, the centrifugal acceleration of the rotating

[3] Again, $H = K + P$ is a constant due to time symmetry whereas P is a constant due to the force of constraint that keeps the particle at a fixed radius.

reference frame, and a portion of the Coriolis acceleration. We greatly simplify the analysis by moving from spherical coordinates to geopotential coordinates as motivated by our earlier work in Section 13.11.3.

15.5.1 Oblate spheroidally symmetric potential energy

Building from the analysis in Sections 15.4.3 and 15.4.4, consider a rotating spherical planet with constant angular rotation rate, $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$, directed through the vertical planetary Cartesian axis. We describe motion from the rotating reference frame, in which the planetary spherical coordinates and planetary Cartesian coordinates are fixed with respect to the rotating planet. This is the same convention taken in Chapter 13 and used throughout this book. As we show, the particle motion maintains a constant axial angular momentum (due to zonal symmetry), a constant Hamiltonian (due to time symmetry), and constant geopotential (due to the imposed constraint). Notably, however, the kinetic energy is not a constant of the motion.

The Lagrangian and the oblate spheroidal geopotential

The spherical coordinate expression for the particle's kinetic energy is

$$K = (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,(\dot{\lambda} + \Omega)^2\cos^2\phi). \tag{15.93}$$

The only change relative to equation (15.79) is the presence of Ω, which arises from the rigid-body rotation of the planet around the polar axis. The gravitational potential energy is just like for the non-rotating case, thus leading to the Lagrangian

$$\begin{aligned}
L &= K - P && (15.94a)\\
&= (m/2)\,(\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,(\dot{\lambda} + \Omega)^2\cos^2\phi) - m\,g_{\mathrm{e}}\,r && (15.94b)\\
&= (m/2)\,[\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}\,(\dot{\lambda} + 2\,\Omega)\cos^2\phi] - m\,(g_{\mathrm{e}}\,r - (1/2)\,\Omega^2\,r^2\cos^2\phi) && (15.94c)\\
&= K^{\mathrm{truncate}} - m\,\Phi. && (15.94d)
\end{aligned}$$

The third equality introduced the truncated kinetic energy

$$K^{\mathrm{truncate}} = K - (m/2)\,\Omega^2\,r^2\cos^2\phi = (m/2)\,[\dot{r}^2 + r^2\,\dot{\phi}^2 + r^2\,\dot{\lambda}\,(\dot{\lambda} + 2\,\Omega)\cos^2\phi], \tag{15.95}$$

which is the kinetic energy absent the contribution from the centrifugal acceleration from the rigid-body planetary rotation. It is notable that K^{truncate} is not guaranteed to be non-negative. In equation (15.94d) we also introduced the geopotential for a rotating spherical planet

$$\Phi(r,\phi) = g_{\mathrm{e}}\,r - (1/2)\,\Omega^2\,r^2\cos^2\phi, \tag{15.96}$$

which we discussed in Section (13.10.4). In particular, surfaces of constant geopotential have larger radius at the equator than at the pole, which characterizes the earth's oblate spheroidal shape.

The Lagrange multiplier and Euler-Lagrange equations

Introducing a Lagrange multiplier to enforce the constraint of motion on a constant geopotential leads to the modified Lagrangian

$$L^* = L + \Lambda\,m\,(\Phi - \Phi^{\mathrm{const}}) = K^{\mathrm{truncate}} - m\,\Phi\,(1 - \Lambda) - \Lambda\,m\,\Phi^{\mathrm{const}}, \tag{15.97}$$

where Φ^{const} is a constant. The corresponding Euler-Lagrange equations of motion are

$$\ddot{r} = r\,\dot{\phi}^2 + r\,\dot{\lambda}\,(\dot{\lambda} + 2\,\Omega)\cos^2\phi - (1-\Lambda)\,\partial\Phi/\partial r \tag{15.98a}$$

$$\frac{\mathrm{d}(r^2\,\dot{\phi})}{\mathrm{d}t} = -r^2\,\dot{\lambda}\,(\dot{\lambda} + 2\,\Omega)\cos\phi\sin\phi - (1-\Lambda)\,\partial\Phi/\partial\phi \tag{15.98b}$$

$$\frac{\mathrm{d}(r^2\,(\dot{\lambda} + \Omega)\cos^2\phi)}{\mathrm{d}t} = 0 \tag{15.98c}$$

$$\Phi = \Phi^{\text{const}}. \tag{15.98d}$$

In the absence of planetary rotation, with $\Omega = 0$, equations (15.98a)–(15.98d) reduce to the Euler-Lagrange equations (15.84a)–(15.84d) for motion around the non-rotating sphere. Furthermore, with some work, and in the absence of the geopotential constraint (i.e., $\Lambda = 0$), we can massage these equations to agree with the spherical coordinate equations (13.134)–(13.136) describing motion around a rotating sphere and derived using Newtonian methods.

Energy constants of the motion

Because the Lagrangian and the gravitational potential energy both have no explicit time dependence, the Hamiltonian, H, is a constant of the motion (see Section 12.9.4), where

$$H = K + m\,g_{\text{e}}\,r = K^{\text{truncate}} + (m/2)\,\Omega^2\,r^2\cos^2\phi + m\,g_{\text{e}}\,r = K^{\text{truncate}} + m\,\Phi + m\,\Omega^2\,r^2\cos^2\phi. \tag{15.99}$$

With the motion constrained to maintain a constant geopotential, $\dot{\Phi} = 0$ and $\dot{H} = 0$, then

$$\frac{\mathrm{d}(K + m\,g_{\text{e}}\,r)}{\mathrm{d}t} = 0 \quad \text{and} \quad \frac{\mathrm{d}(K^{\text{truncate}} + m\,\Omega^2\,r^2\cos^2\phi)}{\mathrm{d}t} = 0. \tag{15.100}$$

In contrast to the case of motion around a non-rotating sphere studied in Section 15.4.4, the kinetic energy is here not a constant of the motion since the particle is not constrained to a constant spherical radius, $\dot{r} \neq 0$. Rather, the particle is constrained to a constant geopotential, which has an oblate spheroidal shape. This facet of the motion adds complexity to the description, which we alleviate in Section 15.5.2 by moving to geopotential coordinates. Until then, it is useful to offer some more details of the spherical coordinate formulation.

Velocity on the geopotential

Motion along the geopotential means that

$$\dot{\boldsymbol{X}} \cdot \nabla\Phi = 0, \tag{15.101}$$

so that the particle velocity is directed parallel to the geopotential surface. Writing the velocity in spherical coordinates according to equation (13.46d)

$$\dot{\boldsymbol{X}} = r\cos\phi\,(\dot{\lambda} + \Omega)\,\hat{\boldsymbol{\lambda}} + r\,\dot{\phi}\,\hat{\boldsymbol{\phi}} + \dot{r}\,\hat{\boldsymbol{r}}, \tag{15.102}$$

and using the spherical coordinate gradient operator (10.54)

$$\nabla = \hat{\boldsymbol{\lambda}}\,(r\,\cos\phi)^{-1}\,\partial_\lambda + \hat{\boldsymbol{\phi}}\,r^{-1}\,\partial_\phi + \hat{\boldsymbol{r}}\,\partial_r, \tag{15.103}$$

renders

$$\dot{\boldsymbol{X}} \cdot \nabla\Phi = \dot{\phi}\,\partial\Phi/\partial\phi + \dot{r}\,\partial\Phi/\partial r = 0, \tag{15.104}$$

which means that

$$r\,\Omega^2\cos\phi\,(r\,\dot\phi\sin\phi - \dot r\cos\phi) + \dot r\,g_{\rm e} = 0. \tag{15.105}$$

Evidently, any radial motion must be accompanied by meridional motion in order to remain on the geopotential. Furthermore, if there is no radial motion then there is no meridional motion, in which case the particle moves along a constant latitude circle.

15.5.2 Oblate spheroidally symmetric earth[4]

The analysis in Section 15.5.1 can be greatly simplified by acknowledging that the earth has evolved to approximate the oblate spheroidal shape of the geopotential (15.96). Following *Veronis* (1973) and *Gill* (1982), and as detailed in Section 13.11.3 (see in particular Figure 13.4), we interpret the radial direction as aligned with the effective gravitational acceleration (central gravity plus planetary centrifugal), so that the geopotential takes on the much simpler form

$$\Phi = g\,r, \tag{15.106}$$

where g is the effective gravitational acceleration and geopotential surfaces are now surfaces of constant r. In this manner the constrained Lagrangian is

$$L = (m/2)\,(\dot r^2 + r^2\,\dot\phi^2 + r^2\,\dot\lambda\,(\dot\lambda + 2\,\Omega)\cos^2\phi) - m\,g\,r + m\,\Lambda\,(\Phi - \Phi^{\rm const}). \tag{15.107}$$

This Lagrangian is nearly the same as for the non-rotating sphere given by equation (15.83), with the exception of the $2\,\Omega$ term. The force of constraint is required to keep the particle moving on a constant geopotential, which here means the particle maintains a fixed $r = R$.

To examine the force of constraint, we generate the Euler-Lagrange equations

$$\ddot r = r\,\dot\phi^2 + r\,\dot\lambda\,(\dot\lambda + 2\,\Omega)\cos^2\phi - (1-\Lambda)\,g \tag{15.108a}$$

$$\frac{{\rm d}(r^2\,\dot\phi)}{{\rm d}t} = -r^2\,\dot\lambda\,(\dot\lambda + 2\,\Omega)\cos\phi\sin\phi \tag{15.108b}$$

$$\frac{{\rm d}(r^2\,(\dot\lambda + \Omega)\cos^2\phi)}{{\rm d}t} = 0 \tag{15.108c}$$

$$\Phi = \Phi^{\rm const} = g\,R. \tag{15.108d}$$

With $r = R$ for the constrained motion, the radial equation (15.108a) allows us to solve for the Lagrange multiplier

$$\Lambda = 1 - (R/g)\,(\dot\phi^2 + \dot\lambda^2\cos^2\phi + 2\,\Omega\,\dot\lambda\cos^2\phi) = 1 - g^{-1}\,(A^{\rm centrifugal} + A^{\rm coriolis}), \tag{15.109}$$

where we introduced the centrifugal acceleration arising from the angular particle motion (as for the non-rotating sphere in equation (15.91))

$$A^{\rm centrifugal} = R\,(\dot\phi^2 + \dot\lambda^2\cos^2\phi), \tag{15.110}$$

as well as the Coriolis acceleration

$$A^{\rm coriolis} = 2\,\Omega\,R\,\dot\lambda\cos^2\phi, \tag{15.111}$$

which is positive for eastward motion and negative if westward. The force of constraint is thus

[4]The analysis in this section is inspired by *Early* (2012).

given by

$$Q_r = \Lambda \frac{\partial P}{\partial r} = m\, g\, [1 - (A^{\text{centrifugal}} + A^{\text{coriolis}})/g]. \tag{15.112}$$

Compared to the non-rotating case in equation (15.92), we here see the inclusion of the Coriolis acceleration contribution as well as the minor difference between g_{e} and g.

15.5.3 An f-plane geopotential surface

We now return to planar symmetry as in Section 15.4.3, here examining motion of a particle as viewed in a rotating reference frame with constant angular rotation rate, $(f/2)\,\hat{\boldsymbol{z}}$. Furthermore, we assume the motion is on an f-plane (Section 25.5), which means that surfaces of constant geopotential from Section 15.5.2 are now approximated as horizontal, and it is only the vertical component of planetary rotation that is considered.

This particle has a kinetic energy

$$K = (m/2)\,(\dot{x}_{\text{I}}^2 + \dot{y}_{\text{I}}^2 + \dot{z}_{\text{I}}^2) = (m/2)\,[(\dot{x} - f\,y/2)^2 + (\dot{y} + f\,x/2)^2 + \dot{z}^2], \tag{15.113}$$

where

$$\dot{X}_{\text{I}} = \dot{\boldsymbol{X}} + (f/2)\,\hat{\boldsymbol{z}} \times \boldsymbol{X} \tag{15.114}$$

relates the velocity measured in the inertial reference frame, $\dot{\boldsymbol{X}}_{\text{I}}$, to the velocity, $\dot{\boldsymbol{X}}$, measured in the rotating reference frame. Expanding the kinetic energy leads to

$$K = (m/2)\,[\dot{x}\,(\dot{x} - f\,y) + \dot{y}\,(\dot{y} + f\,x) + \dot{z}^2] + (m/2)\,(f/2)^2\,(x^2 + y^2). \tag{15.115}$$

We are thus led to the Lagrangian

$$L^{\text{cartesian}} = (m/2)\,[\dot{x}\,(\dot{x} - f\,y) + \dot{y}\,(\dot{y} + f\,x) + \dot{z}^2] - m\,\Phi^{\text{parabolic}}, \tag{15.116}$$

where we introduced the geopotential

$$\Phi^{\text{parabolic}} = g_{\text{e}}\,z - (1/2)\,(f/2)^2\,(x^2 + y^2), \tag{15.117}$$

whose isosurfaces are parabolic.

Following the geopotential coordinate approach from Section 15.5.2, we reinterpret the local vertical direction as perpendicular to surfaces of constant $\Phi^{\text{parabolic}}$, in which case the Lagrangian (15.116) simplifies to

$$L = (m/2)\,[\dot{x}\,(\dot{x} - f\,y) + \dot{y}\,(\dot{y} + f\,x) + \dot{z}^2] - m\,\Phi, \tag{15.118}$$

with the geopotential

$$\Phi = g\,z. \tag{15.119}$$

To constrain the particle motion to remain on a constant geopotential, $\Phi = \Phi^{\text{const}}$, we introduce a Lagrange multiplier to produce the modified Lagrangian

$$L^* = (m/2)\,[\dot{x}\,(\dot{x} - f\,y) + \dot{y}\,(\dot{y} + f\,x) + \dot{z}^2] - m\,\Phi + \Lambda\,(\Phi - \Phi^{\text{const}}), \tag{15.120}$$

which generates the Euler-Lagrange equations

$$\frac{\mathrm{d}(\dot{x} - f\,y)}{\mathrm{d}t} = 0 \tag{15.121a}$$

$$\frac{\mathrm{d}(\dot{y} + f\,x)}{\mathrm{d}t} = 0 \tag{15.121b}$$

$$\frac{\mathrm{d}\dot{z}}{\mathrm{d}t} = -(1 - \Lambda)\,g \tag{15.121c}$$

$$\Phi = \Phi^{\text{const}}. \tag{15.121d}$$

To maintain zero vertical acceleration requires a unit Lagrange multiplier

$$\Lambda = 1, \tag{15.122}$$

which was also found in Section 15.4.3 for motion on a flat non-rotating plane. As for that case, we here find that the force of constraint must exactly balance the weight of the particle. Contrary to the full earth case in Section 15.5.2, there is no contribution to the force of constraint from the Coriolis acceleration. The reason is that we here only consider the local vertical component of the earth's rotation, whereas in Section 15.5.2 we made no such approximation.

The horizontal equations of motion (15.121a) and (15.121b) describe the f-plane inertial oscillations studied in Section 14.5. This horizontal motion is that of a free particle on an f-plane and as observed in the rotating reference frame. Consistent with the motion being free in the horizontal, it maintains a constant kinetic energy

$$K = m\,(\dot{x}^2 + \dot{y}^2)/2 \quad \text{and} \quad \dot{K} = m\,(\dot{x}\,\ddot{x} + \dot{y}\,\ddot{y}) = m\,f\,(\dot{x}\,\dot{y} - \dot{y}\,\dot{x}) = 0. \tag{15.123}$$

15.6 Simple harmonic oscillator

We here study the mechanics of *simple harmonic oscillators*. We start with the case of a single harmonic oscillator and then consider a line of coupled oscillators. We take the continuum limit of the coupled oscillators, thus providing a platform for introducing longitudinal waves, such as the acoustic waves studied in Chapter 49, as well as the use of Lagrangian mechanics for continuous media.

15.6.1 Physical picture

Consider a tiny piece of matter (idealized as a point) with constant mass, m. Assume this mass is constrained to move along one direction on a frictionless table. Equivalently, assume the mass moves in one direction a vacuum without any gravity field. Let the coordinate position, x, of the mass be measured by the trajectory, $x = X(t)$, and apply a horizontal force to the mass that is a function just of the position, $F(x)$. Newton's equation of motion for the point mass is given by

$$m\,\ddot{X} = F(x), \tag{15.124}$$

where $F(x)$ is evaluated at the horizontal position of the mass, $x = X(t)$. Now assume the point mass only moves a small distance from its equilibrium position, $x = \Delta$, which is defined by the position where the force vanishes, $F(\Delta) = 0$. We thus approximate the horizontal force by its leading order Taylor expansion

$$F(x) \approx F(\Delta) + (x - \Delta)\left[\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right]_{x=\Delta} = (x - \Delta)\left[\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right]_{x=\Delta}, \tag{15.125}$$

where higher order terms are dropped, and we set $F(\Delta) = 0$.

15.6.2 Oscillations from a Hooke's law restoring force

FIGURE 15.3: A simple harmonic oscillator as realized by an object of fixed mass m (approximated as a point mass) attached to a massless spring with motion in just one direction. The only force acting on the mass arises from the spring, whose spring constant, Γ, is constant. The trajectory of the point mass, $X(t) = \Delta + \xi(t)$, measures the position relative to the wall on the left, with Δ the equilibrium position (where the spring force vanishes), and $\xi(t)$ the displacement from the equilibrium position. We here depict the system where the spring is extended to the right so that $\xi(t) > 0$. In this case, the restoring force from the spring accelerates the mass to the left.

Now specialize the force to be restorative so that

$$F(x) = -\Gamma\,(x - \Delta) \quad \text{with} \quad \Gamma = \left[\frac{\mathrm{d}F(x)}{\mathrm{d}x}\right]_{x=\Delta} > 0. \tag{15.126}$$

This linear force provides the canonical *Hooke's law* force, such as realized by an idealized massless spring as depicted in Figure 15.3.[5] Introducing the displacement relative to an equilibrium position (see Figure 15.3)

$$\xi(t) = X(t) - \Delta, \tag{15.127}$$

along with the Hooke's law restoring force (15.126), we find Newton's law for the particle trajectory takes the form of the linear *oscillator equation*

$$m\,\ddot{X} + \Gamma\,(X - \Delta) = m\,\ddot{\xi} + \Gamma\,\xi = 0 \Longrightarrow \ddot{\xi} + \omega_0^2\,\xi = 0 \quad \text{with} \quad \omega_0^2 = \Gamma/m. \tag{15.128}$$

A solution to the oscillator equation can be written

$$X(t) - \Delta = \xi(t) = A\cos(\omega_0\,t + \alpha), \tag{15.129}$$

where A is the oscillation amplitude and α a phase shift, with both A and α time independent and specified by initial conditions. We thus find that the Hooke's law restoring force leads to an oscillatory trajectory (15.129) centered on the equilibrium position, $x = \Delta$. The angular frequency, ω_0, determines the period of oscillation according to

$$T^{\text{per}} = 2\pi/\omega_0 = 2\pi\,(m/\Gamma)^{1/2}. \tag{15.130}$$

The period increases with the square root of the mass (longer period for larger mass) and decreases with the square root of the Hooke's law restoring constant (shorter period for larger Hooke's law constant).

15.6.3 Hamiltonian as a constant of the motion

The Hooke's law force has no explicit dependence on time, $\partial F/\partial t = 0$, so that the oscillating point mass has no concern for the time origin. From our discussion of time symmetry in Section 12.9.4,

[5] We encounter a more complex example of Hooke's law in Section 26.8 when studying the relation between stress and strain rate for viscous fluids.

we know that the simple harmonic oscillator maintains a constant Hamiltonian, which is here also equal to the mechanical energy. A constancy of the Hamiltonian via Noether's theorem then means that the oscillator exchanges mechanical energy between its kinetic energy and potential energy while holding their sum constant.

Potential energy and kinetic energy of the oscillator

During its motion, the point mass experiences work done by the spring and this work is given by

$$W = -\int_{\Delta}^{\Delta+\xi} F\,\mathrm{d}x = \Gamma \int_{\Delta}^{\Delta+\xi} (x-\Delta)\,\mathrm{d}x = \Gamma\,\xi^2/2. \tag{15.131}$$

This work to displace the mass renders a potential energy for the point mass relative to the zero potential energy it possesses when located at its equilibrium position with $\xi = 0$. Through the work-energy theorem from Section 11.1.4, we find that temporal changes in the potential energy are associated with temporal changes in kinetic energy

$$W = -m\int_{\Delta}^{\Delta+\xi} \ddot{X}\,\mathrm{d}x = -m\int_{t_0}^{t} \ddot{X}\,\dot{X}\,\mathrm{d}t = -\frac{m}{2}\int_{t_0}^{t} \frac{\mathrm{d}\dot{X}^2}{\mathrm{d}t}\,\mathrm{d}t = -K(t) + K(t_0), \tag{15.132}$$

where

$$K = m\,\dot{X}^2/2 = m\,\dot{\xi}^2/2 \tag{15.133}$$

is the kinetic energy for the oscillating particle. Hence, as the point mass oscillates, changes to its potential energy are exactly compensated by equal and opposite changes to its kinetic energy, thus reflecting the constant mechanical energy for the harmonic oscillator. Another way to see that the mechanical energy remains constant is to note that the sum of the potential plus kinetic energies has a zero time derivative

$$(\mathrm{d}/\mathrm{d}t)\,[m\,\dot{\xi}^2 + \Gamma\,\xi^2]/2 = \dot{\xi}\,[m\,\ddot{\xi} + \Gamma\,\xi] = 0, \tag{15.134}$$

where the final equality made use of the equation of motion (15.128). Indeed, making use of the trajectory (15.129) we readily see that the mechanical energy is given by the constant

$$[m\,\dot{\xi}^2 + \Gamma\,\xi^2]/2 = (A^2/2)\,[m\,\omega_0^2\sin^2(\omega_0\,t+\alpha) + \Gamma\cos^2(\omega_0\,t+\alpha)] = \Gamma\,A^2/2, \tag{15.135}$$

where we set $\omega_0^2 = \Gamma/m$ as per equation (15.128). The total energy is thus proportional to the square of the amplitude and linearly proportional to the Hooke's law constant.

15.6.4 Equipartition of time averaged energies

When time averaged over a single oscillation period of length $2\pi/\omega_0$, the averaged kinetic energy and potential energy are identical

$$\frac{\omega_0}{2\pi}\int_0^{2\pi/\omega_0} (m\,\dot{\xi}^2/2)\,\mathrm{d}t = \Gamma\,A^2/4 \tag{15.136a}$$

$$\frac{\omega_0}{2\pi}\int_0^{2\pi/\omega_0} (\Gamma\,\xi^2/2)\,\mathrm{d}t = \Gamma\,A^2/4. \tag{15.136b}$$

Energy equipartition means that within a single oscillation period, there is an exact exchange between kinetic energy and potential energy, so that their time averages are identical.

Energy equipartition is a rather generic property of linear oscillating systems, and we encounter

it again for linear waves, such as the acoustic waves in Section 49.6.2. It follows as a general result of the *virial theorem* proved in Section 12.7.3. In particular, it holds for systems in which the potential energy is a homogeneous function of degree two (see Section 12.7.1).

15.6.5 Lagrangian formulation

Having established the potential energy (15.131) for the oscillator, we can write the Lagrangian as

$$L = m\,\dot{\xi}^2/2 - \Gamma\,\xi^2, \tag{15.137}$$

with ξ a suitable generalized coordinate that captures the single degree of freedom for the oscillator. The Euler-Lagrange equation is

$$\frac{\mathrm{d}}{\mathrm{d}t}\frac{\partial L}{\partial \dot{\xi}} = \frac{\partial L}{\partial \xi} \Longrightarrow \ddot{\xi} + \omega_0^2\,\xi = 0, \tag{15.138}$$

which is the same as equation (15.128) derived from Newtonian methods.

15.6.6 Further study

The study of harmonic oscillators can be found in most classical mechanics texts, with our treatment following Sections 3.1 and 3.2 of *Marion and Thornton* (1988).

15.7 Coupled harmonic oscillators

We here extend the study of a single harmonic oscillator in Section 15.6 to the case of N identical frictionless point mass particles connected by massless linear Hooke's law springs with identical spring constant, Γ. Let

$$X_{\mathrm{n}}(t) = \mathrm{n}\,\Delta + \xi_{\mathrm{n}}(t) \tag{15.139}$$

be the position of particle n relative to the left-most rigid wall, with $x = \mathrm{n}\,\Delta$ the equilibrium position for particle n and $\xi_{\mathrm{n}}(t)$ the displacement of the particle at time t from its equilibrium. The ξ_{n} displacements serve as generalized coordinates for this system with N degrees of freedom.[6]

FIGURE 15.4: A line of $N = 7$ coupled simple harmonic oscillators as realized by identical point objects with fixed mass, m, each attached to two massless springs and moving in one direction. The only horizontal force acting on the masses arises from the springs, each with identical spring constants, Γ, and equilibrium length, Δ. The trajectory of any particular mass, $X_{\mathrm{n}}(t)$, measures the position relative to the equilibrium at $X_{\mathrm{n}}(t) = 0$, where the force from the springs vanishes. The system is here shown in its equilibrium where the distance between each mass is Δ, and the displacments all vanish, $\xi_{\mathrm{n}} = 0$. Each point mass is attached to two springs, with the end springs attached to a rigid wall.

[6] In Section 12.4.1 that we wrote $X_{(i)}$ for the Cartesian position of particle i. This notation is important to distinguish the particle label from a tensor index. In this section, we instead use the upright n to write X_{n} to distinguish the particle label, n, from a tensor index, n. Additionally, in this section we are only concerned with motion along a single direction, so that any label is a particle label.

To develop the equation of motion, observe that the force acting on a particle is comprised of two terms associated with the two springs, one on the left and one on the right. Consider first the end particles where one of its springs is attached to a rigid wall. For convenience, we label a point at the left wall as $\mathrm{n} = 0$ and $\mathrm{n} = N + 1$ for a point on the right wall. For the $\mathrm{n} = 1$ mass we have the force from the left spring given by

$$F_{\mathrm{n}=0\to\mathrm{n}=1} = -\Gamma\,\xi_1, \tag{15.140}$$

just as for a single harmonic oscillator considered in Section 15.6.2. The force on particle 1 from the right spring is given by

$$F_{\mathrm{n}=2\to\mathrm{n}=1} = -\Gamma\,(\xi_1 - \xi_2). \tag{15.141}$$

We understand the nature of this force by noting that if $\xi_1 > 0$ then the spring is compressed to the right, so that the restoring force is to the left as the spring expands. Conversely, if $\xi_2 > 0$ then the spring is expanded to the right, in which case the particle is itself accelerated to the right. Hence, the equation of motion for this mass is given by

$$m\,\ddot{\xi}_1 = -\Gamma\,\xi_1 - \Gamma\,(\xi_1 - \xi_2). \tag{15.142}$$

Anticipating the force balance that acts on the interior masses, we introduce two dummy deviations, each with fixed value of zero,

$$\xi_0 \equiv 0 \quad \text{and} \quad \xi_{N+1} \equiv 0. \tag{15.143}$$

We thus have the equation of motion for the $\mathrm{n} = 1$ point mass given by

$$M\,\ddot{\xi}_1 = -\Gamma\,(\xi_1 - \xi_0) - \Gamma\,(\xi_1 - \xi_2), \tag{15.144}$$

and analogous considerations hold for the $\mathrm{n} = N$ point mass

$$m\,\ddot{\xi}_N = -\Gamma\,(\xi_N - \xi_{N-1}) - \Gamma\,(\xi_N - \xi_{N+1}). \tag{15.145}$$

The interior masses have analogous equations so that the generic equation of motion for particles $\mathrm{n} = 1, N$ is given by

$$m\,\ddot{\xi}_{\mathrm{n}} = -\Gamma\,(\xi_{\mathrm{n}} - \xi_{\mathrm{n}-1}) - \Gamma\,(\xi_{\mathrm{n}} - \xi_{\mathrm{n}+1}) \Longrightarrow \ddot{\xi}_{\mathrm{n}} = \omega_0^2\,(\xi_{\mathrm{n}+1} - 2\,\xi_{\mathrm{n}} + \xi_{\mathrm{n}-1}). \tag{15.146}$$

It is useful to write the case for $N = 2$ oscillators for reference

$$\ddot{\xi}_1 = \omega_0^2\,(-2\,\xi_1 + \xi_2) \tag{15.147a}$$
$$\ddot{\xi}_2 = \omega_0^2\,(-2\,\xi_2 + \xi_1), \tag{15.147b}$$

as well as for $N = 3$ oscillators

$$\ddot{\xi}_1 = \omega_0^2\,(-2\,\xi_1 + \xi_2) \tag{15.148a}$$
$$\ddot{\xi}_2 = \omega_0^2\,(\xi_3 - 2\,\xi_2 + \xi_1) \tag{15.148b}$$
$$\ddot{\xi}_3 = \omega_0^2\,(-2\,\xi_3 + \xi_2). \tag{15.148c}$$

15.7.1 Mechanical energy for coupled oscillators

Following our discussion of mechanical energy for a single oscillator in Section 15.6.3, we multiply the equation of motion (15.146) by $\dot{\xi}_{\mathrm{n}}$ and sum over the $\mathrm{n} = 1, N$ oscillators. The acceleration

term leads to the time change for the total kinetic energy of the full coupled oscillator system

$$m\sum_{\mathrm{n}=1}^{N}\dot{\xi}_{\mathrm{n}}\,\ddot{\xi}_{\mathrm{n}}=\frac{m}{2}\sum_{\mathrm{n}=1}^{N}\frac{\mathrm{d}\dot{\xi}_{\mathrm{n}}^{2}}{\mathrm{d}t}. \tag{15.149}$$

Summation over the left portion of the force in equation (15.146) can be written

$$\sum_{\mathrm{n}=1}^{N}\dot{\xi}_{\mathrm{n}}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})=\sum_{\mathrm{n}=1}^{N+1}\dot{\xi}_{\mathrm{n}}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1}), \tag{15.150}$$

which follows since $\xi_{N+1}\equiv 0$ so that the extra term in the summation vanishes. The summation over the right portion of the force in equation (15.146) can be written

$$\sum_{\mathrm{n}=1}^{N}\dot{\xi}_{\mathrm{n}}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}+1})=\sum_{\mathrm{n}=2}^{N+1}\dot{\xi}_{\mathrm{n}-1}\,(\xi_{\mathrm{n}-1}-\xi_{\mathrm{n}})=\sum_{\mathrm{n}=1}^{N+1}\dot{\xi}_{\mathrm{n}-1}\,(\xi_{\mathrm{n}-1}-\xi_{\mathrm{n}}). \tag{15.151}$$

To reach the first equality we changed indices on the terms in the summation, and modified the summation limits accordingly. For the second equality we expanded the summation range by noting that $\xi_0\equiv 0$, thus allowing us to bring the lower summation limit from $\mathrm{n}=2$ to $\mathrm{n}=1$. Combining equations (15.150) and (15.151) leads to

$$\Gamma\sum_{\mathrm{n}=1}^{N}\dot{\xi}_{\mathrm{n}}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})+\Gamma\sum_{\mathrm{n}=1}^{N}\dot{\xi}_{\mathrm{n}}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}+1})=\frac{\Gamma}{2}\frac{\mathrm{d}}{\mathrm{d}t}\sum_{\mathrm{n}=1}^{N+1}(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})^{2}, \tag{15.152}$$

which is the time derivative of the potential energy, P, arising from the expansion and contraction of the Hooke's law springs, where

$$P=\frac{\Gamma}{2}\sum_{\mathrm{n}=1}^{N+1}(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})^{2}=\frac{\Gamma}{2}\left[\xi_{1}^{2}+\sum_{\mathrm{n}=2}^{N}(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})^{2}+\xi_{N}^{2}\right], \tag{15.153}$$

where we set $\xi_0=0$ and $\xi_{N+1}=0$.

Bringing the kinetic energy and potential energy together leads to the conservation of mechanical energy for the coupled oscillator system

$$\frac{\mathrm{d}}{\mathrm{d}t}\sum_{\mathrm{n}=1}^{N+1}\left[\frac{m}{2}\,\dot{\xi}_{\mathrm{n}}^{2}+\frac{\Gamma}{2}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})^{2}\right]=0. \tag{15.154}$$

Just as for the single oscillator, we see that the coupled oscillator system maintains a fixed mechanical energy in which energy is exchanged between kinetic and potential energy reservoirs.

15.7.2 Lagrangian formulation

The Lagrangian for the coupled oscillator system is given by

$$L=\sum_{\mathrm{n}=1}^{N+1}\left[\frac{m}{2}\,(\dot{\xi}_{\mathrm{n}})^{2}-\frac{\Gamma}{2}\,(\xi_{\mathrm{n}}-\xi_{\mathrm{n}-1})^{2}\right]. \tag{15.155}$$

To derive the Euler-Lagrange equations we require the following derivatives

$$\frac{\partial L}{\partial \dot{\xi}_{\mathrm{p}}} = m \sum_{\mathrm{n}=1}^{N+1} \dot{\xi}_{\mathrm{n}}\, \delta_{\mathrm{n,p}} = m\, \dot{\xi}_{\mathrm{p}}, \tag{15.156a}$$

$$\frac{\partial L}{\partial \xi_{\mathrm{p}}} = \Gamma \sum_{\mathrm{n}=1}^{N+1} (\xi_{\mathrm{n}} - \xi_{\mathrm{n}-1})\, (\delta_{\mathrm{n,p}} - \delta_{\mathrm{n}-1,\mathrm{p}}) = -\Gamma\, (\xi_{\mathrm{p}+1} - 2\, \xi_{\mathrm{p}} + \xi_{\mathrm{p}-1}), \tag{15.156b}$$

which lead to the Euler-Lagrange equation

$$\ddot{\xi}_{\mathrm{p}} = \omega_0^2\, (\xi_{\mathrm{p}+1} - 2\, \xi_{\mathrm{p}} + \xi_{\mathrm{p}-1}). \tag{15.157}$$

As expected, the Euler-Lagrange equation of motion agrees with Newton's equation (15.146) derived using Newtonian methods.

15.7.3 Further study

Our presentation of coupled harmonic oscillators was inspired by Section 24 of *Fetter and Walecka* (2003), though we made use of a kinematic treatment anticipating the generalized Lagrangian mean approach used in fluid mechanics and introduced in Section 65.3.

15.8 Exercises

EXERCISE 15.1: CONSERVATION OF ENERGY FOR THE FOUCAULT PENDULUM
Using the Euler-Lagrange equations of motion (15.60) and (15.62), show that $\dot{H} = 0$ for the Foucault pendulum, where the Hamiltonian is given by equation (15.63).

Chapter 16

Lagrangian field theory

In this chapter we introduce elements of *classical field theory* from a Lagrangian perspective. We motivate the study of *Lagrangian continuum mechanics* by considering the continuum limit for a system of coupled harmonic oscillators. This limit provides the canonical example of how to extend Lagrangian particle mechanics to Lagrangian continuum mechanics. The continuum expression of Lagrangian mechanics and Hamilton's principle, and the associated continuum *Euler-Lagrange field equations*, are the foundations for both classical and quantum field theory. In particular, it provides a formalism to understand the origin of continuum conservation laws (e.g., momentum, energy, vorticity) that are central to a continuum description of fluid motion.

CHAPTER GUIDE

This chapter relies on the formulation of Lagrangian mechanics and Hamilton's principle from Chapterd 12 and 15. We follow standard treatments from *Fetter and Walecka* (2003) (chapters 4, 6, and 8), chapter 12 of *Goldstein* (1980), and chapter 9 of *José and Saletan* (1998).

16.2 Continuum limit of coupled harmonic oscillators

Further study of the discrete coupled oscillator system from Section 15.7 involves the introduction of discrete normal modes and the examination of energy moving through discrete waves (e.g., see Section 24 of *Fetter and Walecka* (2003)). However, that analysis takes us somewhat outside the main topic of this book. Instead, we here examine the continuum limit of the oscillator system. The purpose of this study is to extend discrete Lagrangian mechanics and Hamilton's principle to the continuum, thus providing a direct connection to fluid mechanics and classical field theory.

16.2.1 Continuum limit

We continue to work in a classical physical system, so that we have no concern for the quantum nature of molecular and atomic matter constituents. As such, the continuum limit is here considered as a mere mathematical transition from discrete classical matter to continuous classical matter. This approach is physically naive in the face of quantum mechanics. Even so, it provides a suitable mathematical framework for studying the classical mechanics of continuous media, and as such it serves the needs of this book. We further discuss the physical basis for the continuum limit in Chapter 17.

The continuum limit for the coupled harmonic oscillator system is realized by the following:

$$\Delta \to \mathrm{d}x \qquad \text{equilibrium distance betwen particles becomes infinitesimal} \tag{16.1a}$$

$$N \to \infty \qquad \text{infinite number of particles} \tag{16.1b}$$

$$(\mathrm{N}+1)\,\Delta = \ell \qquad \text{equilibrium length remains constant} \tag{16.1c}$$

$$m/\Delta = \sigma \qquad \text{mass per length} \tag{16.1d}$$

$$\Gamma\,\Delta = \tau \qquad \text{compressive/expansive force} \tag{16.1e}$$

$$\mathrm{n}\,\Delta = x \qquad \text{continuous coordinate for equilibrium position} \tag{16.1f}$$

$$\xi_{\mathrm{n}}(t) \to \xi(x,t) \qquad \text{displacement becomes function of space and time.} \tag{16.1g}$$

The displacement function, $\xi(x,t)$, measures the displacement of an infinitesimal piece of matter whose equilibrium position is x. As such, the coordinate x acts as a parameter that labels an infinitesimal piece of matter whose equilibrium position is x and whose instantaneous position is $x + \xi(x,t)$.[1]

We take the continuum limit starting from two different points. First we focus on the equation of motion (15.146) for the coupled oscillators, which is the topic of Section 16.2.2. Alternatively, we take the continuum limit of the Lagrangian and then derive the corresponding Euler-Lagrange equations, with this approach considered in Section 16.2.3.

[1] The displacement field, $\xi(x,t)$, is a one-dimensional version of the vector field, $\boldsymbol{\xi}(\boldsymbol{x},t)$, used for the *generalized Lagrangian mean* of Section 65.3.

16.2.2 Continuum limit and the wave equation

Introducing the above notation, yet without taking the continuum limit, brings the coupled oscillator equation (15.146) into the form

$$\ddot{\xi}_{\mathrm{n}} = \frac{\Gamma}{m}\left(\xi_{\mathrm{n}+1} - 2\,\xi_{\mathrm{n}} + \xi_{\mathrm{n}-1}\right) \tag{16.2a}$$

$$= \frac{\Gamma\,\Delta}{m/\Delta}\,\frac{\xi_{\mathrm{n}+1} - 2\,\xi_{\mathrm{n}} + \xi_{\mathrm{n}-1}}{\Delta^2} \tag{16.2b}$$

$$= \frac{\tau}{\sigma}\left[\frac{\xi_{\mathrm{n}+1} - 2\,\xi_{\mathrm{n}} + \xi_{\mathrm{n}-1}}{\Delta^2}\right]. \tag{16.2c}$$

To take the continuum limit, note that the finite difference on the right hand side approximates the second order spatial derivative operator, so that in the continuum limit we recover the one dimensional *wave equation*

$$(\partial_{tt} - c^2\,\partial_{xx})\,\xi = 0, \tag{16.3}$$

with the wave speed given by

$$c = (\tau/\sigma)^{1/2}. \tag{16.4}$$

We studied the mathematics of the wave equation (16.3) in Section 3.6 in the context of hyperbolic partial differential equations. A general solution is given by

$$\xi(x,t) = A(x - c\,t) + B(x + c\,t), \tag{16.5}$$

where A and B are arbitrary smooth functions determined by the initial conditions and boundary conditions. The solution $A(x - c\,t)$ is a signal moving in the $+\hat{\boldsymbol{x}}$ direction, whereas $B(x - c\,t)$ is a signal moving in the $-\hat{\boldsymbol{x}}$ direction, both moving at speed c.

We have restricted attention to motion constrained to a line whereby the harmonic oscillators render a series of alternative rarefactions and compressions that lead to wave-like motions along that line. Upon taking the continuum limit, we find that each piece of the continuum oscillates about its equilibrium position, again with the oscillations in a direction aligned with the waves. Such motions are the defining characteristic of *longitudinal waves*. The longitudinal waves resulting from the continuum limit of coupled harmonic oscillators offers a prototype for the acoustic waves studied in Chapter 49.

16.2.3 Continuum limit of the Lagrangian

Rather than taking the continuum limit of the equation of motion as in Section 16.2.2, we here consider the continuum limit of the Lagrangian and then derive the corresponding Euler-Lagrange equation of motion. This approach accords with the methods of classical field theory and it will serve many purposes in this book.

Recall the discrete Lagrangian given by equation (15.155)

$$L = \sum_{\mathrm{n}=1}^{N+1}\left[\frac{m}{2}\,(\dot{\xi}_{\mathrm{n}})^2 - \frac{\Gamma}{2}\,(\xi_{\mathrm{n}} - \xi_{\mathrm{n}-1})^2\right]. \tag{16.6}$$

The continuum limit from Section 16.2.2 brings the kinetic energy to

$$\frac{m}{2}\sum_{\mathrm{n}=1}^{N+1}(\dot{\xi}_{\mathrm{n}})^2 = \frac{\sigma}{2}\sum_{\mathrm{n}=1}^{N+1}(\dot{\xi}_{\mathrm{n}})^2\,\Delta \longrightarrow \frac{\sigma}{2}\int_0^{\ell}(\partial_t\xi)^2\,\mathrm{d}x, \tag{16.7}$$

where we set $m = \sigma\,\Delta$ according to equation (16.1d), and made the correspondence

$$\sum_{\mathrm{n}=1}^{N+1} \Delta \longrightarrow \int_0^\ell \mathrm{d}x. \tag{16.8}$$

Similarly, the continuum limit of the potential energy yields

$$\frac{\Gamma}{2}\sum_{\mathrm{n}=1}^{N+1}(\xi_\mathrm{n} - \xi_{\mathrm{n}-1})^2 = \frac{\Gamma\,\Delta}{2}\sum_{\mathrm{n}=1}^{N+1}\frac{(\xi_\mathrm{n} - \xi_{\mathrm{n}-1})^2}{\Delta^2}\,\Delta \longrightarrow \frac{\tau}{2}\int_0^\ell (\partial_x\xi)^2\,\mathrm{d}x, \tag{16.9}$$

where we set $\Gamma\,\Delta = \tau$ according to equation (16.1e). As a result, the Lagrangian has the continuum limit

$$L = \sum_{\mathrm{n}=1}^{N+1}\left[\frac{m}{2}\,(\dot{\xi}_\mathrm{n})^2 - \frac{\Gamma}{2}\,(\xi_\mathrm{n} - \xi_{\mathrm{n}-1})^2\right] \longrightarrow \frac{1}{2}\int_0^\ell [\sigma\,(\partial_t\xi)^2 - \tau\,(\partial_x\xi)^2]\,\mathrm{d}x \equiv \int_0^\ell \mathcal{L}\,\mathrm{d}x, \tag{16.10}$$

where we defined the *Lagrangian density*

$$\mathcal{L} = [\sigma\,(\partial_t\xi)^2 - \tau\,(\partial_x\xi)^2]/2. \tag{16.11}$$

Now observe that

$$\frac{\partial}{\partial t}\frac{\partial\mathcal{L}}{\partial(\partial_t\xi)} + \frac{\partial}{\partial x}\frac{\partial\mathcal{L}}{\partial(\partial_x\xi)} = \sigma\,\partial_{tt}\xi - \tau\,\partial_{xx}\xi = \sigma\,(\partial_{tt}\xi - c^2\,\partial_{xx}\xi) = 0. \tag{16.12}$$

This result suggests a means to derive the Euler-Lagrange equation using a continuum version of Hamilton's principle, which is the topic of Section 16.3.

16.2.4 Further study

Section 25 of *Fetter and Walecka* (2003) works through the continuum limit of a string, which accords quite closely to the continuum limit of simple harmonic oscillators considered in the present section.

16.3 Hamilton's principle and the Euler-Lagrange equations

The continuum limit considered in Section 16.2 suggests that we can study the mechanics of continuous media using the methods of Lagrangian mechanics and Hamilton's principle, and that we can pursue this approach without concern for the discrete nature of matter. In this section we explore the rudiments of the resulting field theory for scalar fields. Extensions to vector fields are straightforward, as we show when deriving the Euler equations using Hamilton's principle.

16.3.1 The action for a continuous field

In Section 12.6 we applied Hamilton's principle to the trajectories of discrete particles moving through space, with the spatial position specified by generalized coordinates and the position along a trajectory parameterized by time. Hamilton's principle states that the physically realized trajectory is that which makes the action stationary. Here we postulate that Hamilton's principle for point particles can be extended to continuous matter whose mechanics is described by space-time fields. Many steps in the derivation here are extensions of the discrete particle discussion, so much here reflects that earlier presentation.

To pursue this approach, consider a 1+1 dimensional field, $\psi = \psi(x,t)$, that is a function of one space coordinate and time. For example, $\psi(x,t)$ can represent the displacement field, $\xi(x,t)$, introduced by the continuum limit of the oscillators studied in Section 16.2. In this manner, the continuum extension of the discrete particle action defined by equation (12.63) is here given by

$$\mathcal{S} = \int_{t_A}^{t_B} L \, \mathrm{d}t = \int_{t_A}^{t_B} \left[\int_0^{\ell} \mathcal{L}(\psi, \partial_t\psi, \partial_x\psi, x, t) \, \mathrm{d}x \right] \mathrm{d}t, \tag{16.13}$$

where $\mathcal{L}$ is the Lagrangian density and the physical system lives on a finite space domain, $x \in [0, \ell]$, and evolves over the time range, $t \in [t_A, t_B]$. We refer to this space-time domain as R, and its boundary is ∂R. Note the presence of both space and time derivatives inside the action in equation (16.13), as per the use of both space and time as field parameters. Evidently, the Lagrangian density, $\mathcal{L}$, is a functional of the field and its derivatives (i.e., a function of a function), and it is a function of the position in space and time, (x,t). Furthermore, it is an implicit function of (x,t) through its dependence on $\psi(x,t)$ and its derivatives, and it is an explicit function of (x,t) through other prescribed functions that contribute to the Lagrangian. In Section 16.3.8 we emphasize the need to pay careful attention to this functional dependence of the Lagrangian density.

16.3.2 Variation of the field

In the action (16.13), it is the field, $\psi(x,t)$, that is the continuum extension of the generalized coordinates used in the discrete particle mechanics action (12.63). Correspondingly, it is the field that is varied when varying the continuum action.[2] Let $\psi(x,t)$ be the physically realized field and introduce a virtual variation around that field according to

$$\psi(x,t|\epsilon) = \psi(x,t) + \epsilon\, \chi(x,t) = \psi(x,t) + \delta\psi(x,t). \tag{16.14}$$

The first equality introduced a non-dimensional parameter, ϵ, that scales the perturbation field, χ, thus defining a one-parameter family of functions, $\psi(x,t|\epsilon)$. The second equality in equation (16.14) introduced the δ notion commonly used for variations (see Section 12.6). We emphasize that it is the field that is varied, so that the field parameters, (x,t), are the same across the equalities of equation (16.14). Consequently, the δ operator commutes with space and time derivatives.

Figure 16.1 illustrates the field variation (16.14). There is a nonzero variation, $\delta\psi(x,t) = \epsilon\, \chi(x,t)$, for space-time points that are not on the space-time boundary, $(x,t) \notin \partial R$. In contrast, the field is specified along ∂R to be the physically realized field, so that on the space-time boundary there is no variation

$$\delta\psi(x,t) = 0 \quad \forall\, (x,t) \in \partial R \Longleftrightarrow \frac{\partial \psi(x,t|\epsilon)}{\partial \epsilon} = 0 \quad \forall\, (x,t) \in \partial R. \tag{16.15}$$

[2]There are some authors, such as section 3.2 of *Ryder* (1985), who vary the field as well as the space-time point. Doing so combines the derivation of the Euler-Lagrange field equations with derivation of the Noether theorem conservation laws. We choose to keep the derivations separate to accord with the standard practice in discrete particle mechanics.

FIGURE 16.1: Illustrating the variation of a field for use in Hamilton's principle for continuous media. The field, $\psi(x, t)$, is specified along the boundary of the domain, ∂R, where R is the space domain $x \in [0, \ell]$ and time domain $t \in [t_A, t_B]$. When not on ∂R, then there is a nonzero, $\delta\psi(x, t)$, whereas $\delta\psi = 0$ on the boundary, ∂R. This figure is inspired by Figure 25.3 of *Fetter and Walecka* (2003).

16.3.3 Variation of the action

Hamilton's principles says that the physically realized field, $\psi(x, t|\epsilon = 0)$, makes the action stationary, which is mathematically stated as

$$\text{Hamilton's principle} \Longrightarrow \left[\frac{\mathrm{d}\mathcal{S}}{\mathrm{d}\epsilon}\right]_{\epsilon=0} = \left[\frac{\mathrm{d}}{\mathrm{d}\epsilon}\int_R \mathcal{L}\,\mathrm{d}x\,\mathrm{d}t\right]_{\epsilon=0} = 0. \tag{16.16}$$

Making use of the δ shorthand leads to

$$\text{Hamilton's principle} \Longrightarrow \delta\mathcal{S} = \delta\left[\int_R \mathcal{L}\,\mathrm{d}x\,\mathrm{d}t\right] = 0 \quad \text{with} \quad \delta = [\mathrm{d}/\mathrm{d}\epsilon]_{\epsilon=0}\,. \tag{16.17}$$

In varying the action we only vary the field and its derivatives, with the space-time domain, R, unchanged. Hence, the variation operator commutes with the space-time integral

$$\delta\mathcal{S} = \int_R \delta\mathcal{L}\,\mathrm{d}x\,\mathrm{d}t. \tag{16.18}$$

Variation of the Lagrangian density is computed according to the chain rule

$$\delta\mathcal{L} = \left[\frac{\partial\mathcal{L}}{\partial\psi}\right]_{\partial_t\psi,\partial_x\psi}\delta\psi + \left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi}\delta(\partial_t\psi) + \left[\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi}\delta(\partial_x\psi). \tag{16.19}$$

We exposed subscripts to denote which terms are held fixed during the partial functional derivative operation. This equation makes it clear that variation of the Lagrangian density occurs at a fixed space-time point, which explains why there are no $\partial\mathcal{L}/\partial t$ nor $\partial\mathcal{L}/\partial x$ terms. Correspondingly, under this variation we consider (x, t) as space-time parameters so that the ∂_x and ∂_t operators acting on ψ commute with the variation operator

$$\delta\mathcal{L} = \frac{\partial\mathcal{L}}{\partial\psi}\,\delta\psi + \frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\,\partial_t(\delta\psi) + \frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\,\partial_x(\delta\psi). \tag{16.20}$$

Further rearranging the space-time operators leads to the equivalent expression

$$\delta\mathcal{L} = \left[\frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)} - \frac{\partial}{\partial x}\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\right]\delta\psi + \frac{\partial}{\partial t}\left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\,\delta\psi\right] + \frac{\partial}{\partial x}\left[\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\,\delta\psi\right]. \tag{16.21}$$

16.3.4 Euler-Lagrange field equations

Plugging the result (16.21) into the action variation (16.18) leads to

$$\delta\mathcal{S} = \int_R \delta\psi\left[\frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)} - \frac{\partial}{\partial x}\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\right]\mathrm{d}x\,\mathrm{d}t, \tag{16.22}$$

where we set $\delta\psi = 0$ for points on ∂R, which eliminated the total time and space derivative terms. Since $\delta\psi$ is an arbitary variation of the field, $\delta\mathcal{S} = 0$ only if the term in the square bracket vanishes for each space and time point. We thus conclude that Hamilton's principle leads to the continuum *Euler-Lagrange equations*

$$\delta\mathcal{S} = 0 \Longrightarrow \frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right] - \frac{\partial}{\partial x}\left[\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)}\right] = 0. \tag{16.23}$$

A practical point is important to emphasize here. Namely, when performing the partial derivative on $\mathcal{L}$ with respect to ψ and its derivatives, $\partial_t\psi$ and $\partial_x\psi$, each of the other variables in the Lagrangian density are held fixed. However, when performing the space and time partial derivatives, ∂_x and ∂_t, we only maintain the complement space and time variable fixed. We offer more details on these points in Section 16.3.8.

16.3.5 Natural kinematic boundary conditions

As just seen in Section 16.3.4, the Euler-Lagrange field equations arise by setting the field variation, $\delta\psi$, to zero on both the spatial and temporal boundaries. This assumption is typical of many treatments given that it offers a sensible generalization of the discrete case in Section 12.6, in which the variation vanishes at the initial and final times. However, for continuum mechanics the question of spatial boundary conditions is often of primary importance, thus prompting us to question whether setting $\delta\psi = 0$ on the spatial boundaries is necessary.

In particular, consider a situation where the fluid is bounded by a static material boundary, $\partial\mathcal{R}$. All fields, whether the actual physical field or variations around this field, must satisfy the relevant kinematic conditions at material boundaries. In terms of the Lagrangian density, the kinematic boundary condition is given by

$$\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)} = 0 \quad \text{on } \partial\mathcal{R}, \tag{16.24}$$

or its generalization to three dimensions

$$\hat{\boldsymbol{n}}\cdot\frac{\partial\mathcal{L}}{\partial(\nabla\psi)} = n_x\frac{\partial\mathcal{L}}{\partial(\partial_x\psi)} + n_y\frac{\partial\mathcal{L}}{\partial(\partial_y\psi)} + n_z\frac{\partial\mathcal{L}}{\partial(\partial_z\psi)} = 0 \quad \text{on } \partial\mathcal{R}, \tag{16.25}$$

where $\hat{\boldsymbol{n}}$ is the outward normal along $\partial\mathcal{R}$. If this boundary condition is satisfied, then the Euler-Lagrange equation (16.23) follows even without specifying how $\delta\psi$ behaves on the spatial boundaries. The boundary condition (16.25) corresponds to the no normal flow condition holding at static material boundaries, as described in Section 20.4.1. Hence, we refer to equation (16.25) as the *natural kinematic boundary condition* or *natural boundary condition*.

What if the boundary is dynamical, such as occurs in free boundary problems? For example, the boundary could represent the material interface between the ocean and atmosphere, in which an alternative kinematic boundary condition arises as discussed in Section 20.4.2. In this case the boundary itself is dynamical and so it must be incorporated into Hamilton's principle. This situation is more subtle than when the boundary is static, and we explore an example in Section 50.2 when studying potential flow in a homogeneous fluid layer.

16.3.6 Mechanical equivalence of Lagrangians

In Section 12.6.6 we noted that the mechanics is unchanged if the Lagrangian for a particle system is modified by a total time derivative of a function of the generalized coordinates. Likewise, for a continuum field theory, the mechanics is unchanged if the Lagrangian density is modified by a time derivative or any space derivatives of functions that are dependent on the fields. The reason, as in Section 12.6.6, is that upon integrating over space-time, these added terms reduce to boundary terms, and upon taking a variation the boundary terms drop out since there is no variation of the fields at the space-time boundaries.

More specifically, consider the two Lagrangian densities

$$\mathcal{L}^{\text{new}} = \mathcal{L}^{\text{old}} + \partial_t \Gamma(\psi, \partial_t\psi, \partial_x\psi, x, t) + \partial_x \Sigma(\psi, \partial_t\psi, \partial_x\psi, x, t), \tag{16.26}$$

where Γ and Σ are arbitrary functions of the field, ψ, its derivatives, as well as the space and time points. To show the equivalance, consider a space-time domain $R = [x_A, x_B] \otimes [t_A, t_B]$, so that the action transforms into

$$\begin{aligned} \mathcal{S}^{\text{new}} = \mathcal{S}^{\text{old}} &+ \int_{x_A}^{x_B} \left(\Gamma[\psi(t_B), \partial_t\psi(t_B), \partial_x\psi(t_B), x, t_B] - \Gamma[\psi(t_A), \partial_t\psi(t_A), \partial_x\psi(t_A), x, t_A]\right) \mathrm{d}x \\ &+ \int_{t_A}^{t_B} \left(\Sigma[\psi(x_B), \partial_t\psi(x_B), \partial_x\psi(x_B), x_B, t] - \Sigma[\psi(x_A), \partial_t\psi(x_A), \partial_x\psi(x_A), x_A, t]\right) \mathrm{d}t \end{aligned} \tag{16.27}$$

The added terms in the first integral are evaluated at the time boundaries, t_A and t_B, whereas the second integral is evaluated at the space boundaries, x_A and x_B. The field, ψ, is held fixed at the space-time boundaries; i.e., it is not varied. Hence, these extra integral terms have zero variation so that

$$\delta\mathcal{S}^{\text{new}} = \delta\mathcal{S}^{\text{old}}, \tag{16.28}$$

which then means that the associated Euler-Lagrange equation is unchanged. We make use of this symmetry of the action in Section 50.2.9 when developing Hamilton's principle for potential flow.

16.3.7 Example Lagrangian densities

We have many opportunities in this book to use a Lagrangian density to derive the correspondingly Euler-Lagrange equations. Here we provide a few examples that lead to linear wave equations.

Acoustic wave equation

As studied in Section 16.2, the Lagrangian density

$$\mathcal{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2, \tag{16.29}$$

with σ and τ constants, renders the wave equation as the Euler-Lagrange equation

$$(\partial_{tt} - c^2\,\partial_{xx})\,\psi = 0, \tag{16.30}$$

where the wave speed is $c = \sqrt{\tau/\sigma}$ (equation (16.4)). Notice that the dimensions of $\mathcal{L}$ are energy per length, which accords with this being a wave equation in a single spatial dimension. The Lagrangian (16.29) and wave equation (16.30) also hold for the more general case of a tension that is a function of time, $\tau = \tau(t)$, and a mass density that is a function of space, $\sigma = \sigma(x)$, in which case the wave speed is a function of space and time

$$c^2(x,t) = \tau(t)/\sigma(x). \tag{16.31}$$

We derived the Lagrangian density (16.29) in Section 16.2 by taking the continuum limit of coupled harmonic oscillators, where $\psi(x,t)$ represents the $\hat{\boldsymbol{x}}$-displacement of a particle from its equilibrium position, so that linear fluctuations are *longitudinal waves* (wave motion in the same direction of the particle displacement). An analogous analysis leads to the same Lagrangian density for a tight string, with $\psi(x,t)$ now measuring the transverse displacements of the string from its equilibrium position (see Section 25 in *Fetter and Walecka* (2003)), and with linear oscillations leading to *transverse waves*.

Returning to the continuum harmonic oscillator, we note that it is directly related to the study of acoustic waves in a fluid. We pursue this study in Chapter 49, thus encountering the Lagrangian density

$$\mathcal{L} = [c_{\rm s}^{-2}\,(\partial_t p')^2 - (\nabla p')^2]/(2\,\rho_{\rm e}), \tag{16.32}$$

where $\rho_{\rm e}$ is the mass density of the background fluid state, $c_{\rm s}$ is the sound speed in the fluid, and p' is the perturbation pressure. In this case the Euler-Lagrange equation is the acoustic wave equation

$$\partial_t[(\rho_{\rm e}\,c_{\rm s}^2)^{-1}\,\partial_t p'] - \nabla\cdot(\rho_{\rm e}^{-1}\,\nabla p') = 0, \tag{16.33}$$

which, in the special case of $\rho_{\rm e}$ and $c_{\rm s}$ independent of space and time, gives the wave equation

$$(\partial_{tt} - c_{\rm s}^2\,\nabla^2)\,p' = 0. \tag{16.34}$$

Note that the physical dimensions of the Lagrangian density (16.32) are not energy per volume, so that the terms in the Lagrangian are thought of as pseudo-energy densities.

Sine-Gordon and Klein-Gordon wave equations

For another example, consider

$$\mathcal{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2 - \sigma\,\Gamma^2\,(1-\cos\psi), \tag{16.35}$$

where ψ is here a non-dimensional field. The corresponding Euler-Lagrange equation is known as the *sine-Gordon equation*

$$\partial_{tt}\psi - c^2\,\partial_{xx}\psi + \Gamma^2\sin\psi = 0. \tag{16.36}$$

As shown in Section 9.1.1 of *José and Saletan* (1998), the sine-Gordon equation is the continuum limit of a coupled pendulum-spring system, with Γ proportional to the gravitational acceleration. For small ψ, the sine-Gordon Lagrangian (16.35) and wave equation (16.36) reduce to the *Klein-Gordon* Lagrangian and Klein-Gordon equation

$$\mathcal{L} = [\sigma\,(\partial_t\psi)^2 - \tau\,(\partial_x\psi)^2]/2 + \sigma\,\Gamma^2\,\psi^2 \quad \text{and} \quad (\partial_{tt} - c^2\,\partial_{xx} + \Gamma^2)\,\psi = 0. \tag{16.37}$$

16.3.8 Care with the partial derivative operations

As noted earlier in this section, the Lagrangian density, $\mathcal{L}$, is a functional of the field, ψ, as well as its space and time derivatives,

$$\frac{\partial \psi(x,t)}{\partial t} = \left[\frac{\partial \psi(x,t)}{\partial t}\right]_x \quad \text{and} \quad \frac{\partial \psi(x,t)}{\partial x} = \left[\frac{\partial \psi(x,t)}{\partial x}\right]_t, \tag{16.38}$$

where the subscripts on the right hand side of these equations indicate those variables held fixed while performing the partial derivative. We typically do not need this extra adornment for partial derivatives acting on functions of space and time. But the Lagrangian density is a bit more complicated object, and so it is important to clarify what is meant by its derivatives.

With ψ and its derivatives explicit functions of (x,t), then $\mathcal{L}$ is an implicit function of (x,t). There are additional physical systems where the Lagrangian density picks up an explicit space and time dependence, such as when waves move through a space and time dependent background media (Section 48.5). Such added space and time dependence does not alter the derivation of the Euler-Lagrange field equation, since in that derivation we only vary the field and its derivatives. However, the distinction between implicit versus explicit functional dependence can easily lead to confusion when performing partial derivative manipulations involving ∂_t and ∂_x operations, such as when deriving the continuum conservation laws in Section 16.4. We thus find it useful to here write these derivatives for the record.

The partial time derivative of $\mathcal{L}$, computed at a fixed x position, is given by

$$\left[\frac{\partial \mathcal{L}}{\partial t}\right]_x = \left[\frac{\partial \mathcal{L}}{\partial \psi}\right]_{\partial_t\psi,\partial_x\psi} \frac{\partial \psi}{\partial t} + \left[\frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi} \frac{\partial^2 \psi}{\partial t^2} + \left[\frac{\partial \mathcal{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi} \frac{\partial^2 \psi}{\partial x \partial t} + \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,x}. \tag{16.39}$$

Exposing the subscripts on the $\mathcal{L}$ partial derivatives helps to distinguish the time derivative on the left hand side from the time derivative appearing in the final term on the right hand side. Since distinguishing these two derivatives is the primary point of confusion, it is sufficient to abbreviate this equation with the more succinct expression

$$\frac{\partial \mathcal{L}}{\partial t} = \frac{\partial \mathcal{L}}{\partial \psi}\frac{\partial \psi}{\partial t} + \frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\frac{\partial^2 \psi}{\partial t^2} + \frac{\partial \mathcal{L}}{\partial(\partial_x\psi)}\frac{\partial^2 \psi}{\partial x \partial t} + \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,x}. \tag{16.40}$$

A similar expression holds for the partial space derivative computed at a fixed time,

$$\left[\frac{\partial \mathcal{L}}{\partial x}\right]_t = \left[\frac{\partial \mathcal{L}}{\partial \psi}\right]_{\partial_t\psi,\partial_x\psi} \frac{\partial \psi}{\partial x} + \left[\frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\right]_{\psi,\partial_x\psi} \frac{\partial^2 \psi}{\partial t \partial x} + \left[\frac{\partial \mathcal{L}}{\partial(\partial_x\psi)}\right]_{\psi,\partial_t\psi} \frac{\partial^2 \psi}{\partial x^2} + \left[\frac{\partial \mathcal{L}}{\partial x}\right]_{\psi,\partial_t\psi,\partial_x\psi,t}, \tag{16.41}$$

which also has the succinct form

$$\frac{\partial \mathcal{L}}{\partial x} = \frac{\partial \mathcal{L}}{\partial \psi}\frac{\partial \psi}{\partial x} + \frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\frac{\partial^2 \psi}{\partial t \partial x} + \frac{\partial \mathcal{L}}{\partial(\partial_x\psi)}\frac{\partial^2 \psi}{\partial x^2} + \left[\frac{\partial \mathcal{L}}{\partial x}\right]_{\psi,\partial_t\psi,\partial_x\psi,t}. \tag{16.42}$$

Note that some authors (e.g., chapter 12 of *Goldstein* (1980)), write $\mathrm{d}/\mathrm{d}t$ and $\mathrm{d}/\mathrm{d}x$ for the left hand side operators in equations (16.39) and (16.41), referring to these derivatives as "total time" and "total space" derivatives. However, that notation is non-standard in the field theory literature and can lead to additional confusions.

16.3.9 Generalized spatial coordinates

For simplicity, we derived the Euler-Lagrange equation (16.23) using the 1+1 dimensinoal (x, t) case using Cartesian coordinates for space. That derivation can be readily generalized to three dimensions in space, in which case the domain, R, now includes a three dimensional region of space, $\mathcal{R}$, along with a time interval. When taking the variation of the field, we now assume it vanishes on the higher dimensional domain boundary, ∂R. Otherwise, all steps follow as per the 1+1 dimensional case.

As when studying discrete particle mechanics, we often find that Cartesian space coordinates are less suited to the symmetry of the problem. We are thus motivated to introduce general spatial coordinates, ξ^a, as considered in the general tensor analysis of Chapters 8 and 9.[3] In this case, variation of the action takes the form

$$\delta\mathcal{S} = \int_R \delta\mathcal{L}\,\sqrt{\det(\mathbb{g})}\,\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3\,\mathrm{d}t, \tag{16.43}$$

where $\det(\mathbb{g})$ is the determinant of the spatial metric tensor as detailed in Section 9.5.2. Following through the Cartesian coordinate derivation requires us now to keep track of $\det(\mathbb{g})$, which leads to the action variation

$$\int_R \delta\psi\left[\frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right] - \frac{1}{\sqrt{\det(\mathbb{g})}}\frac{\partial}{\partial\xi^a}\left[\sqrt{\det(\mathbb{g})}\,\frac{\partial\mathcal{L}}{\partial(\partial_{\xi^a}\psi)}\right]\right]\sqrt{\det(\mathbb{g})}\,\mathrm{d}\xi^1\,\mathrm{d}\xi^2\,\mathrm{d}\xi^3\,\mathrm{d}t, \tag{16.44}$$

where we assume the summation convention for the spatial coordinates, $a = 1, 2, 3$, and where we assumed $\det(\mathbb{g})$ has no explicit time dependence. Setting $\delta\mathcal{S} = 0$ then leads to the Euler-Lagrange equation

$$\frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right] - \frac{1}{\sqrt{\det(\mathbb{g})}}\frac{\partial}{\partial\xi^a}\left[\sqrt{\det(\mathbb{g})}\,\frac{\partial\mathcal{L}}{\partial(\partial_{\xi^a}\psi)}\right] = 0. \tag{16.45}$$

16.4 Conservation laws

In this section we derive a suite of conservation laws that are maintained by the continuous media as described by the Euler-Lagrange field equation (16.23), here written for three space dimensions and using Cartesian coordinates

$$\frac{\partial\mathcal{L}}{\partial\psi} - \frac{\partial}{\partial t}\left[\frac{\partial\mathcal{L}}{\partial(\partial_t\psi)}\right] - \frac{\partial}{\partial x^a}\left[\frac{\partial\mathcal{L}}{\partial(\partial_{x^a}\psi)}\right] = 0. \tag{16.46}$$

[3] Do not confuse the use of ξ^a for general space coordinates with the displacement field, $\xi(x, t)$, used for the coupled oscillators in Section 16.2.

16.4.1 Budget for the Hamiltonian density

Return to the partial time derivative in equation (16.40) and make use of the Euler-Lagrange equation (16.46) to write

$$\frac{\partial \mathcal{L}}{\partial t} = \frac{\partial \mathcal{L}}{\partial \psi}\frac{\partial \psi}{\partial t} + \frac{\partial \mathcal{L}}{\partial(\partial_t \psi)}\frac{\partial^2 \psi}{\partial t^2} + \frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\frac{\partial^2 \psi}{\partial x^a \partial t} + \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}} \tag{16.47a}$$

$$= \left[\frac{\partial}{\partial t}\left[\frac{\partial \mathcal{L}}{\partial(\partial_t \psi)}\right] + \frac{\partial}{\partial x^a}\left[\frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\right]\right]\frac{\partial \psi}{\partial t} + \frac{\partial \mathcal{L}}{\partial(\partial_t \psi)}\frac{\partial^2 \psi}{\partial t^2} + \frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\frac{\partial^2 \psi}{\partial x^a \partial t} + \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}} \tag{16.47b}$$

$$= \frac{\partial}{\partial t}\left[\frac{\partial \mathcal{L}}{\partial(\partial_t \psi)}\frac{\partial \psi}{\partial t}\right] + \frac{\partial}{\partial x^a}\left[\frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\frac{\partial \psi}{\partial t}\right] + \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}}, \tag{16.47c}$$

with rearrangement leading to

$$\frac{\partial}{\partial t}\left[\frac{\partial \mathcal{L}}{\partial(\partial_t \psi)}\frac{\partial \psi}{\partial t} - \mathcal{L}\right] + \frac{\partial}{\partial x^a}\left[\frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\frac{\partial \psi}{\partial t}\right] = -\left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}}. \tag{16.48}$$

Following the discrete case discussed in Section 12.10, introduce the *generalized (or canonical) momentum density*, $\mathcal{P}$, the *Hamiltonian density*, $\mathcal{H}$, along with the energy flux, $\boldsymbol{F}$, according to

$$\mathcal{P} \equiv \frac{\partial \mathcal{L}}{\partial(\partial_t \psi)} \quad \text{and} \quad \mathcal{H} = \mathcal{P}\,\partial_t \psi - \mathcal{L} \quad \text{and} \quad F^a = \frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\frac{\partial \psi}{\partial t}. \tag{16.49}$$

These definitions bring equation (16.48) to the form of a budget equation for the Hamiltonian density

$$\partial_t \mathcal{H} + \nabla\cdot\boldsymbol{F} = -\left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}}. \tag{16.50}$$

Evidently, the Hamiltonian density at a point in space evolves according to the convergence of the flux, $\boldsymbol{F}$, as well as any explicit time dependence of the Lagrangian density.

When the Lagrangian density has no explicit dependence on time so that

$$\mathcal{L} = \mathcal{L}(\psi, \partial_t\psi, \partial_x\psi, \boldsymbol{x}), \tag{16.51}$$

then the budget equation (16.50) reduces to the *Hamiltonian continuity equation*

$$\partial_t \mathcal{H} + \nabla\cdot\boldsymbol{F} = 0. \tag{16.52}$$

This equation is written in the form of a continuum conservation law, with such conservation laws encountered throughout this book.[4] Evidently, for the special case of a time independent spatial domain, and with the flux, $\boldsymbol{F}$, having zero normal projection at the domain boundary, we are led to the conservation of the domain integrated Hamiltonian

$$\frac{\mathrm{d}H}{\mathrm{d}t} = 0 \quad \text{with} \quad H = \int_{\mathcal{R}} \mathcal{H}\,\mathrm{d}V, \tag{16.53}$$

where $\mathcal{R}$ is the spatial domain. This result constitutes an expression of Noether's theorem arising from time symmetry.

[4]See Section 27.12 for more discussion on such continuum conservation laws.

16.4.2 The stress-energy-momentum tensor

The derivation in Section 16.4.1 can be generalized to yield a budget equation built from elements of the *stress-energy-momentum tensor*. To streamline the derivation, make use of the space-time tensor notation from Section 8.5.4, in which we introduce the Greek index, $\alpha = 0, 1, 2, 3$ with $\alpha = 0$ corresponding to the time index and $\alpha = 1, 2, 3$ for space. In this manner the Euler-Lagrange field equation (16.46) becomes

$$\frac{\partial \mathcal{L}}{\partial \psi} - \frac{\partial}{\partial x^\alpha}\left[\frac{\partial \mathcal{L}}{\partial(\partial_\alpha \psi)}\right] = 0. \tag{16.54}$$

The space-time derivative of the Lagrangian density is given by (again, being careful with derivatives as discussed in Section 16.3.8)

$$\frac{\partial \mathcal{L}}{\partial x^\beta} = \frac{\partial \mathcal{L}}{\partial \psi}\frac{\partial \psi}{\partial x^\beta} + \frac{\partial \mathcal{L}}{\partial_\alpha \psi}\frac{\partial^2 \psi}{\partial x^\beta \partial x^\alpha} + \left[\frac{\partial \mathcal{L}}{\partial x^\beta}\right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{16.55}$$

Use of the Euler-Lagrange equation (16.54) leads to

$$\delta^\alpha_\beta \frac{\partial \mathcal{L}}{\partial x^\alpha} = \frac{\partial}{\partial x^\alpha}\left[\frac{\partial \mathcal{L}}{\partial_\alpha \psi}\frac{\partial \psi}{\partial x^\beta}\right] + \left[\frac{\partial \mathcal{L}}{\partial x^\beta}\right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}, \tag{16.56}$$

which can be written

$$\partial_\alpha T^\alpha_\beta = -\left[\frac{\partial \mathcal{L}}{\partial x^\beta}\right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq \beta}}. \tag{16.57}$$

where we defined the *stress-energy-momentum tensor*

$$T^\alpha_\beta = -\delta^\alpha_\beta \mathcal{L} + \frac{\partial \mathcal{L}}{\partial_\alpha \psi}\frac{\partial \psi}{\partial x^\beta}. \tag{16.58}$$

The budget equation (16.57) includes the Hamiltonian density budget equation (16.50) for the case of $\beta = 0$

$$T^0_0 = -\mathcal{L} + \frac{\partial \mathcal{L}}{\partial_t \psi}\frac{\partial \psi}{\partial t} = \mathcal{H} \qquad \text{Hamiltonian density} \tag{16.59a}$$

$$T^a_0 = \frac{\partial \mathcal{L}}{\partial_{x^a} \psi}\frac{\partial \psi}{\partial t} = F^a \qquad \text{Hamiltonian density flux.} \tag{16.59b}$$

For $\beta = b > 0$ then the budget equation (16.57) becomes

$$\partial_\alpha T^\alpha_b = -\left[\frac{\partial \mathcal{L}}{\partial x^b}\right]_{\psi, \partial_\alpha \psi, x^{\alpha \neq b}}. \tag{16.60}$$

For example, if the Lagrangian is not an explicit function of x^b then we are led to the conservation law

$$\partial_t T^0_b + \partial_a T^a_b = 0. \tag{16.61}$$

This conservation law results from spatial symmetry with respect to x^b, and as such it follows from Noether's theorem. Following equations (16.59a) and (16.59b) we interpret the tensor elements

as

$$T^0_{\ b} = \frac{\partial \mathcal{L}}{\partial_t \psi}\frac{\partial \psi}{\partial x^b} \qquad \text{momentum density} \tag{16.62a}$$

$$T^a_{\ b} = -\mathcal{L}\,\delta^a_{\ b} + \frac{\partial \mathcal{L}}{\partial_{x^a}\psi}\frac{\partial \psi}{\partial x^b} \qquad \text{stress tensor.} \tag{16.62b}$$

We have the opportunity to apply these budget equations to a variety of physical systems within this book. Notably, specific applications can lead to rather tedious mathematical manipulations that are, in contrast, transparent using the general formalism presented here.

16.4.3 An auxiliary functional for deriving conservation laws

For some purposes, such as when deriving the wave-action conservation law in Section 48.5, it is useful to introduce an auxiliary functional (*Hayes*, 1970)

$$\mathcal{F}(\psi,\Psi) = \frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\frac{\partial \Psi}{\partial t} + \frac{\partial \mathcal{L}}{\partial(\partial_a\psi)}\frac{\partial \Psi}{\partial x^a} + \frac{\partial \mathcal{L}}{\partial \psi}\Psi \tag{16.63a}$$

$$= \frac{\partial}{\partial t}\left[\Psi\frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\right] + \frac{\partial}{\partial x^a}\left[\Psi\frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\right] \tag{16.63b}$$

$$= \partial_t(\Psi\,\mathcal{P}) + \frac{\partial}{\partial x^a}\left[\Psi\frac{\partial \mathcal{L}}{\partial(\partial_{x^a}\psi)}\right]. \tag{16.63c}$$

In these equations, ψ satisifies the Euler-Lagrange equation (16.46), whereas $\Psi = \Psi(\boldsymbol{x}, t)$ is a function to be specified. The equality (16.63b) follows from the Euler-Lagrange equation, thus revealing that the auxiliary functional, $\mathcal{F}(\psi,\Psi)$, is a total 4-divergence. The equality (16.63c) introduced the generalized momentum density, $\mathcal{P}$, from equation (16.49).

Specifying $\Psi = \partial\psi/\partial t$ in equation (16.63c) leads to

$$\mathcal{F} = \left[\frac{\partial(\mathcal{H}+\mathcal{L})}{\partial t}\right]_{\boldsymbol{x}} + \partial_a F^a = \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\boldsymbol{x}} - \left[\frac{\partial \mathcal{L}}{\partial t}\right]_{\psi,\partial_t\psi,\partial_x\psi,\boldsymbol{x}}, \tag{16.64}$$

where F^a are components to the energy flux (16.49), we introduced the Hamiltonian density, $\mathcal{H}$, also given by equation (16.49), and made use of the various partial derivative steps detailed in Section 16.4.1 for the second equality. As discussed in Section 16.4.1, if the Lagrangian density has no explicit time dependence, then the Hamiltonian density satisfies the continuity equation (16.50). We derive the momentum conservation equations from Section 16.4.2 through setting $\Psi = \partial_a\psi$. In Section 48.5 we introduce yet another choice appropriate for the study of waves.

16.4.4 Further study

Section 2.12 of *Olbers et al.* (2012) provides example Lagrangians for fluid mechanical systems.

16.5 Variational methods for linear waves

The Euler-Lagrange equations for the acoustic and Klein-Gordon wave equations from Section 16.3.7 can be written

$$\frac{\delta \mathcal{S}}{\delta\psi} = \frac{\partial \mathcal{L}}{\partial \psi} - \frac{\partial}{\partial t}\left[\frac{\partial \mathcal{L}}{\partial(\partial_t\psi)}\right] - \frac{\partial}{\partial x}\left[\frac{\partial \mathcal{L}}{\partial(\partial_x\psi)}\right] = \widehat{D}\psi = 0, \tag{16.65}$$

where $\widehat{D}$ is the linear partial differential operator,

$$\widehat{D} = -(\partial_{tt} - c^2\,\partial_{xx} + \Gamma^2), \tag{16.66}$$

for the Klein-Gordon wave equation with constant c, and with $\Gamma = 0$ for the acoustic wave equation. This result suggests that we write the action for this, and other, linear non-dissipative waves in the bilinear form

$$\mathcal{S} = \frac{1}{2}\int_R \psi\,(\widehat{D}\psi)\,\mathrm{d}x\,\mathrm{d}t. \tag{16.67}$$

This action vanishes identically when ψ is a solution to the wave equation, as per equation (16.65), yet the action is non-zero for a general function. It follows that variation of the action can be written

$$2\,\delta\mathcal{S} = \int_R (\delta\psi)\,\widehat{D}\psi\,\mathrm{d}x\,\mathrm{d}t + \int_R \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}x\,\mathrm{d}t, \tag{16.68}$$

with integration by parts bringing the second right hand side term into the form

$$\begin{aligned}\int_R \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}x\,\mathrm{d}t = &\int_R \delta\psi\,(\widehat{D}\psi)\,\mathrm{d}x\,\mathrm{d}t \\ &- \int_R \partial_t(\psi\,\partial_t\delta\psi - \delta\psi\,\partial_t\psi)\,\mathrm{d}x\,\mathrm{d}t + c^2\int_R \partial_x(\psi\,\partial_x\delta\psi - \delta\psi\,\partial_x\psi)\,\mathrm{d}x\,\mathrm{d}t.\end{aligned} \tag{16.69}$$

Two of the boundary terms vanish since $\delta\psi = 0$ on ∂R, in which case

$$\int_R \psi\,(\widehat{D}\delta\psi)\,\mathrm{d}x\,\mathrm{d}t = \int_R \delta\psi\,(\widehat{D}\psi)\,\mathrm{d}x\,\mathrm{d}t + \int_R [-\partial_t(\psi\,\partial_t\delta\psi) + c^2\,\partial_x(\psi\,\partial_x\delta\psi)]\,\mathrm{d}x\,\mathrm{d}t. \tag{16.70}$$

The temporal boundary term vanishes if we assume either ψ or $\delta(\partial_t\psi)$ vanishes at temporal boundaries, whereas the spatial boundary term vanishes if ψ or $\delta(\partial_x\psi)$ vanishes at the spatial boundaries.[5] Assuming the boundary conditions indeed vanish, which then make $\widehat{D}$ a self-adjoint operator, brings about the action variation

$$\delta\mathcal{S} = \int_R (\delta\psi)\,\widehat{D}\psi\,\mathrm{d}x\,\mathrm{d}t, \tag{16.71}$$

with Hamilton's principle, $\delta\mathcal{S} = 0$, again leading to the wave equation, $\widehat{D}\psi = 0$.

The above presentation is a bit circular since we compute the wave operator, $\widehat{D}$, from the Euler-Lagrange equation, and the Euler-Lagrange equation requires the Lagrangian density, $\mathcal{L}$. However, the discussion suggests a complementary means to connect the variational framework of Hamilton's principle to the study of linear waves. Namely, all we need is the linear self-adjoint wave operator, $\widehat{D}$, rather than the Lagrangian density, $\mathcal{L}$. This approach is useful since the Lagrangian can be a bit tricky to determine for some linear wave systems, such as for Rossby waves where it is necessary to introduce auxiliary fields (see page 293 of *Olbers et al.* (2012)). So by writing the action in the form of equation (16.67), we directly connect the variational framework to the study of linear waves via knowledge of the wave operator rather than the wave Lagrangian. We offer examples throughout the study of geophysical waves in Part IX. One important caveat is that the action for some wave systems cannot be written in the bilinear form (16.67), such as the interface waves from Chapter 50.

[5] In considering these boundary conditions, recall that δ commutes with space and time derivatives, as detailed in Section 16.3.2.

Part III

Fluid kinematics

In this part of the book we focus on the kinematics of a continuous fluid media. We motivate the study of continuous media in Chapter 17 by noting the huge space and time scale separation between molecular motions and the motion of macroscopic fluid elements. These considerations offer a physical complement to the mathematical continuum limit of coupled oscillators presented in Section 16.2. Thereafter we develop kinematics for classical non-relativistic fluid flow. We take inspiration from treatments given in the continuum mechanics literature (e.g., chapter 4 of *Malvern* (1969)), though with a bias towards elements particularly useful in fluid mechanics (e.g., chapter 2 of *Truesdell* (1954)). There are a variety of rather subtle points connected with fluid kinematics, and such subtleties can lead to confusion (it certainly has for this author!). The interested student is encouraged to read a variety of treatments to survey the presentations, as each author stresses unique nuances that can be important both for understanding and for applications.

Kinematic properties of flows in an inertial reference frame also hold for flow on steady rotating planets such as considered in this book. The reason is that steady rigid-body rotation does not directly impart strain to the flow, where strain refers to the relative motion between fluid particles (Chapter 18). Rotation does impart a planetary component to the vorticity of geophysical fluids, with important implications for the study of vorticity in Part VII. However, for the purpose of fluid kinematics studied in this part of the book, we can safely ignore planetary rotation.

Eulerian and Lagrangian reference frames

The *Eulerian and Lagrangian reference frames* provide dual kinematic descriptions of fluid flows. The Eulerian frame describes fluid motion relative to a frame fixed in the laboratory whereas the Lagrangian frame follows a moving material fluid particle. The Eulerian frame is inertial (when the laboratory is not accelerating), whereas the Lagrangian frame is non-inertial since fluid particles generally accelerate. Having two descriptions of the same motion provides a powerful synergy that is extensively used in fluid mechanics. Fully realizing this synergy requires skills to move between the Eulerian and Lagrangian descriptions, with tools from mathematical transformation theory of Part I used for this purpose. Elements of Eulerian and Lagrangian kinematics are the focus of Chapter 18, and Chapter 19 further develops the kinematics of material lines, areas, and volumes.

We acknowledge that for most flows encountered in geophysical fluid mechanics, a Lagrangian description has severe practical limitations. These limitations arise from the chaotic and turbulent nature of the flow that render a description based on fluid particle trajectories of little use after even a brief time. Nevertheless, Lagrangian formulations offer deep insights to the fundamental theorems of fluid mechanics, thus motivating us to study and to use Lagrangian kinematics in this book.

A historical note is appropriate here. As emphasized by *Truesdell* (1953), as well as Section 14 of *Truesdell* (1954), it was Euler who first introduced the material coordinates used with the Lagrangian reference frame. Even so, we retain the term "Lagrangian description" to accord with its common usage in geophysical fluid mechanics, while also sometimes replacing "Lagrangian" with "material". Relatedly, again according to *Truesdell* (1953), it was d'Alembert who introduced the spatial coordinates used with the Eulerian description.

Mass and matter conservation are part of fluid kinematics

The conservation of mass plays a central role in physics. For fluids, mass conservation constrains the flow regardless what forces act on the fluid. Hence, we include mass conservation as a part of fluid kinematics rather than fluid dynamics. Mass conservation, and its expression as volume conservation for non-divergent flows, are the topics of Chapters 20 and 22. Chapter 21

develops the allied study of matter conservation and matter flow, with this study forming the foundations for *tracer mechanics* that we return to in earnest within Part XII in this book.

FLUID KINEMATICS + FLUID DYNAMICS = FLUID MECHANICS

Kinematics is concerned with the intrinsic properties of motion, including properties of the space and time in which motion occurs. It is the complement to dynamics, which is concerned with the causes of motion that arise through the action of forces. In one sense, kinematics deduces the acceleration whereas dynamics deduces the forces, with Newton's second law linking the two via the equation of motion: $\boldsymbol{F} = m\,\boldsymbol{a}$. In fluid mechanics, kinematics studies the flow of a fluid and its matter constituents, whereas dynamics studies the forces causing the motion. Furthermore, as discussed in Chapter 14, symmetries of a mechanical system lead, through Noether's Theorem, to dynamical conservation laws. That is, symmetries, which embody kinematic properties, lead to dynamical invariants maintained by the motion, with these invariants constraining the motion. The intellectual avenues pursued in developing a mechanical description of fluid motion are many and varied, with fluid kinematics and fluid dynamics intimately woven into the fabric of that description.

A KINEMATICAL RESULT IS VALID FOREVER

As motivation for studying this part of the book, we offer the following quote from page 2 of *Truesdell* (1954), with Clifford Truesdell one the giants of 20th century continuum mechanics who was clearly fond of kinematics.

> All dynamical statements I have relegated to parenthetical sections, appendices, or footnotes, not in a foolish attempt to diminish their physical importance, but rather to let the argument course freely, uninterrupted by merely interpretative remarks, and to leave the propositions free for application to such special dynamical situations as may be of interest either now or in the future–for I cannot too strongly urge that a kinematical result is a result valid forever, no matter how time and fashion may change the "laws" of physics.

Chapter 17

Continuum approximation

Viewed macroscopically, a fluid deforms continuously when applying a force so that a fluid has no preferred shape. Correspondingly, a fluid responds to a shearing stress by moving.[1] Ordinary gases and liquids are canonical examples of fluids, with gases filling any container with its molecules widely separated, whereas molecules in liquids are much closer together so that liquids are far less compressible than gases.

For geophysical fluid mechanics, we are concerned with the atmosphere (mostly a gas) and the ocean (mostly a liquid). We are furthermore interested in macroscopic properties of fluid motion, with no interest in describing molecular degrees of freedom. Nor do we consider rarefied gas dynamics, which is a subject appropriate for the upper bounds of the atmosphere where pressures are extremely low and the molecular mean free path relatively large. For these reasons we pursue a phenomenological approach that makes use of conservation laws describing the motion of a continuous fluid media. This treatment is based on the *continuum approximation*, which assumes that mathematical limits for fluid volumes tending to zero are reached on length and time scales very large compared to molecular space and time scales.[2] The temporal realization of the continuum approximation is based on recognizing that macroscopic motion (e.g., advection, waves, and mixing) evolves with time scales far longer than the time scales of molecular motions. Hence, from a macroscopic perspective, we assume that all fluid motions are continuous in both space and time.

The huge space and time scale separation that supports the continuum approximation allows us to make use of differential calculus for describing the mechanics of fluid motion. That is, the continuum approximation makes fluid mechanics a continuous field theory, thus sitting within the broader discipline of *continuum mechanics*. Correspondingly, the differential laws describing fluid motion are partial differential equations. Even so, it must be admitted that the equations of continuum mechanics are motivated by the continuum approximation rather than deductively resulting from it. That is, a deductive derivation of continuum field theory, starting from molecular dynamics, is nontrivial even for an ideal gas, and largely non-existent for liquids. For our purpose, we remain satisfied to postulate that a continuum description is suited for the fluid mechanics of atmosphere and ocean flows, and to examine the postulate *a posteriori* via experimental measurements. Centuries of experiments with fluid motions in the environment and laboratory lend credence to the continuum description. We consider these tests to offer sufficient motivation to use continuum mechanics as the foundation for our study of geophysical fluid mechanics.

[1] A stress is a force per area, and we study stresses in Chapter 26. A shearing stress gives rise to fluid acceleration that causes fluid elements to deform.

[2] The continuum approximation used for continuum mechanics is not to be confused with the *continuum hypothesis* found in mathematical set theory.

READER'S GUIDE TO THIS CHAPTER

This chapter presents salient points supporting our use of a space and time continuous description of fluid mechanics. Section 17.2 summarizes the key results and Section 17.3 provides a bit more detail by quoting from kinetic theory. Our overall goal here is to unpack the dictum *macroscopically small yet microscopically large*, which summarizes the regime considered by continuum mechanics. For this purpose, we borrow from the kinetic theory of gases as treated in statistical physics books such as *Reif* (1965) and *Huang* (1987). Chapter 1 of *Salmon* (1998) also provides a compelling discussion with application to geophysical fluid mechanics. No prior exposure to these treatments is necessary, nor do we dive into the many details.

We return to elements of this chapter in Section 27.5 when describing *local thermodynamic equilibrium*. Together, the continuum approximation and the hypothesis of local thermodynamic equilibrium form two key pillars of continuum mechanics.

17.1 Loose ends

- Add a figure for Section 17.2.4.
- Can one be more precise about the scale in Figure 17.2 where measurements become fuzzy?

17.2 A variety of length scales

Matter is comprised of molecules. However, fluid mechanics is not concerned with the motion of individual molecular degrees of freedom. Rather, fluid mechanics is concerned with phenomenological conservation laws satisfied by a continuous fluid material. This approach represents an idealization that is supported by centuries of successful descriptions of macroscopic fluid motion.

In this section we outline certain properties of matter that motivate the continuum approximation and the corresponding study of continuum mechanics. More details are offered in Section 17.3, although a full discussion is outside the purview of fluid mechanics, with interested readers encouraged to penetrate the literature in statistical physics and kinetic theory.

FIGURE 17.1: Schematic to illustrate the three length scales considered when making the continuum approximation. The blue circles represent molecules with diameter L_{molecule}. On average, molecules are separated by the mean free path, $L_{\text{mfp}} \approx 1000\, L_{\text{molecule}}$. The smallest macroscopic length scale of interest for fluid mechanics is denoted L_{macro}. There is no objective value for L_{macro}, though for our purposes we assume it is on the order of $L_{\text{macro}} \sim 10^{-4}$ m. In this case, $L_{\text{macro}} \approx 10^3\, L_{\text{mfp}}$ for an ideal gas at standard conditions. A region of air with volume L_{macro}^3 contains roughly 10^{13} air molecules, whereas that same volume contains roughly 10^{16} water molecules. For either case, the Law of Large Numbers greatly helps in taking the continuum limit. Note that this schematic is certainly not drawn to scale!

17.2.1 Macroscopic and microscopic length scales

In fluid mechanics, as in other areas of continuum mechanics, we are concerned with the motion of regions of matter that are macroscopically small (e.g., $L_{\text{macro}} \sim 10^{-4}$ m) yet microscopically large (e.g., $L_{\text{macro}} \gg L_{\text{mfp}} \sim 10^{-7}$ m, where L_{mfp} is the molecular mean free path). For example, a region of air with volume L_{macro}^3 contains roughly 10^{13} air molecules at standard temperature ($T_{\text{stand}} = 0°\text{C} = 273.15$ K) and standard atmospheric pressure ($p_{\text{stand}} = 101.325 \times 10^3$ Pa), whereas that same volume contains roughly 10^{16} water molecules. These numbers illustrate the notions of macroscopically small yet microscopically large. That is, a macroscopically small region generally contains an enormous number of microscopic molecules. It is only when reaching length scales on the order of the molecular mean free path that we truly need to be concerned with the discrete nature of matter. Figure 17.1 offers a schematic to illustrate these quite distinct length scales.

17.2.2 Fields at each space point

When measured on length scales of the mean free path, material properties exhibit very large fluctuations on time scales of order $L_{\text{mfp}}/v_{\text{rms}}$, where v_{rms} is the root-mean-square speed of a fluid molecule (see Section 17.3.4). However, on macroscopic scales encompassing many molecular degrees of freedom, fluid matter appears continuous in both space and time. The incredibly large number of molecules within a macroscopically tiny region motivates our assumption that physical properties are homogeneous over regions of size L_{macro}. For our purposes, this *continuum approximation* works with macroscopically small but finite sized fluid elements whose mean dynamical properties (e.g., velocity, vorticity) and thermodynamical properties (e.g., mass density, matter concentration, temperature, pressure, specific entropy) are defined at each point within the continuous fluid media and at each time instance. As a result, we assume that any differential space

FIGURE 17.2: The measurement of mass density of a fluid becomes erratic for volumes smaller than that determined by the molecular mean free path, $\delta V_{\text{mfp}} \sim L_{\text{mfp}}^3$. For fluid mechanics we are concerned with macroscopic length scales much larger than the mean free path, $L_{\text{macro}} \gg L_{\text{mfp}}$, in which case the density is a smooth function of space and time. This figure is adapted from Figure 1.2.1 of *Batchelor* (1967).

increment, $\mathrm{d}\boldsymbol{x}$, has magnitude on the order of L_{macro}, even though we make use of differential calculus and its associated infinitesimals.

Let us be a bit more precise by considering the measurement of mass density for a prescribed region of fluid, δV. To compute the mass density we take the ratio of the mass of fluid in the region, δm, to the region volume. When the region volume is macroscopic, and thus contains many molecules, we can maintain a relatively fixed mass since molecular fluctuations have a relatively tiny effect on δm. Hence, we can maintain a precise measurement of the mass density, $\delta m/\delta V$. However, when the volume of the region become microscopic, whereby it has a volume on the order of $\delta V \sim L_{\text{mfp}}^3$, then molecular fluctuations can generally lead to a relatively large fluctuation in the region mass. We thus lose the notion of a smooth and continuous mass density when the volume approaches that set by the molecular mean free path. This situation is depicted in Figure 17.2.

The ratio of the molecular mean free path to the macroscopic length scale is known as the *Knudsen number*

$$\text{Kn} = \frac{L_{\text{mfp}}}{L_{\text{macro}}}. \tag{17.1}$$

For this book, we are concerned with fluid conditions where the mean free path is microscopic so that the Knudsen number is tiny

$$\text{Kn} \ll 1. \tag{17.2}$$

For tiny Knudsen numbers, we are led to make use of the continuum approximation. The continuum approximation allows us to employ fluid properties that take values at each point within a space and time continuum, $(\boldsymbol{x}, t)$. For example, we make use of the mass density, $\rho(\boldsymbol{x}, t)$, fluid velocity, $\boldsymbol{v}(\boldsymbol{x}, t)$, pressure $p(\boldsymbol{x}, t)$, temperature $T(\boldsymbol{x}, t)$, tracer concentration, $C(\boldsymbol{x}, t)$, and other fields.

We contrast the above to the study of a rarefied gas, such as in the outer reaches of the earth's atmosphere. With a relatively small number density of molecules, rarefied gases have macroscopic mean free paths so that there are relatively few molecular collisions in a given time increment. Correspondingly, a rarefied gas is far from thermodynamic equilibrium and the continuum approximation is not well suited to its description.

17.2.3 Reynolds number and the macroscopic length scale

The continuum field equations of fluid mechanics are formally established for fluid motions with length scales on the order of L_{macro} and larger. We stated earlier that L_{macro} is on the order of 10^{-4} m, with that length loosely based on noting that most macroscopic measurements in a fluid cannot distinguish features smaller than a millimetre. We here describe another means to determine L_{macro}.

Namely, we set L_{macro} to the length scale at which the Reynolds number is order unity

$$\text{Re}_{\text{macro}} = \frac{U\, L_{\text{macro}}}{\nu} \sim 1. \tag{17.3}$$

In this equation, $\nu > 0$ is the kinematic viscosity (dimensions squared length per time), which is a function of the fluid. The velocity scale, U, is set by the scale for a macroscopic fluid velocity fluctuation. The Reynolds number measures the ratio of inertial accelerations (accelerations felt by fluid elements) to frictional accelerations from viscous forces (forces due to the rubbing of fluid elements against one another in the presence of viscosity). We provide more details concerning the Reynolds number when studying fluid stresses in Chapter 26. For present purposes, we note that when the Reynolds number is on the order of unity, viscous forces play a leading role in the acceleration of the fluid. Furthermore, at this scale the viscous accelerations serve to dissipate kinetic energy of the macroscopic motion, with this dissipation a particularly important process in fluid turbulence. We are thus motivated to define L_{macro} as the length scale where viscosity is of leading order importance.

The kinematic viscosity is the ratio of the *dynamic viscosity* and the mass density. For air, the kinematic viscosity is (page 75 of *Gill* (1982))

$$\nu_{\text{air}} = \frac{1.7 \times 10^{-5}\ \text{kg m}^{-1}\ \text{s}^{-1}}{1.3\ \text{kg m}^{-3}} = 1.3 \times 10^{-5}\ \text{m}^2\ \text{s}^{-1}, \tag{17.4}$$

and a typical fluid velocity fluctuation has a scale 10^{-1} m s^{-1}, so that

$$L_{\text{macro}} \approx 10^{-4}\ \text{m} = 0.1\ \text{mm}. \tag{17.5}$$

Water has a kinematic viscosity (page 75 of *Gill* (1982))

$$\nu_{\text{water}} = \frac{10^{-3}\ \text{kg m}^{-1}\ \text{s}^{-1}}{1000\ \text{kg m}^{-3}} \approx 10^{-6}\ \text{m}^2\ \text{s}^{-1}, \tag{17.6}$$

and a fluid velocity fluctuation about 10 times smaller than air. Hence, the macroscopic length scale for water is on the order of that for air, both of which are roughly 10^{-4} m. We are thus further compelled to consider the macroscopic length scale to be on the order 10^{-4} m.

17.2.4 Resolution of measurements and simulations

When we measure fluid motions in the laboratory or field, we generally do not measure the motions at scales on the order of L_{macro}. That is, our measurement devices generally have a spatial resolution coarser than L_{macro}, so that $L_{\text{measure}} \gg L_{\text{macro}}$. Likewise, numerical simulations are generally designed using discrete grids with length scales $L_{\text{numerical}} \gg L_{\text{macro}}$. The equations describing motions at the measurement/simulation length scales involve effects from fluctuations occurring at the smaller (unmeasured) scales. The reason for this coupling is that the fluid equations are nonlinear so that scales interact. These fluctuations, generally associated with turbulent or chaotic motions, have statistical correlations that can play a role, sometimes a dominant role,

in the evolution of flow features at the measured/simulated scales. The parameterization of these correlations in terms of measured/simulated motions constitutes the *turbulence closure* problem. We do not study turbulence closure in this book though we do identify the role of turbulence at certain points.

It is important to acknowledge the limited ability of macroscopic measurements to accurately characterize fine scale motions. For this purpose define a gradient length scale

$$L_{\text{gradient}} = \frac{|\boldsymbol{v}|}{|\nabla \boldsymbol{v}|}, \tag{17.7}$$

where $\boldsymbol{v}$ is the velocity of a fluid element relative to some mean velocity, and $|\nabla \boldsymbol{v}|$ is the magnitude of velocity gradients. Decomposing fluctuations into Fourier modes allows us to see that an accurate measurement of velocity fluctuations with length scales L_{gradient} requires a measurement length scale that satisfies

$$2\,\pi\, L_{\text{measure}} \leq L_{\text{gradient}}. \tag{17.8}$$

This constraint means that to measure velocity fluctuations on a scale L_{gradient} requires a finer measurement sampling with $L_{\text{measure}} = L_{\text{gradient}}/(2\,\pi)$. Note that this discussion of length scales transfers seamlessly over to time scales through dividing the length scale by the velocity scale. Correspondingly, fluctuations with time scales shorter than $2\,\pi\, T_{\text{measure}}$ cannot be accurately measured.

17.2.5 Fields at each time instance

The continuum approximation means that fields are defined at every point in the space continuum and at each time in the time continuum. As motivation for the time continuum, we note that there are a huge number of molecular collisions per second, with molecules moving at incredibly high speeds (see Section 17.3 for some numbers). There are added features of the continuous time assumption that are best studied as part of the hypothesis of local thermodynamic equilibrium in Section 27.5.

17.3 Results from kinetic theory

If the reader is content to accept the continuum approximation on face value, then the material in this section can be readily skipped. For others, this section outlines results from the kinetic theory of ideal gases in support of the continuum approximation. Deductive treatments that transition from molecular mechanics to macroscopic fluid mechanics is a topic of the kinetic theory of gases and liquids, which is outside our scope. In Section 17.3.7, we provide literature pointers for those wishing more rigor.

17.3.1 A mole and Avogadro's number

There are a tremendous number of molecules in the tiniest drop of water or puff of air. Just how many? To answer this question, we introduce the notion of a mole of matter. A mole is defined as the mass of a material substance that contains Avogadro's number of that substance, where

$$A^{\text{v}} = 6.022 \times 10^{23}\ \text{mole}^{-1}. \tag{17.9}$$

Avogadro's number, A^{v}, is the proportionality constant converting from one molar mass of a substance to the mass of a substance. Avogadro's number is conventionally specified so that one mole of the carbon isotope, ^{12}C, contains exactly 12 grams. Hence, 12 grams of ^{12}C contains

6.022×10^{23} atoms of ^{12}C. Avogadro's number provides a connection between scales active in the microscopic world of molecules to the macroscopic world of everyday experience.

Dry air (air with no water vapor) is comprised of oxygen molecules O_2, at roughly 22% by molecular mass, and nitrogen molecules N_2, at roughly 78% molecular mass.[3] The molar mass of dry air is thus

$$M^{\text{air}} = 0.22 * 32 \text{ g mole}^{-1} + 0.78 * 28 \text{ g mole}^{-1} \approx 28.8 \text{ g mole}^{-1}. \tag{17.10}$$

Pure (fresh) water is comprised of two hydrogen atoms and one oxygen atom. The molar mass of pure water is thus given by

$$M^{\text{water}} = 2 * 1 \text{ g mole}^{-1} + 16 \text{ g mole}^{-1} = 18 \text{ g mole}^{-1}. \tag{17.11}$$

17.3.2 Ideal gas law

The ideal gas law is given by

$$p\,V = n\,R^{\text{g}}\,T, \tag{17.12}$$

where p is the pressure, V is the volume, n is the number of moles, R^{g} is the universal gas constant,[4] and T is the absolute or thermodynamic temperature (temperature relative to absolute zero). Measuring the temperature in Kelvin leads to the universal gas constant

$$R^{\text{g}} = 8.314 \text{ J mole}^{-1} \text{ K}^{-1} = 8.314 \text{ kg m}^2 \text{ s}^{-2} \text{ mole}^{-1} \text{ K}^{-1}, \tag{17.13}$$

where the second equality replaced the energy unit, Joule, by its MKS equivalent,

$$\text{J} = \text{kg m}^2 \text{ s}^{-2}. \tag{17.14}$$

Use of the ideal gas law (17.12) says that one mole of ideal gas at standard temperature ($T_{\text{stand}} = 0°\text{C} = 273.15$ K) and standard atmospheric pressure ($p_{\text{stand}} = 101.325 \times 10^3$ Pa) occupies the following volume

$$V = \frac{n\,R^{\text{g}}\,T_{\text{stand}}}{p_{\text{stand}}} \tag{17.15a}$$

$$= \frac{(1 \text{ mole})\,(8.314 \text{ kg m}^2 \text{ s}^{-2} \text{ mole}^{-1} \text{ K}^{-1})\,(273.15 \text{ K})}{101.325 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-2}} \tag{17.15b}$$

$$\approx 2.25 \times 10^{-2} \text{ m}^3, \tag{17.15c}$$

where we introduced the MKS units for pressure (force per unit area)

$$\text{Pa} = \text{N m}^{-2} = \text{kg m}^{-1} \text{ s}^{-2}. \tag{17.16}$$

[3] We here ignore the presence of other trace gases, such as CO_2 and H_2O, although these gases are critical for understanding atmospheric radiation and hence the earth's energy budget.

[4] We write R^{g} rather than the more conventional R to distinguish from R commonly used in this book for the radius of a sphere.

Hence, the number density (number of molecules per volume) for a mole of ideal gas is given by

$$n^{\text{gas}} = \frac{\text{number per mole}}{\text{volume per mole}} \tag{17.17a}$$

$$= \frac{A^{\text{v}}}{V} \tag{17.17b}$$

$$= \frac{6.022 \times 10^{23}}{2.25 \times 10^{-2}\ \text{m}^3} \tag{17.17c}$$

$$= 2.68 \times 10^{25}\ \text{m}^{-3}. \tag{17.17d}$$

Specializing to air, we compute the mass density of air at standard temperature and pressure as

$$\rho^{\text{air}} = \frac{M^{\text{air}}}{V} = \frac{28.8 \times 10^{-3}\ \text{kg}}{2.25 \times 10^{-2}\ \text{m}^3} = 1.28\ \text{kg m}^{-3}, \tag{17.18}$$

where we set $M^{\text{air}} = 28.8 \times 10^{-3}$ kg according to equation (17.10). This ideal gas density is close to the 1.225 kg m^{-3} density measured for air at standard conditions, thus supporting use of the ideal gas law for dry air. Differences arise from trace constituents in air as well as inter-molecular forces (an ideal gas has no inter-molecular forces).

17.3.3 Molecular mean free path

We are in search of length scales relevant for molecular motion. One length scale is that of the molecule itself. Another is set by the distance between molecular collisions. The molecular mean free path is the mean distance that a molecule travels before colliding with another molecule. Arguments from kinetic theory of gases, applied to an ideal gas, lead to the expression

$$L_{\text{mfp}} = \frac{1}{\pi\,\sqrt{2}\,n^{\text{gas}}\,d^2} \tag{17.19}$$

where d is the diameter of the molecule. The mean diameter of air molecules is roughly

$$d_{\text{molecule air}} \approx 2 \times 10^{-10}\ \text{m}. \tag{17.20}$$

Hence, the mean free path for air molecules at standard temperature and pressure is

$$L_{\text{mfp}} = \frac{1}{\pi\,\sqrt{2}\,n^{\text{gas}}\,d^2_{\text{molecule air}}} \tag{17.21a}$$

$$= \frac{1}{\pi\,\sqrt{2}\,(2.68 \times 10^{25}\ \text{m}^{-3})\,(2 \times 10^{-10}\ \text{m})^2} \tag{17.21b}$$

$$= 2 \times 10^{-7}\ \text{m}. \tag{17.21c}$$

The mean free path for an air molecule is roughly 1000 times larger than the molecular diameter (e.g., Figure 17.1).

17.3.4 Root mean square molecular speed

What is the mean speed for molecules moving through a gas? Again, kinetic theory for ideal gases offers an explicit expression, here written in terms of the pressure and density of the gas

$$v_{\text{rms}} = \sqrt{\frac{3\,p}{\rho}} = \sqrt{\frac{3\,R^{\text{g}}\,T}{M}}. \tag{17.22}$$

Note the direct relation between pressure, temperature, and speed. That is, molecules move faster at higher temperature, and thus impart larger pressure on their surrounding environment. At standard pressure and temperature, the root-mean-square speed for an air molecule is given by

$$v_{\text{rms}} = \sqrt{\frac{3\,p_{\text{stand}}}{\rho^{\text{air}}}} \tag{17.23a}$$

$$= \sqrt{\frac{3\,(101.325 \times 10^3 \text{ kg m}^{-1} \text{ s}^{-2})}{1.28 \text{ kg m}^{-3}}} \tag{17.23b}$$

$$= 487 \text{ m s}^{-1}. \tag{17.23c}$$

To get a sense for the relative scale of this speed, note that the speed of sound in air at standard temperature and pressure is 331 m s^{-1}. So these molecules are moving faster than sound! These speeds are correspondingly much higher than the speeds typical for fluid elements in the atmosphere and ocean.

17.3.5 Time scales for molecular collisions

Assuming one collision occurs within a mean free path, and the molecules are moving at the root-mean-square speed, we can estimate the time between collision according to

$$t_{\text{collision}} = \frac{L_{\text{mfp}}}{v_{\text{rms}}} \tag{17.24}$$

The corresponding time for air is given by

$$t_{\text{air}} = \frac{2 \times 10^{-7} \text{ m}}{487 \text{ m s}^{-1}} = 4.1 \times 10^{-10} \text{ s}. \tag{17.25}$$

Inverting this number, we see that there are roughly $t_{\text{air}}^{-1} = 2.5 \times 10^9$ s^{-1} collisions per second. The huge number of molecular collisions per second means that for all macroscopic processes, including highly turbulent geophysical fluid flow, the dynamical time scales for the macroscopic motion are many orders of magnitude longer than the time scales for molecular motions.

17.3.6 Macroscopically small and microscopically large

For environmental measurements of the atmosphere and ocean, or for conventional measurements in laboratories, we can detect differences in fluid properties (e.g., mass density, velocity, tracer concentration, thermodynamic state properties) for length scales on the order of

$$L_{\text{macro}} = 10^{-4} \text{ m}. \tag{17.26}$$

For macroscopic purposes, fluid properties are homogeneous over regions with length scales on the order of L_{macro}. Although macroscopically rather tiny, a fluid region of volume L_{macro}^3 is huge microscopically. We can see so by computing the number of molecules in this region.

At standard conditions, a volume of air of size L_{macro}^3 contains

$$N_{\text{air molecules}} = V\,n^{\text{gas}} = (10^{-4} \text{ m})^3\,(2.68 \times 10^{25} \text{ m}^{-3}) \approx 3 \times 10^{13} \text{ air molecules}. \tag{17.27}$$

To compute the number of water molecules in this same volume, we first use the water mass

density of

$$\rho^{\text{water}} \approx 10^3 \text{ kg m}^{-3} \tag{17.28}$$

to determine the water mass in this region

$$M^{\text{water}} = \rho^{\text{water}} V = (1000 \text{ kg m}^{-3})\,(10^{-12} \text{ m}^3) = 10^{-9} \text{ kg}. \tag{17.29}$$

Water has a molar mass of 0.018 kg mole^{-1}, so a volume of $(10^{-4}\text{ m})^3$ contains

$$N_{\text{water molecules}} = \left(\frac{10^{-9}\text{ kg}}{0.018\text{ kg mole}^{-1}}\right) \times 6.022 \times 10^{23} \text{ molecules mole}^{-1} = 3 \times 10^{16} \text{ water molecules}. \tag{17.30}$$

Water thus has roughly 10^3 more molecules in this volume than air at standard pressure, which reflects the roughly 10^3 times larger mass density for water. Evidently, both water and air contain a huge number of molecules in this macroscopically tiny region.

17.3.7 Further study

Pedagogical treatments of the ideal gas law and kinetic theory can be found in most books on introductory physics or chemistry. *Vallis* (2017) provides extensions of the ideal gas law for an atmosphere with moisture.

For discussions of the continuum approximation reflecting that given here, see the discussion on page 1 of *Olbers et al.* (2012), or the more thorough treatments given in Section 1.2 of *Batchelor* (1967) and Section 1.4 of *Kundu et al.* (2016). Chapter 1 of *Salmon* (1998) offers an even more thorough treatment, touching on elements from kinetic theory and details for how to coarse grain average over molecular degrees of freedom (see his pages 3 and 4 and Sections 9, 10, and 11). A rigorous account of kinetic theory is offered in many treatments of statistical mechanics. That given by *Reif* (1965) and *Huang* (1987) are accessible to those with a physics undergraduate training. When reading the statistical mechanics literature, look for discussions of the "hydrodynamical limit," which concerns the transition from discrete particle mechanics to continuum mechanics.

Chapter 18

Fundamentals of fluid kinematics

In describing and understanding fluid motion, we use the dual lenses offered by the *Eulerian* and the *Lagrangian* descriptions. The Eulerian description uses a spatial description with coordinates that are fixed in Euclidean space, whereas the Lagrangian reference frame uses a material description with coordinates that are fixed on fluid particles. These dual (spatial versus material) descriptions form the foundation for fluid kinematics. The Eulerian description is more commonly used in fluid mechanics since the kinematic property of central focus is the fluid velocity as a field. In contrast, the Lagrangian approach is more commonly used in solid mechanics, in which the central kinematic focus concerns the trajectories or motion of material particles relative to a reference configuration. Even so, a Lagrangian description offers insights into the conceptual foundations of fluid mechanics (indeed, for all continuum mechanics). We thus give attention to the needs of both Eulerian and Lagrangian kinematics in this chapter, and elsewhere in this book.

READER'S GUIDE TO THIS CHAPTER

This chapter introduces concepts and tools used in nearly every subsequent chapter of this book. We require elements of the tensor analysis from Part I to systematically transform between the Eulerian and Lagrangian descriptions, and we review the salient formalism in this chapter to keep the discussion self-contained. References for this chapter include the text by *Salmon* (1998), who provides an accessible treatment of Eulerian and Lagrangian fluid mechanics. Chapter 4 of *Aris* (1962) offers a lucid treatment of fluid kinematics in the context of tensor analysis. Chapter 4 of *Malvern* (1969) provides a summary of the various kinematic perspectives used in continuum mechanics, with Eulerian (spatial) and Lagrangian (material) two of the four descriptions that have been used in continuum mechanics.[a]

[a] The other two are the *referential description* and the *relative description*. We make some use of the referential description in Section 18.6, which is commonly used in elasticity theory and applications in such areas as seismology (e.g., *Tromp* (2024)).

18.1 Loose ends

- Maxey-Riley equations

- Unify the discussion of invariance of the material time derivative in Sections 18.9 and 18.10. Also, introduce the notion of a scalar field and its invariance, thus rendering invariance of the material time operator when acting on the scalar field.

- Discuss material time derivative in non-Cartesian coordinates acting on a vector. Connect to the metric acceleration from Section 13.9.4.

18.2 Strong and weak formulations

The continuum approximation (Chapter 17) allows us to consider fluid flow from a field theoretic perspective, whereby physical properties are described by fields that take on values at each point of a space and time continuum. Consequently, we make use of a differential equation formulation of the governing fluid equations as well as an integral formulation. The differential equation formulation is sometimes referred to as the *strong* formulation. This name is motivated by the need to make "strong" assumptions about the smoothness of the continuum fields. Absent such smoothness assumptions, the differential equations lack predictive skill. Even so, some fluid phenomena (e.g., shocks) do not satisfy the necessary smoothness assumptions, thus making the strong formulation unsuitable for such fluid phenomena. In those cases, one must employ an integral formulation non-smooth flows, with the integral formulation known as the *weak* formulation since it requires fewer assumptions about smoothness.

In this book, we are not concerned with shocks or other strong discontinuities in the fluid flow. Consequently, we can make use of both the strong and weak formulations. We are thus afforded a connection between the weak and strong formulations through the *Leibniz-Reynolds transport theorem* derived in Section 21.2.4. Each formulation is suited for particular needs. For example, the strong formulation provides a more concise view of the fluid equations and allows for familiar manipulations/transformations based on the rules of differential calculus studied in Part I. In contrast, the weak formulation is needed to develop budgets over finite fluid regions. Correspondingly, the weak formulation provides a starting point for the derivation of finite volume budgets that serve as the basis for certain numerical methods (e.g., *Griffies et al.* (2020)).

18.3 Conceptually partitioning the continuum

As part of a continuum description of fluid motion, we make use of conceptual physical systems to frame the mechanics and describe the motion. We start by describing the material fluid particle in Section 18.3.1, which is a zero-dimensional point moving with the fluid flow, and then expand to infinitesimal fluid regions (fluid parcels and fluid elements) that are bounded by imagined partitions. The boundaries can be either open or closed to matter and energy exchange depending on the character of the fluid. There is no pretense that the partitions used to define parcels and elements can be experimentally determined. Rather, partitions are drawn within the continuum fluid by the theorist for purposes of formulation and conceptualization. We are afforded the ability to draw these partitions through our use of the continuum description of fluid mechanics.[1]

18.3.1 Fluid particles

A point in Euclidean space is specified by a spatial coordinate, $\boldsymbol{x}$, and an instant in *Newtonian time* is specified by the time, t. Euclidean space plus Newtonian time is referred to as a *Galilean space-time*. Each point within a matter continum undergoes motion according to the laws of continuum mechanics. We define a *fluid particle* as a zero dimensional mathematical point that follows motion of the continuous material fluid, with that motion specified by the velocity field (left panel in Figure 18.1). Since it has zero spatial extent, a fluid particle has no impact on the flow. Notably, a fluid particle is not a molecule or atom since even molecules and atoms have nonzero spatial extent and so impact their surroundings. Even so, it does represesent a point in the material fluid continuum rather than just a point in space.

[1] This conceptual formulation of fluid mechanics, namely as a continuous collection of infinitesimally small fluid elements, originates from the work of Leonard Euler (1707-1783) (see *Truesdell* (1953) the long footnote on pages 30-31 of *Truesdell* (1954)).

FIGURE 18.1: Schematic of the motion in space-time for the conceptual systems used in our considerations of fluid kinematics. Left panel: a fluid particle has zero spatial extent and has zero impact on the flow. Its motion in space-time defines a path/trajectory as determined by integral curves of the velocity field, $\boldsymbol{v}(\boldsymbol{x}, t)$. Note that slope of the curve on this space-time diagram is the inverse of the velocity: slope $= \mathrm{d}t/\mathrm{d}x = 1/u$. The trajectories of fluid particles define the Lagrangian reference frame. Middle panel: a material fluid parcel is comprised of a fixed material content (and thus a fixed mass) and fixed thermodynamic properties. Fluid parcels are infinitesimal deformable regions of a perfect fluid whose motion within a straining velocity field changes the parcel's shape. The center of mass for the fluid parcel follows a path that is approximated by that of a fluid particle at the center of mass. Right panel: a fluid element is comprised of a fixed mass but with matter and thermodynamic properties exchanged across its boundary, here depicted by the loss of dark gray matter and increase of light gray matter through exchanges with the surrounding fluid. The fluid element moves with the barycentric velocity (see Section 21.1), which is the center of mass velocity for the constituents contained in the fluid element. Both fluid parcels and fluid elements change their shape in the presence of fluid strain. Over time, a fluid parcel and a fluid element change their shape, with most realistic flows resulting in flows that require a reinitialization of the parcel/element boundaries in order to maintain coherency as identifiable fluid regions.

The position of a fluid particle in space and time is uniquely specified by its material coordinate plus time (we discuss material coordinates in Section 18.5.1). The trajectory or pathline of a fluid particle is an *integral curve* of the velocity field, where each point along a trajectory has a tangent that defines the velocity vector (Section 18.11).[2] The accumulation of a continuum of fluid particle trajectories define the pathlines that prescribe the Lagrangian or material reference frame (Section 18.4).

Fluid particles are directly analogous to *test mass particles* in Newtonian gravitation that are used to map gravitational field lines, and *test electric charges* in electromagnetism used for mapping the electromagnetic field. However, fluid particles have zero mass and are fully defined kinematically through specifying the velocity field. Fluid particles can be used to study perfect fluids, which necessarily have a single matter constitutent, as well as real fluids with multiple matter constituents. For the perfect fluid, fluid particles trace out integral curves of the velocity field, whereas for a real fluid the fluid particles provide integral curves for the *barycentric velocity* studied in Section 21.1.

Some books define fluid particles as finite sized fluid regions, much like the fluid parcel described in Section 18.3.2 or the fluid element in Section 18.3.4. Some treatments also suggest that a fluid particle is akin to a fluid molecule. We instead find it conceptually simpler and far less problematic to define a fluid particle as a mathematical point with zero spatial extent and zero mass, thus serving solely as a conceptual probe for the fluid flow and as a means to specify the Lagrangian reference frame.

[2]When orienting time along the vertical axis, then the tangent to the trajectory is actually the inverse velocity: slope $= \mathrm{d}t/\mathrm{d}x = 1/u$. We follow the convention used in special relativity, where the trajectory is known as the *world line*, and world lines live within the cone bounded by the world line of photons.

18.3.2 Material fluid parcels in perfect fluids

For many purposes we find it useful to study fluid mechanics in the absence of irreversible processes such as friction, heat exchange, and diffusive mixing. In this case the fluid is referred to as an *ideal fluid* or equivalently a *perfect fluid*. We prefer the term *perfect fluid* for our studies in order to avoid confusions with an ideal gas often found useful in studying the atmosphere. Namely, ideal gases can posses irreversible processes so that they need not be perfect fluids.

Perfect fluid mechanics is concerned with motion of a homogeneous fluid (e.g., pure water) with zero viscosity (no friction), and in the absence of any heat exchange (adiabatic).[3] In describing perfect fluids we commonly make use of *material fluid parcels*, which are infinitesimal deformable fluid regions (middle panel in Figure 18.1) comprised of many fluid particles. A material fluid parcel maintains a fixed matter content so that it has a fixed mass. Furthermore, it does not experience irreversible exchanges of momentum arising from friction since the perfect fluid has zero viscosity. Hence, its only interaction with the surrounding fluid environment is through reversible mechanical exchanges from pressure. The material fluid parcel is thus a closed thermodynamic system that is open to reversible mechanical interactions.

A material parcel is not a point. Rather, it has an infinitesimal volume that deforms with the flow. Conceptually we can imagine the material fluid parcel as a tiny region of fluid surrounded by a perfectly slippery bag that is also perfectly insulating. This bag is closed to matter exchange so that its enclosed fluid particles are not exchanced with surrounding environment. Even so, the fluid parcel deforms in response to mechanical interactions mediated by pressure. Additionally, the bag expands or contracts according to the density of the fluid within the bag. This conceptual picture is qualified by noting that we never have occasion or need to precisely specify the boundary of a material fluid parcel. Rather, we make use of the conceptual framework provided by fluid parcels as a means to formulate the differential equations of perfect fluid mechanics.

18.3.3 Finite sized material objects in perfect fluids

Any extended region in a perfect fluid, either infinitesimal or finite, open or closed, remains exactly coherent (fixed matter content) as the region moves through the fluid. The reason for such coherency is that a perfect fluid supports no mixing or other irreversible processes that would act to diffuse the matter content. A closed material region in a perfect fluid is a finite volume generalization of a material fluid parcel. Conversely, a material fluid parcel is the infinitesimal limit of a closed material fluid region. Likewise, we can define finite sized material regions of any shape, each of which retains a fixed mass and fixed matter content as it moves through a perfect fluid. We study the kinematics of perfect fluid material lines, surfaces, and volumes in Chapter 19.

18.3.4 Fluid elements in real fluids

A fluid element is an infinitesimal and deformable fluid region of fixed mass yet non-fixed matter and non-fixed thermodynamic properties (right panel in Figure 18.1). For a homogeneous fluid comprised of a single matter constituent and no irreversible processes, then a fluid element reduces to a material fluid parcel. However, there is a distinction for real fluids such as the ocean and atmosphere, both of which have multiple constituents and support irreversible processes.

The exchange of matter across the boundary of a fluid element arises from the irreversible mixing of matter constituents within the fluid (Sections 21.1 and 64.3). As detailed in Section

[3] We study frictional stresses arising from viscosity in Chapter 26, with viscosity the means for the irreversible transfer of momentum within a non-perfect fluid. We study enthalpy in the Chapter 23, with a perfect fluid maintaining constant enthalpy since it is entirely adiabatic.

21.1, diffusive matter exchange leaves the mass of the fluid element unchanged since the fluid element velocity is determined by its center of mass (*barycentric velocity*). Just as for a material fluid parcel, we have no need to experimentally specify the boundary of a fluid element. Instead, fluid elements are conceptual systems used to formulate the differential equations of a real fluid. Much of the kinematics in the current chapter holds for both material fluid parcels and fluid elements. However, in Chapter 20 and elsewhere, we make the distinction when studying the kinematics of multi-constituent fluids.

Many authors do not distinguish between material fluid parcels and fluid elements, choosing instead to retain a single overloaded term for both a perfect fluid and real fluid. However, this overloaded terminology can lead to confusion. We are thus motivated to maintain a distinction between fluid parcel (single component perfect fluid with no mixing) and fluid element (multi-component real fluid with mixing). The distinction offers an added signal for when the fluid under study is perfect (fluid parcel) or real (fluid element).

18.3.5 Test fluid element in real fluids

A *test fluid element* is a fluid element that has no effect on the surrounding fluid environment and is used as a conceptual probe of the fluid much like the fluid particle in Section 18.3.1. Unlike the fluid particle, the test fluid element has nonzero spatial extent and it can exchange matter and energy with its surrounding environment. The test fluid element is of particular use when studying buoyancy in Chapter 31. In that context, we further refine our treatment of the test fluid element, where we assume that it feels the same contact forces as the fluid, but distinct body forces.[4]

18.3.6 Finite sized fluid region in real fluids

A finite sized region within a real fluid is the most general subsystem we consider, with the region having boundaries that are open to the exchange of matter, mechanical forces, and thermodynamic properties with the surrounding environment. Here, we are often concerned with details of the region boundary and study the transport of properties across that boundary.

18.3.7 Comments

Throughout the study of fluid kinematics, it is important to maintain an appreciation for the continuum approximation. In particular, the continuum approximation affords information about the continuous velocity field at each point of space and each instance of time. The velocity field allows us to determine fluid particle trajectories (via time integration), as well as the motion of fluid parcels in perfect fluids and fluid elements in real fluids. As part of a diagnostic framework for laboratory or field experiments, it can be useful to seed the fluid flow with a large number of tiny objects that approximate fluid particles whose motion approximates fluid particle trajectories. Similarly, in numerical experiments we may seed the flow with numerical fluid particles and compute their trajectories (*van Sebille et al.*, 2018). If we initially seed these particles in a tiny region, then deformation of the region provides the means to study deformation of fluid parcels and fluid elements as they move through the fluid. Likewise, seeding particles over larger regions allows one to study how finite sized regions are deformed.

When thinking about fluids parcels and elements, we should acknowledge that they are convenient concepts, and yet we do not delineate their boundaries either conceptually or in practice. This situation contrasts the study of other areas of continuum mechanics, where discrete regions

[4] We study contact and body forces in Sections 25.2 and 26.2.

of the media are identifiable. For a fluid, the notion of identifying a fluid element, such as by wrapping a tiny region of fluid with an imaginary permeable sack, is a fiction that works for some thought experiments, but it is not taken literally. The perspective leads us to discount (i.e., consider incorrect) a description of continuum mechanics that depends on fluid elements as distinct and identifiable objects. Rather, we aim for a theoretical description independent of details for the fluid element boundaries. In this case, we are afforded the ability to describe a fluid as continuum matter with properties that are unambiguously defined at every point in the fluid.

18.4 Lagrangian and Eulerian descriptions

There are two reference frames commonly used as the basis for describing motion of a fluid continuum. For the continuous fluid motions considered in this book, these two reference frames retain a 1-to-1 and invertible relation that allows for the mathematical and conceptual transformation between the frames.

- Lagrangian or material description: This description makes use of a reference frame that is defined by motion of material fluid particles (Section 18.3.1). That is, the Lagrangian reference frame is comoving with the continuum of fluid particles. The mechanical description aims to determine the continuum of trajectories, with each trajectory delineated by a continuous material coordinate that labels each fluid particle. The Lagrangian reference frame is non-inertial since fluid particles generally experience accelerations via changes to their speed and/or direction.

- Eulerian or laboratory description: This description makes use of a fixed reference frame that observes fluid motion from fixed spatial positions, $\boldsymbol{x}$, within a "laboratory". This *Eulerian* description measures fluid properties as the fluid streams by a fixed observer. It is not concerned with determining trajectories. Instead, Eulerian kinematics focuses on fluid properties as continuous fields that are functions of spatial position $\boldsymbol{x}$ and time t.

The Eulerian and Lagrangian descriptions complement one another. The Lagrangian description lends itself to insights partly due to its direct analog to point particle mechanics of Part II in this book. Alternatively, the Eulerian description is commonly more straightforward when developing numerical methods for simulations, or when making laboratory or field measurements. Throughout this book, we make use of both Eulerian and Lagrangian kinematic descriptions. A goal of this chapter is to provide the foundation for these two descriptions and to develop tools for transforming between them.

In non-geophysical treatments of fluid mechanics, it is typical to assume that the laboratory reference frame of the Eulerian observer is fixed in space, and thus is an inertial reference frame. However, for geophysical fluid mechanics we generally consider an Eulerian reference frame fixed with respect to the rotating planet (a rotating laboratory frame), and as such the earth laboratory frame is not inertial. However, the discussion in this chapter is not concerned with the non-inertial features that give rise to planetary centrifugal and Coriolis accelerations (see Chapter 13). Instead, we note that the constant rotation of the planet does not impart any strain to the fluid.[5] Consequently, non-rotating fluid kinematics is sufficient for most purposes of geophysical fluid kinematics.

[5]This point is made more formally when studying the kinematics of fluid strain in Section 19.3.

FIGURE 18.2: A short segment of a fluid particle trajectory. The trajectory passes through the point $\boldsymbol{x} = \boldsymbol{X}(T)$ at time T and $\boldsymbol{x} + \delta\boldsymbol{x} = \boldsymbol{X}(T + \delta T)$ at time $T + \delta T$. Eulerian kinematics describes the fluid flow from the perspective of an observer fixed with respect to the laboratory frame. Lagrangian kinematics describes the fluid flow from the perspective of an observer comoving with fluid particles.

18.5 Material and spatial coordinates

A material description is afforded by the Lagrangian reference frame, whereby each fluid particle is labeled with a material coordinate, $\boldsymbol{a}$ and measures time, T, thus leading to the $\boldsymbol{a}$-space or material space description.[6] This description complements the Eulerian or $\boldsymbol{x}$-space description, whereby each point in Euclidean space, $\boldsymbol{x}$, is labeled by its position relative to a fixed origin and with time, t. The $\boldsymbol{a}$-space description determines the history of each material fluid particle's motion, whereas the $\boldsymbol{x}$-space description determines the fluid motion as viewed at each spatial point $\boldsymbol{x}$. Note that $t = T$ since we are working with universal Newtonian time. However, it is very useful to distinguish the two when taking time derivatives, as it is important to know whether the time derivative is computed holding $\boldsymbol{x}$ fixed or $\boldsymbol{a}$ fixed.

18.5.1 Fluid particle trajectories

In describing the motion of a classical point particle (Chapter 13), we specify its spatial position according to a time dependent position vector, $\boldsymbol{X}(T)$. At a given time, T, the position vector points to $\boldsymbol{x}$, in which case we write

$$\boldsymbol{x} = \boldsymbol{X}(T) \qquad \text{point particle.} \tag{18.1}$$

A sample trajectory is shown in Figure 18.2. We emphasize the notation convention used here, which may seem pedantic but in later discussions proves essential. Namely, the time dependent spatial position of a particle is denoted with, $\boldsymbol{X}(T)$, whose instantaneous space position is denoted by the lowercase, $\boldsymbol{x}$. This convention aims to distinguish time dependent functions, such as $\boldsymbol{X}(T)$, from the value of these functions, $\boldsymbol{x}$, evaluated at a time instance. In Section 18.6 we introduce the fluid *motion*, which serves as a more suitable means to distinguish points on a particle trajectory from points in space.

[6]The continuum mechanics literature often writes $\boldsymbol{X}$ rather than $\boldsymbol{a}$ for the material particle label. That nomenclature is motivated since $\boldsymbol{X}$ is commonly chosen as the initial Cartesian position at a referential time. We instead write the material coordinate as $\boldsymbol{a}$ since, as noted in Section 18.5.2, there are examples whereby one, two, or three of the $\boldsymbol{a}$ coordinates are not Euclidean space positions, but instead they are determined by, for example, the buoyancy or tracer concentration.

When there are N discrete particles, we distinguish the various particle trajectories by introducing a discrete label for each of the trajectories (e.g., see Section 11.5). The spatial position of particle i at time T is thus written

$$\boldsymbol{x} = \boldsymbol{X}_{(i)}(T). \tag{18.2}$$

When the matter is a continuum, then the discrete label becomes a continuous vector, $\boldsymbol{a}$, which is referred to as the *material* coordinate along with material time, T. At time T, the spatial position of a fluid particle labelled by the material coordinate, $\boldsymbol{a}$, is written

$$\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{a}, T) \qquad \text{continuum of matter.} \tag{18.3}$$

The continuous vector, $\boldsymbol{a}$, labels a point of matter within the continuum fluid. Correspondingly, by allowing time to progress, the function $\boldsymbol{X}(\boldsymbol{a}, T)$ provides the trajectory for the fluid particle labelled by the material coordinate, $\boldsymbol{a}$.

In this book we ignore special relativistic effects of fluid particles. Consequently, both the material reference frame and the laboratory reference frame measure the same universal Newtonian time, $t = T$. In contrast, the spatial coordinates are distinct for the Eulerian and Lagrangian references frames. Again, the spatial coordinates for the Eulerian frame are given by the position relative to a fixed laboratory frame, whereas the three components of a material Lagrangian coordinate remains fixed according to its value assigned to each fluid particle. Additionally, the three coordinates for both the Eulerian and Lagrangian description must be linearly independent to allow for a unique specification of the fluid particle.

18.5.2 Example material coordinates

One common choice for material coordinate is the spatial position of each fluid particle at the referential time,

$$\boldsymbol{a} = \text{coordinate position at } T = t_0 \text{ for particle labelled by } \boldsymbol{a}. \tag{18.4}$$

As a slightly more refined example, consider a perfect fluid (single material component with no irreversible processes). For this fluid, the specific entropy of each fluid parcel remains fixed at its initial value. When the fluid is placed in a gravitational field, layers of constant specific entropy are generally found to be monotonically stacked, or *stratified*, in the vertical direction (Chapter 31). As a result, we can uniquely specify a fluid parcel by giving its horizontal coordinate position, (x, y), as well as the specific entropy. The material coordinates for a parcel can thus be written as

$$\boldsymbol{a} = \text{horizontal coordinate position and } \theta \text{ value at } T = t_0, \tag{18.5}$$

where we write θ as a measure of the specific entropy (or potential temperature as discussed in Section 24.3). As indicated by this example, the physical dimensions of material coordinates can generally differ. It is this generality that necessitates the use of general tensor methods when developing the mechanical equations using arbitrary Lagrangian coordinates. The mathematical physics of these *generalized vertical coordinates* are detailed in Part XI of this book. For the current chapter we assume the Lagrangian coordinates are Cartesian, as given by the initial Cartesian positions as in equation (18.4).

18.6 The motion field

The discussion in Section 18.5 is directly motivated by particle mechanics, and it serves as a useful introduction to fluid kinematics. It also serves to emphasize the primary role of fluid

particle trajectories. We here go a bit further to help understand what is happening as the continuum fluid evolves. For this purpose, we borrow from the *referential description* used in continuum mechanics (e.g., Section 4.3 of *Malvern* (1969) and Chapter 1 of *Tromp* (2024)).

18.6.1 Motion as a mapping

We conceive of the fluid motion over time as the motion of a matter continuum through Euclidean space. Let us define the fluid *motion* field, $\boldsymbol{\varsigma}$, as a mapping between the continuous matter distribution in a reference state and the matter distribution in a future state. We write this mapping as[7]

$$\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T) \quad \text{and} \quad x^i = \varsigma^i(\boldsymbol{a}, T). \tag{18.6}$$

The motion, $\boldsymbol{\varsigma}$, is a function of the material coordinate, a^I, which labels a fluid particle, and the material time, T. We write uppercase, $I = 1, 2, 3$, as tensor indices used for material coordinates. Equation (18.6) says that the spatial point, $\boldsymbol{x}$, for a fluid particle in the spatial manifold, $\mathcal{S}$, is known once we specify the material coordinate, $\boldsymbol{a}$, as well as the time, $T = t$. The motion of the continuum of fluid particles provides a map that continuously reshapes and deforms the fluid continuum as it moves through Euclidean space.

By fixing a particular material coordinate, $\boldsymbol{a}$, and letting time progress, the motion, $\boldsymbol{\varsigma}(\boldsymbol{a}, T)$, defines a fluid particle trajectory just as we saw in Section 18.5

$$\boldsymbol{\varsigma}(\boldsymbol{a}, T) = \boldsymbol{X}(\boldsymbol{a}, T). \tag{18.7}$$

Given this identity, we could have maintained the Section 18.5 notation rather than introduce this new symbol, $\boldsymbol{\varsigma}$. Indeed, in some cases in this book we find it more convenient to use the notation $\boldsymbol{X}(\boldsymbol{a}, T)$ in order to directly connect to the notation used for describing the trajectories of point particles in Part II of this book. However, the new notation proves helpful for other occastions, particularly in Chapter 19 when studying the motion of coherent regions of fluid.

18.6.2 Depicting the motion and its inverse

We illustrate the motion field and the corresponding mapping of the fluid continuum in Figure 18.3. The base or reference state of the fluid continuum is referred to as $\mathcal{B}$, and it defines a smooth *reference manifold* on which we can perform differential calculus (i.e., there are no rips or discontinuities in the fluid continuum). Each point of $\mathcal{B}$ is specified by a value for the material (or Lagrangian) coordinate, $\boldsymbol{a}$. As time progresses, the motion field smoothly and invertibly maps each point of $\mathcal{B}$ to a deformed state of the fluid continuum. A point in the deformed fluid state is described by a point in the manifold, $\mathcal{S}$. We measure a position on $\mathcal{S}$ using the spatial (or Eulerian) coordinates, x^i according to the mapping (18.6). We thus refer to $\mathcal{S}$ as the *spatial manifold*.

Since the mapping provided by the motion is invertible, there is an inverse mapping, Σ. The inverse mapping takes each point occupied by fluid in the spatial manifold, $\mathcal{S}$, to a unique point on the reference manifold, $\boldsymbol{B}$. That is, given the Eulerian position of a fluid particle, $\boldsymbol{x}$, we have a unique material coordinate $\boldsymbol{a}$, which is specified by the inverse motion

$$\boldsymbol{a} = \boldsymbol{\Sigma}(\boldsymbol{x}, t) \quad \text{and} \quad a^I = \Sigma^I(\boldsymbol{x}, t)). \tag{18.8}$$

[7] The Greek letter, ς, is a stylized version of σ. We use ς for the motion since σ is used elsewhere in this book for generalized vertical coordinate. We also avoid the notation of φ and Φ for the motion and its inverse, which is commonly used in the continuum mechanics literature. We instead reserve Φ for the geopotential, as commonly used in the geophysical fluids literature.

FIGURE 18.3: The motion of each fluid particle maps the fluid continuum from the referential manifold, $\mathcal{B}$, at time $t = T = t_0$, to a deformed state at $t = T > t_0$ that is represented as points on the spatial manifold, $\mathcal{S}$. A point in the referential manifold is specified by the material (Lagrangian) coordinates, a^I, whereas a point in the spatial manifold is specified by its spatial (Eulerian) location, x^i. The motion field, ς, defines the one-to-one invertible map from $\mathcal{B}$ to $\mathcal{S}$, whereas the inverse motion, Σ, defines the map from $\mathcal{S}$ to $\mathcal{B}$. We here depict the $\boldsymbol{a}$-space and $\boldsymbol{x}$-space coordinates as orthogonal Cartesian coordinates, yet they can be arbitrary coordinates by making use of the general tensor formalism in Chapters 8 and 9. This figure is adapted from Figure 1.2 of *Tromp* (2024).

The invertible nature of the mapping means that a fluid particle trajectory does not split, nor do two trajectories occupy the same point at the same time. We acknowledge that fluid particle trajectories generally become increasingly complex in turbulent flow (and even for some laminar flows), thus making the Lagrangian description less convenient after a certain time, and motivating the reinitialization of fluid particle trajectories. However, so long as trajectories do not split or merge, the trajectories are well defined in principle, and so is the corresponding Lagrangian formulation.

18.7 Material and spatial representations

According to the presentation in Section 18.6, we specify a point on the reference manifold, $\mathcal{B}$, using Lagrangian coordinates, $(\boldsymbol{a}, T)$, with this specification identifying a particular material fluid particle. We then specify the position of a fluid particle on the spatial manifold, $\mathcal{S}$, using Eulerian coordinates, $(\boldsymbol{x}, t)$, with this specification identifying a particular point in space. The one-to-one and invertible motion field, $\boldsymbol{\varsigma}$, affords the ability to move seamlessly between the reference manifold and the spatial manifold. For example, by specifying the material point, $(\boldsymbol{a}, T)$, on $\mathcal{B}$, then that information uniquely specifies the fluid particle's spatial location, $(\boldsymbol{x}, t)$, on $\mathcal{S}$, according to

$$\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T) \quad \text{and} \quad t = T. \tag{18.9}$$

Alternatively, by specifying the spatial point of a fluid particle, $(\boldsymbol{x}, t)$, on $\mathcal{S}$, then we uniquely specify the material point $(\boldsymbol{a}, T)$ on $\mathcal{B}$, as per the inverse motion

$$\boldsymbol{a} = \boldsymbol{\Sigma}(\boldsymbol{x}, t) \quad \text{and} \quad T = t. \tag{18.10}$$

18.7.1 Motion as a coordinate transformation

Equation (18.9) has the appearance of an invertible coordinate transformation between spatial and material coordinates (e.g., Section 9.1). However, the coordinate transformations from Chapter 9 provide two alternative coordinate representations for points on a single manifold, whereas, as

illustrated by Figure 18.3, equation (18.9) is a mapping between two points on two manifolds, one point on the reference manifold and one on the spatial manifold. Even so, the motion field provides a smooth, one-to-one and invertible relation between these points. Consequently, we are afforded an alternative interpretation of the motion field as a coordinate transformation via equation (18.9). That is, the motion field defines a *point transformation* between a spatial (Eulerian) representation of a fluid particle and a material (Lagrangian) representation of the same fluid particle.[8] We make use of the general tensor analysis from Chapter 9 to formalize the mathematical transformation between the two coordinates and their respective representations of fluid properties.

18.7.2 The deformation matrix

In our analysis of fluid flow, we make routine use of the spatial coordinates ($\boldsymbol{x}$-space) of an Eulerian description and material coordinates ($\boldsymbol{a}$-space) of a Lagrangian description. We here introduce the transformation matrix allowing us to readily move between descriptions. Recall that in Section 10.2.1 we encountered the transformation matrix between Cartesian and spherical coordinates. We later consider a transformation matrix for moving between inertial and rotating (non-inertial) reference frames in Sections 18.9 and 18.10. Here, we develop the transformation matrix between $\boldsymbol{x}$-space and $\boldsymbol{a}$-space. Since the motion is invertible, so too is the transformation matrix, which means that its *Jacobian* (determinant) remains nonzero.

The transformation matrix is given by the matrix of partial derivatives, and we organize this matrix according to the following convention[9]

$$F^i{}_I = \frac{\partial \varsigma^i}{\partial a^I} \equiv \begin{bmatrix} \partial\varsigma^1/\partial a^1 & \partial\varsigma^1/\partial a^2 & \partial\varsigma^1/\partial a^3 \\ \partial\varsigma^2/\partial a^1 & \partial\varsigma^2/\partial a^2 & \partial\varsigma^2/\partial a^3 \\ \partial\varsigma^3/\partial a^1 & \partial\varsigma^3/\partial a^2 & \partial\varsigma^3/\partial a^3 \end{bmatrix}. \tag{18.11}$$

The upper Eulerian label, i, denotes the row and the lower material label, I, is the column. The transformation matrix, $F^i{}_I$, provides a means to measure how trajectories are deformed by the flow. Namely, each element of $F^i{}_I$ measures how much the i-component of a fluid particle trajectory is modified when altering the I-component of the material coordinate. *Malvern* (1969) refers to $F^i{}_I$ as a two-point tensor, given that it connects points in $\boldsymbol{x}$-space to points in $\boldsymbol{a}$-space. However, as discussed in Section 9.1.4, the transformation matrix is *not* a tensor, so we do not refer to $F^i{}_I$ as a tensor.[10] Rather, we refer to the transformation matrix, $F^i{}_I$, as the *deformation matrix* in deference to its role as the transformation matrix between spatial and material coordinates, and given its measure of how the flow deforms.

In Chapter 19 we study how the deformation matrix leads to the evolution of vector connecting two material points in the fluid. As a preface to that discussion, consider the special case where the material coordinate is the initial position, $\boldsymbol{a} = \boldsymbol{X}(\boldsymbol{a}, T = 0)$. In this case, the partial derivatives measure how particle trajectories are modified when altering the initial position of the particles. If the fluid has no deformation, then particle trajectories remain unaffected if changing the material coordinate (i.e., the initial position), in which case the deformation matrix is the identity tensor

$$F^i{}_I = \delta^i{}_I \quad \text{if there is no flow deformation.} \tag{18.12}$$

Generally each component of the deformation matrix is nonzero so that trajectories are deformed by the flow and as such they are dependent on the initial position.

[8] This perspective follows from Section 4.11 of *Aris* (1962).

[9] We make use of covariant and contravariant notation in equation (18.11), with the upstairs and downstairs tensor labels.

[10] We discuss the distinction between a second order tensor and a matrix in Section 1.7.7.

The Jacobian determinant of the deformation matrix can be written in either of the following ways

$$\det(F^i_{\ I}) = \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} = \det \begin{bmatrix} \partial\varsigma^1/\partial a^1 & \partial\varsigma^1/\partial a^2 & \partial\varsigma^1/\partial a^3 \\ \partial\varsigma^2/\partial a^1 & \partial\varsigma^2/\partial a^2 & \partial\varsigma^2/\partial a^3 \\ \partial\varsigma^3/\partial a^1 & \partial\varsigma^3/\partial a^2 & \partial\varsigma^3/\partial a^3 \end{bmatrix}. \tag{18.13}$$

We make use of the notation $\partial\boldsymbol{\varsigma}/\partial\boldsymbol{a}$ for the Jacobian as it offers a useful means to distinguish between the determinant of the deformation (18.11), versus the determinant of the inverse deformation written as $\partial\boldsymbol{a}/\partial\boldsymbol{\varsigma}$.

18.7.3 A discrete algorithm for the deformation matrix

To help further our understanding of the deformation matrix (18.11), we here sketch an algorithm for its discrete approximation. For this purpose, consider two-dimensional flow and write the trajectory of a particular fluid particle using Cartesian coordinates

$$\boldsymbol{X}(T) = X^1(T)\,\hat{\boldsymbol{x}} + X^2(T)\,\hat{\boldsymbol{y}}, \tag{18.14}$$

and use a Cartesian representation for the corresponding material coordinate

$$\boldsymbol{a} = a^1\,\hat{\boldsymbol{x}} + a^2\,\hat{\boldsymbol{y}}. \tag{18.15}$$

Now lay down a two-dimensional lattice with discrete indices (e, f) for each of the nodal points (grid points) on the lattice, and with corresponding spatial coordinates

$$\boldsymbol{x}(e, f) = x(e, f)\,\hat{\boldsymbol{x}} + y(e, f)\,\hat{\boldsymbol{y}}. \tag{18.16}$$

Initialize fluid particles at each of the lattice grid points,

$$\boldsymbol{X}(e, f; T = 0) = \boldsymbol{x}(e, f) = \boldsymbol{a}(e, f), \tag{18.17}$$

with the discrete material coordinates defined by the initial positions. Then time step the trajectories using the velocity field to compute the particle pathlines, $\boldsymbol{X}[\boldsymbol{a}(e, f); T]$, as illustrated in Figure 18.4. At any particular time, the position of a fluid particle is found by interpolating from the lattice grid points. Setting the material coordinates equal to the initial position then leads to the finite difference approximation to the deformation matrix

$$F^i_{\ I} = \begin{bmatrix} F^1_{\ 1} & F^1_{\ 2} \\ F^2_{\ 1} & F^2_{\ 2} \end{bmatrix} \approx \begin{bmatrix} \frac{X^1(e+1,f;T)-X^1(e-1,f;T)}{X^1(e+1,f;0)-X^1(e-1,f;0)} & \frac{X^1(e,f+1;T)-X^1(e,f-1;T)}{X^2(e,f+1;0)-X^2(e,f-1;0)} \\ \frac{X^2(e+1,f;T)-X^2(e-1,f;T)}{X^1(e+1,f;0)-X^1(e-1,f;0)} & \frac{X^2(e,f+1;T)-X^2(e,f-1;T)}{X^2(e,f+1;0)-X^2(e,f-1;0)} \end{bmatrix}. \tag{18.18}$$

If the grid is regular in both directions, then the initial positions have a separation, Δ, given by the grid spacing so that

$$F^i_{\ I} \approx \frac{1}{2\Delta} \begin{bmatrix} X^1(e+1, f; T) - X^1(e-1, f; T) & X^1(e, f+1; T) - X^1(e, f-1; T) \\ X^2(e+1, f; T) - X^2(e-1, f; T) & X^2(e, f+1; T) - X^2(e, f-1; T) \end{bmatrix}. \tag{18.19}$$

This expression illustrates how the deformation matrix provides a measure of trajectory spreading as fluid particles move away from their initial positions. As a check on the formulation, consider the case without any deformation. In this case $X^1(e, f; T) = X^1(e; T)$ and $X^2(e, f; T) = X^2(f; T)$ so that the transformation matrix is diagonal, and furthermore, $X^1(e+1; T) - X^1(e-1; T) = 2\,\Delta$ and $X^2(f+1; T) - X^2(f-1; T) = 2\,\Delta$, so that the transformation matrix is the identity.

FIGURE 18.4: Illustrating the computational algorithm of Section 18.7.3 used to approximate the deformation matrix, $F^i{}_I$. The left panel shows the two-dimensional grid with nodal points defining the initial positions for fluid particles. Each position on the grid is labeled by a unique integer (e, f). The initial position of each particle is taken as the material coordinate, with the discrete label (e, f) maintained by the particles as they evolve. The right panel shows the pathlines for the fluid particles after time $T > 0$. When working on a discrete grid, the position of the fluid particles is not generally at a nodal point. Hence, the position must be found by interpolating betwen the node points.

18.7.4 Jacobian as the ratio of volumes

We here establish the Jacobian of the deformation matrix as the ratio of the coordinate volume of fluid parcels as written using position space coordinates and material space coordinates. This property holds at each point within the continuum fluid so that it also holds on fluid elements.

Volume of an infinitesimal region of space within the fluid continuum

Consider the volume of an infinitesimal region of space. For simplicity, write this volume in terms of Cartesian coordinates

$$\mathrm{d}V(\boldsymbol{x}) = \mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z. \tag{18.20}$$

The $\boldsymbol{x}$ argument is introduced on the left hand side to distinguish this volume, which has dimensions L^3, from the volume written in material coordinates[11]

$$\mathrm{d}V^{\mathrm{L}}(\boldsymbol{a}) = \mathrm{d}a\,\mathrm{d}b\,\mathrm{d}c, \tag{18.21}$$

where $\boldsymbol{a} = (a^1, a^2, a^3) = (a, b, c)$ are coordinates in material space. Note that $\mathrm{d}V^{\mathrm{L}}(\boldsymbol{a})$ does not generally have dimension L^3, since the dimension for each component of the material coordinates is not necessarily length (e.g., see the example in equation (18.5)).

The two volumes are related by the Jacobian of transformation between $\boldsymbol{x}$-space coordinates and $\boldsymbol{a}$-space coordinates

$$\mathrm{d}V(\boldsymbol{x}) = \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}}\,\mathrm{d}V^{\mathrm{L}}(\boldsymbol{a}). \tag{18.22}$$

This relation indicates that the Jacobian of the deformation matrix measures the ratio of the volume written in terms of position coordinates to the volume written in terms of material coordinates

$$\frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} = \frac{\mathrm{d}V(\boldsymbol{x})}{\mathrm{d}V^{\mathrm{L}}(\boldsymbol{a})}. \tag{18.23}$$

[11] The L superscript on equation (18.21) is not a tensor label. Rather, it signals the volume of a tiny material region that is specified by material coordinates. We need the extra adornment to distinguish this volume using material coordinates from the volume using Eulerian coordinates, $\mathrm{d}V(\boldsymbol{x})$.

Hence, the Jacobian is a function of space according to the ratio of the volume of a fluid element in $\boldsymbol{x}$-space to the volume in $\boldsymbol{a}$-space. This is a key kinematic result of great practical value for transforming between Eulerian and Lagrangian coordinates.

Volume of an infinitesimal fluid element

The above results have been formulated for an arbitrary region of the fluid continuum. Hence, the expressions also hold when evaluated on an arbitrary material fluid parcel or fluid element. We use the notation δV for the parcel/element volume, in terms of which the above relations take the form

$$\delta V(\boldsymbol{x}) = \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}}\, \delta V^{\mathrm{L}}(\boldsymbol{a}) \Longrightarrow \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} = \frac{\delta V(\boldsymbol{x})}{\delta V^{\mathrm{L}}(\boldsymbol{a})}. \tag{18.24}$$

Hence, when evaluated on a moving material parcel, the Jacobian measures the ratio of the parcel volume written in terms of position coordinates to the parcel volume written in terms of material coordinates. In the particular case where the material coordinates are the initial fluid particle positions, then the Jacobian measures the ratio of the instantaneous volume of a fluid element at a point $\boldsymbol{\varsigma}(\boldsymbol{a}, T) = \boldsymbol{x}$, to its initial volume

$$\frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{\varsigma}(0)} = \frac{\delta V(\boldsymbol{x})}{\delta V(0)}. \tag{18.25}$$

18.7.5 Further study

This video from the *National Committee for Fluid Mechanics Films* offers insightful visualizations to help understand Eulerian and Lagrangian fluid descriptions. This lecture from Prof. Brunton provides a lucid discussion of fluid kinematics related to finite time Lyapunov exponents, whose calculation requires estimating the transformation matrix in Section 18.7.3 along with its eigenvalues and eigenvectors.

18.8 Lagrangian and Eulerian time derivatives

As noted in Section 18.5.2, we assume non-relativistic motion so that the material reference frame and the spatial reference frame both measure the same universal Newtonian time, t. However, when computing time derivatives, the spatial frame does so by fixing the space coordinate, $\boldsymbol{x}$, whereas the material frame does so by fixing the material coordinate, $\boldsymbol{a}$. These two time derivatives generally measure distinct changes in the fluid since one is computed in the laboratory frame and the other in the material frame. Relating their changes constitutes a key result of fluid kinematics. We derive an expression for the relation by first focusing on time derivatives acting on scalar fields, such as the temperature, and then derive the relation for vector fields, such as the velocity.

18.8.1 Infinitesimal space-time increment of a function

Consider a fluid property as represented by a space-time dependent scalar field, Π. For example, Π could be the temperature, mass density, or velocity component. When measured at a point in space this fluid property is written mathematically as

$$\Pi = \Pi(\boldsymbol{x}, t). \tag{18.26}$$

The difference between $\Pi(\boldsymbol{x}, t)$ and $\Pi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}, t + \mathrm{d}t)$ delivers the differential space and time increment, computed to leading order via a Taylor series expansion

$$\mathrm{d}\Pi = \Pi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}, t + \mathrm{d}t) - \Pi(\boldsymbol{x}, t) \tag{18.27a}$$

$$= \mathrm{d}t\, \partial_t \Pi + \mathrm{d}\boldsymbol{x} \cdot \nabla \Pi. \tag{18.27b}$$

In this equation, $\mathrm{d}t$ is the infinitesimal time increment, and $\mathrm{d}\boldsymbol{x}$ is the vector of infinitesimal space increments. For example, making use of Cartesian coordinates leads to the increment

$$\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{x}}\, \mathrm{d}x + \hat{\boldsymbol{y}}\, \mathrm{d}y + \hat{\boldsymbol{z}}\, \mathrm{d}z. \tag{18.28}$$

We ignore higher order terms in equation (18.27b) since the space and time increments are infinitesimal.[12]

18.8.2 Total time derivative of a function

In fluid mechanics, it is often useful to sample properties of the fluid from moving reference frames. In this case, the sampling position is a function of time. Determining how a field evolves when sampled in this moving reference frame requires us to allow the sampling position to itself be a function of time. Operationally, we have the total time derivative of Π determined by dividing both sides of equation (18.27b) by the infinitesimal time increment

$$\frac{\mathrm{d}\Pi}{\mathrm{d}t} = \frac{\partial \Pi}{\partial t} + \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} \cdot \nabla \Pi. \tag{18.29}$$

The first term measures the time derivative of Π at the specific space point, $\boldsymbol{x}$, and as such it measures the Eulerian time derivative. The second term accounts for changes in Π arising from movement of the reference frame relative to a point, $\boldsymbol{x}$, according to the velocity, $\mathrm{d}\boldsymbol{x}/\mathrm{d}t$. Equation (18.29) holds regardless the velocity of the moving frame. Even so, we find it useful to specialize to the two common reference frames used in fluid mechanics.

18.8.3 Eulerian: evolution measured in the spatial frame

The Eulerian time derivative considers the evolution of a fluid property when sampled at a fixed space point

$$\text{Eulerian time derivative} = \frac{\partial \Pi(\boldsymbol{x}, t)}{\partial t}. \tag{18.30}$$

This result follows from specializing the total time derivative in equation (18.29) to the case of fixed spatial points, so that $\mathrm{d}\boldsymbol{x}/\mathrm{d}t = 0$. In the geophysical fluids literature, the Eulerian time derivative is often termed the *time tendency* and flows with a nonzero time tendency are said to be *developing flows* or *evolving flows*. When the Eulerian time derivative vanishes everywhere the flow is said to be in a *steady state* or in a *steady flow* condition, with all points in the laboratory frame measuring a zero time change for fluid properties. Note that steady flows are not generally static; rather, they are simply unchanging locally.

18.8.4 Lagrangian: evolution measured in the material frame

The Lagrangian or material time derivative measures the evolution of a fluid property sampled along the trajectory of a moving fluid particle. The Lagrangian time derivative for a field is thus

[12] Mathematically, equation (18.27b) defines the *exterior derivative* of a scalar field.

FIGURE 18.5: Illustrating the distinctions between the Eulerian (laboratory) and Lagrangian (material) reference frames for describing fluid motion. For the Eulerian description we consider a fixed control volume in the laboratory frame and measure properties as the fluid moves through the volume. For the Lagrangian description we tag fluid particles and measure fluid properties as sampled along the particle trajectories. The Eulerian representation of the material time derivative has two terms, one due to time changes local to the fixed laboratory point, and one due to the advection of properties that are swept by the local position.

written

$$\text{Lagrangian time derivative} = \frac{\mathrm{D}\Pi}{\mathrm{D}t} = \frac{\partial \Pi}{\partial t} + \boldsymbol{v} \cdot \nabla \Pi. \tag{18.31}$$

The second equality follows by setting $\mathrm{d}\boldsymbol{x}/\mathrm{d}t = \boldsymbol{v}$ in equation (18.29) since we are sampling points along the fluid particle trajectory $\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{a}, t)$. The operator $\partial/\partial t$ is the Eulerian time derivative from equation (18.30), whereas $\boldsymbol{v} \cdot \nabla$ is referred to as the *advection* operator. Use of the capital D for the material time operator

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v} \cdot \nabla \tag{18.32}$$

signals that the time derivative is computed along a fluid particle trajectory. This notation distinguishes the material time derivative from the more generic total time derivative of equation (18.29). In some texts the material time derivative is referred to as the *convective time derivative*, since the term "convection" is often used rather than our preferred term "advection".[13] It is also sometimes referred to as the *substantial time derivative* since it refers to the time changes following a material substance.

Equation (18.32) provides an Eulerian expression (right hand side) to the material time derivative, $\mathrm{D}/\mathrm{D}t$. There are two Eulerian contributions: the local (fixed space point) time tendency $\partial/\partial t$ and advection, $\boldsymbol{v} \cdot \nabla$. Advection arises in the Eulerian reference frame due to the fluid passing by the fixed laboratory observer, whereas it is absent from the material reference frame since the material frame moves with the fluid particles. Figure 18.5 illustrates the differences between the Eulerian and Lagrangian perspectives.

A *steady flow* is one with zero Eulerian time derivatives so that a steady flow does not imply a vanishing Lagrangian time derivative. Rather, a steady flow is a statement that the flow is time independent when viewed from the Eulerian (laboratory) reference frame. Hence, a steady flow generally has changing properties when sampled along a fluid particle trajectory. That is, there can be a nonzero Lagrangian evolution (via advection) even when the Eulerian time tendency vanishes.

18.8.5 Lagrangian time derivative formulated from the motion

Rather than start from the total time derivative (18.29), it is instructive to work in the moving material frame *a priori* by using the motion field, $\boldsymbol{\varsigma}(\boldsymbol{a}, T)$, described in Section 18.6. For this purpose, consider a scalar fluid property, Π, as measured on a fluid particle, in which case we

[13] In the geophysical fluids literature, "convection" generally refers to vertical motion induced by gravitational instability, such as when heavy fluid is above light fluid. In contrast, the engineering literature often refers to "convection" in the same manner as we use the term "advection."

introduce the notation[14]

$$\Pi^{\mathrm{L}}(\boldsymbol{a}, T) \quad \Longleftarrow \text{sampling } \Pi \text{ on a trajectory } \boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T) \text{ at time } T = t. \tag{18.33}$$

In words, $\Pi^{\mathrm{L}}(\boldsymbol{a}, T)$ is the property, Π, evaluated on a fluid particle trajectory $\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T)$. As a complement, measuring the property, Π, at a spatial point renders the Eulerian representation[15]

$$\Pi^{\mathrm{E}}(\boldsymbol{x}, t) \quad \Longleftarrow \text{sampling } \Pi \text{ at a spatial point } \boldsymbol{x} \text{ at time } t. \tag{18.34}$$

Since the arguments differ, the functions Π^{L} and Π^{E} are generally distinct. The Eulerian and Lagrangian values for the fluid property agree when they are evaluated at the same point in space and time, hence

$$\Pi^{\mathrm{L}}(\boldsymbol{a}, T) = \Pi^{\mathrm{E}}(\boldsymbol{x}, t) \quad \text{if } \boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T) \text{ and } t = T. \tag{18.35}$$

The time derivative of $\Pi^{\mathrm{L}}(\boldsymbol{a}, T)$ following the fluid particle motion is given by the partial derivative

$$\frac{\partial \Pi^{\mathrm{L}}(\boldsymbol{a}, T)}{\partial T} = \quad \text{time derivative following particle motion,} \tag{18.36}$$

which is computed while holding the material coordinates fixed. The chain rule renders the Eulerian expression for the same time derivative

$$\frac{\partial \Pi^{\mathrm{L}}(\boldsymbol{a}, T)}{\partial T} = \frac{\partial \Pi^{\mathrm{E}}[\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T), t = T]}{\partial T} \tag{18.37a}$$

$$= \frac{\partial \Pi^{\mathrm{E}}(\boldsymbol{x}, t)}{\partial t} + \frac{\partial \boldsymbol{\varsigma}(\boldsymbol{a}, T)}{\partial T} \cdot \nabla \Pi^{\mathrm{E}}(\boldsymbol{x}, t) \tag{18.37b}$$

$$= (\partial_t + \boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) \cdot \nabla) \Pi^{\mathrm{E}}(\boldsymbol{x}, t), \tag{18.37c}$$

$$= (\partial_t + \boldsymbol{v}^{\mathrm{E}}(\boldsymbol{x}, t) \cdot \nabla) \Pi^{\mathrm{E}}(\boldsymbol{x}, t). \tag{18.37d}$$

In equation (18.37c) we introduced the Lagrangian expression for the particle velocity

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) \equiv \boldsymbol{v}[\boldsymbol{\varsigma}(\boldsymbol{a}, T), T] = \left[\frac{\partial \boldsymbol{\varsigma}(\boldsymbol{a}, T)}{\partial T}\right], \tag{18.38}$$

where, again, the time derivative is computed while holding the material coordinate, $\boldsymbol{a}$, fixed. For equation (18.37d) we equated the Lagrangian and Eulerian expressions for the particle velocity when they are evaluated at the same point in space and time

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) = \boldsymbol{v}^{\mathrm{E}}(\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T), t = T). \tag{18.39}$$

Equation (18.37d) accords with equation (18.31).

18.8.6 Sample material time derivative operations

The material time derivative operator is perhaps the most important operator in fluid mechanics, and its relation to the Eulerian time derivative plus advection is a key result of fluid kinematics. Therefore, it is critical to develop experience with this operator and its generalizations. The examples here offer a starting point.

[14] The L superscript is *not* a tensor label.

[15] In most occasions throughout this book, we do not expose the E superscript to denote an Eulerian expression for a fluid property. The reason is that we mostly employ an Eulerian description, with the associated functional dependence, $(\boldsymbol{x}, t)$.

Material invariant or material constant

Consider a scalar function, $\Pi(\boldsymbol{x}, t)$, that remains constant on a material trajectory so that its material time derivative vanishes

$$\frac{\mathrm{D}\Pi}{\mathrm{D}t} = 0. \tag{18.40}$$

Material constancy is generally referred to as *material invariance*. We may also say that the property, Π, is *materially conserved*. At a fixed point in space, a materially invariant property has its Eulerian time derivative arising only via advection

$$\frac{\partial \Pi}{\partial t} = -\boldsymbol{v} \cdot \nabla \Pi. \tag{18.41}$$

Recall the case of a wave characteristic whereby $\partial \Pi / \partial t = \omega$. Wave characteristics are material if the fluid particle velocity satisfies $\boldsymbol{k} \cdot \boldsymbol{v} = \omega$.[16]

We garner geometric insight into relation (18.41) by introducing the unit normal vector to the surface of constant Π

$$\hat{\boldsymbol{n}} = \frac{\nabla \Pi}{|\nabla \Pi|}. \tag{18.42}$$

Material invariance of Π thus means that the normalized Eulerian time tendency equals to the negative of the projection of the velocity into the direction normal to constant Π surfaces

$$\frac{\partial \Pi / \partial t}{|\nabla \Pi|} = -\boldsymbol{v} \cdot \hat{\boldsymbol{n}}. \tag{18.43}$$

That is, the normal projection of the fluid particle velocity, $\boldsymbol{v}$, is matched precisely to the moving surface of constant Π. Hence, the fluid particle does not cross the surface. We return to this result in Section 20.4.2 when studying the kinematic boundary conditions at a variety of surfaces.

Time derivative measured in a general moving frame

Now consider a reference frame moving at an arbitrary velocity, $\boldsymbol{v}^{(s)}$. Examples include the quasi-Lagrangian reference frames of a float in the ocean or balloon in the atmosphere. Due to their finite size and associated drag effects, these objects only approximate material particle motion, so that $\boldsymbol{v}^{(s)} \neq \boldsymbol{v}$. Returning to the general expression (18.29) for the total time derivative, we have the time derivative operator as measured in this non-material moving reference frame

$$\frac{\mathrm{D}^{(s)}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}^{(s)} \cdot \nabla. \tag{18.44}$$

A function that remains constant within this general moving frame thus satisfies

$$\frac{\mathrm{D}^{(s)}\Pi}{\mathrm{D}t} = 0 \Longrightarrow \frac{\partial \Pi}{\partial t} = -\boldsymbol{v}^{(s)} \cdot \nabla \Pi. \tag{18.45}$$

[16] In one space dimension and for linear non-rotating gravity waves (Section 53.5), the wave phase speed is given by ω/k so that the wave characteristics are material if the fluid particle speed matches the wave speed, $|v| = \omega/k$. The ratio of the particle speed to the wave speed is known as the Froude number. The Froude number is typically much less than unity, though highly nonlinear behavior (e.g., hydraulic jumps as discussed in Chapter 3 of *Acheson* (1990) and throughout *Pratt and Whitehead* (2008)) occurs when the Froude number reaches unity or larger (see Exercise 36.4).

Introducing the normal direction $\hat{\boldsymbol{n}} = |\nabla\Pi|^{-1}\,\nabla\Pi$ leads to

$$\frac{\partial\Pi/\partial t}{|\nabla\Pi|} = -\boldsymbol{v}^{(s)}\cdot\hat{\boldsymbol{n}}, \tag{18.46}$$

which is an analog to the material invariance condition (18.43).

18.8.7 Worked example: velocity and acceleration from a trajectory

Following example 3.2 from *Kundu et al.* (2016), consider a one-dimensional fluid motion whereby the trajectory of a fluid particle is given by

$$\boldsymbol{X}(t) = \hat{\boldsymbol{x}}\,X(t) = \hat{\boldsymbol{x}}\left[K\,(t-t_0) + x_0^3\right]^{1/3}, \tag{18.47}$$

where K is a constant with dimensions volume per time and x_0 is the particle position at time $t = t_0$. The particle velocity and particle acceleration are determined through time differentiation

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \hat{\boldsymbol{x}}\,\frac{K}{3\,X^2} \qquad \text{and} \qquad \frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2} = -\hat{\boldsymbol{x}}\,\frac{2K^2}{9\,X^5}. \tag{18.48}$$

The Eulerian velocity field is then determined by

$$\boldsymbol{v}(\boldsymbol{x},t) \equiv \left[\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t}\right]_{\boldsymbol{x}=\boldsymbol{X}(t)} = \hat{\boldsymbol{x}}\,\frac{K}{3\,x^2}, \tag{18.49}$$

which reveals that the flow is steady since there is no time dependence to the Eulerian velocity field. The Eulerian acceleration is given by the material time derivative of the Eulerian velocity, which is equal to the second time derivative of the trajectory evaluated at the field point

$$\frac{\mathrm{D}u}{\mathrm{D}t} = \frac{\partial u}{\partial t} + \boldsymbol{v}\cdot\nabla u = 0 + u\,\partial_x u = -[K/(3\,x^2)]\,[(2K)/(3\,x^3)] = -\frac{2\,K^2}{9\,x^5} = \left[\frac{\mathrm{d}^2X(t)}{\mathrm{d}t^2}\right]_{\boldsymbol{x}=\boldsymbol{X}(t)}. \tag{18.50}$$

18.8.8 Material time derivative of a vector field

We now develop the material time derivative of a vector field, such as the velocity. We expect there to be a bit more baggage to carry around since a vector field representation requires basis vectors, with such vectors generally a function of space and time. Indeed, as we see, the application to a vector field requires the covariant derivative operator from Section 9.11. In this subsection we are careful with the upstairs and downstairs tensor indices, since the distinction is important when working with general tensors as in Chapters 8 and 9.

To start, consider Cartesian coordinates in Euclidean space. There is no special treatment needed in this case, in which each component of a vector field, $\boldsymbol{G} = \hat{\boldsymbol{x}}\,G^1 + \hat{\boldsymbol{y}}\,G^2 + \hat{\boldsymbol{z}}\,G^3$, has a material time derivative

$$\mathrm{D}G^m/\mathrm{D}t = (\partial_t + \boldsymbol{v}\cdot\nabla)\,G^m = (\partial_t + v^n\,\partial_n)\,G^m. \tag{18.51}$$

That is, for Cartesian coordinates in Euclidean space, each component of a vector field has a material time derivative with the same form as that for a scalar field. Extending to arbitrary coordinates requires us to take into account the space-time dependence of the basis vectors used to represent a vector. The same ideas arose in Chapter 13 when deriving expressions for the velocity and acceleration of a particle using spherical coordinates. So let us write the vector field

according to

$$\boldsymbol{G} = G^m \, \vec{e}_m, \tag{18.52}$$

where $\vec{e}_m$ are basis vectors for the chosen coordinate system. The material time operator acting on $\boldsymbol{G}$ now takes on the form

$$\frac{\mathrm{D}\boldsymbol{G}}{\mathrm{D}t} = (\partial_t + v^n \, \partial_n) \, (G^m \, \vec{e}_m). \tag{18.53}$$

For Cartesian coordinates, the basis vectors $\vec{e}_m$ are space-time constants, in which case we recover equation (18.51). Allowing for space-time dependence requires us to make use of the discussion in Section 9.11, in which

$$\frac{\mathrm{D}\boldsymbol{G}}{\mathrm{D}t} = \partial_t (G^m \, \vec{e}_m) + v^n \, (\nabla_n \, G^m) \, \vec{e}_m = G^m \, \partial_t \vec{e}_m + \vec{e}_m \, (\partial_t + v^n \, \nabla_n) G^m. \tag{18.54}$$

In this equation we introduced the covariant derivative acting on a vector component

$$\nabla_n G^m = \partial_n G^m + \Gamma^m_{np} \, G^p, \tag{18.55}$$

and with $\Gamma^m_{np} = \Gamma^m_{pn}$ the Christoffel symbols (Section 9.11) that measure the spatial dependence of the basis vectors

$$\partial_n \, \vec{e}_m = \Gamma^p_{nm} \, \vec{e}_p. \tag{18.56}$$

In spherical coordinates the basis vectors are time independent, in which case $\partial_t \vec{e}_m = 0$. However, this time derivative term is present in some other coordinates, such as the generalized vertical coordinates studied in Part XI of this book.

18.8.9 Summarizing some terminology

We here summarize some terminology used to refer to the variety of equations in geophysical fluid mechanics. Some of this terminology was introduced in this chapter, whereas others will be encountered later.

- PROGNOSTIC: This is an equation that determines the time tendency (Eulerian evolution) of a quantity such as the temperature or velocity.
- DIAGNOSTIC: This is an equation that determines the value of a field at a particular time instance. An example is the non-divergence condition satisfied by velocity in an incompressible flow (Chapter 22) as well in a Boussinesq ocean (Chapter 30). There are generally no time derivatives appearing in diagnostic equations, though this property is generally a function of the chosen coordinate system.
- STEADY STATE: All Eulerian time derivatives vanish, so that all fluid properties are time independent when measured in the laboratory frame.
- MATERIAL INVARIANCE: The Lagrangian time derivative vanishes for a property that is a material invariant.

18.9 Galilean transformation

Recall from Section 11.1.3 that Galilean invariance means that the laws of motion are the same in all inertial reference frames. Furthermore, two inertial reference frames can only be moving with a constant velocity relative to one another. As for the particle, Galilean invariance for a fluid means that the material acceleration of a fluid particle remains the same when viewed

in an arbitrary inertial reference frame. Some care is required when translating this invariance into a mathematical statement when decomposing the material acceleration into its Eulerian components. Our considerations here provide a useful warmup to the more general discussion in Section 18.10, where we transform space and time derivative operators between an inertial frame and a rotating frame.

Operationally, we determine whether an equation is Galilean invariant by examining the differential operators appearing in the equation. Hence, in the following we examine how differential operators transform when moving to a Galilean boosted reference frame. We then examine how the material time operator transforms, since this operator appears in the calculation of velocity and acceleration.

18.9.1 Galilean transformation

A Galilean transformation is given by the linear space-time transformation

$$\bar{t} = t \qquad \text{and} \qquad \overline{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{U}t \qquad \text{and} \qquad \overline{\boldsymbol{v}} = \boldsymbol{v} + \boldsymbol{U}. \tag{18.57}$$

By convention, we say that the barred coordinates are those measured in the moving (boosted) reference frame and the unbarred are measured in the rest frame. However, since both reference frames are inertial, there is no experiment on a Galilean invariant physical system that can determine which frame is at rest or which is moving. Instead, what is relevant is that the two inertial frames are moving relative to one another. Furthermore, note that time remains unchanged (universal Newtonian time), whereas the position of a point in the new frame equals to that in the original reference frame plus a contribution from the constant velocity, $\boldsymbol{U}$. The inverse transformation is trivially given by

$$t = \bar{t} \qquad \text{and} \qquad \boldsymbol{x} = \overline{\boldsymbol{x}} - \boldsymbol{U}\bar{t} \qquad \text{and} \qquad \boldsymbol{v} = \overline{\boldsymbol{v}} - \boldsymbol{U}. \tag{18.58}$$

18.9.2 Transformation matrix

We make use of the transformation matrix formalism to derive relations between the partial differential operators, with details of the transformation matrix presented in Section 9.9. The reader having skipped that section should still be able to understand the gist of the following. For simplicity we work in the 1+1 dimensional case with time along with one space dimension.

Writing the space and time coordinates as

$$(t, x) = (x^0, x^1) \quad \text{and} \quad (\bar{t}, \overline{x}) = (x^{\overline{0}}, x^{\overline{1}}) \tag{18.59}$$

renders the transformation of partial derivatives (following the chain rule)

$$\frac{\partial}{\partial x^{\overline{\alpha}}} = \frac{\partial x^\alpha}{\partial x^{\overline{\alpha}}} \frac{\partial}{\partial x^\alpha}, \tag{18.60}$$

where $\alpha = 0, 1$ is a tensor index that has $\alpha = 0$ for the time coordinate. The transformation matrix for the Galilean transformation is thus given by the 2×2 matrix

$$\frac{\partial x^{\overline{\alpha}}}{\partial x^\alpha} = \begin{bmatrix} \partial x^{\overline{0}}/\partial x^0 & \partial x^{\overline{0}}/\partial x^1 \\ \partial x^{\overline{1}}/\partial x^0 & \partial x^{\overline{1}}/\partial x^1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ U & 1 \end{bmatrix}, \tag{18.61}$$

and the inverse is

$$\frac{\partial x^\alpha}{\partial x^{\overline{\alpha}}} = \begin{bmatrix} 1 & 0 \\ -U & 1 \end{bmatrix}. \tag{18.62}$$

The Jacobian determinant of the transformation matrix is unity, so that the Galilean transformation always has an inverse.

18.9.3 Transforming the differential operators

Given the transformation matrix, we can compute the Eulerian time derivative as measured in the moving frame by using the chain rule

$$\frac{\partial}{\partial x^{\overline{0}}} = \frac{\partial x^0}{\partial x^{\overline{0}}}\frac{\partial}{\partial x^0} + \frac{\partial x^1}{\partial x^{\overline{0}}}\frac{\partial}{\partial x^1} = \frac{\partial}{\partial x^0} - U\frac{\partial}{\partial x^1} = \frac{\partial}{\partial t} - U\frac{\partial}{\partial x}. \tag{18.63}$$

In words, this identity says that the time derivative computed between two inertial reference frames differs due to an advective term (with the constant Galilean boost velocity) arising from the relative motion of the two inertial observers. The space derivatives are related by

$$\frac{\partial}{\partial x^{\overline{1}}} = \frac{\partial x^0}{\partial x^{\overline{1}}}\frac{\partial}{\partial x^0} + \frac{\partial x^1}{\partial x^{\overline{1}}}\frac{\partial}{\partial x^1} = \frac{\partial}{\partial x^1}, \tag{18.64}$$

so that the space derivative operator remains form invariant under a Galilean transformation. This result holds also for the other two space dimensions. We thus find that the material time derivative operator is form invariant under a Galilean transformation

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla \tag{18.65a}$$

$$= \frac{\partial}{\partial \overline{t}} + \boldsymbol{U}\cdot\overline{\nabla} + (\overline{\boldsymbol{v}} - \boldsymbol{U})\cdot\overline{\nabla} \tag{18.65b}$$

$$= \frac{\partial}{\partial \overline{t}} + \overline{\boldsymbol{v}}\cdot\overline{\nabla} \tag{18.65c}$$

$$= \frac{\overline{\mathrm{D}}}{\mathrm{D}\overline{t}}\,, \tag{18.65d}$$

where we used the shorthand

$$\overline{\boldsymbol{v}}\cdot\overline{\nabla} = \overline{u}\,\frac{\partial}{\partial x^{\overline{1}}} + \overline{v}\,\frac{\partial}{\partial x^{\overline{2}}} + \overline{w}\,\frac{\partial}{\partial x^{\overline{3}}}. \tag{18.66}$$

So although the individual pieces to the material time operator are modified by a Galilean transformation, the material time derivative operator is form invariant. Hence, if a function has a material time derivative $\mathrm{D}\Pi/\mathrm{d}t$ in one inertial reference frame, it has the same material time operator in any other inertial reference frame. To be more precise, let Π represent some scalar property. When measured at a space-time point $\mathscr{P}$ using the coordinate system x^α we write

$$\Pi(\mathscr{P}) = A(x^\alpha), \tag{18.67}$$

and its material time derivative is

$$\frac{\mathrm{D}\Pi(\mathscr{P})}{\mathrm{D}t} = (\partial_t + v^m\,\partial_m)\,A. \tag{18.68}$$

Likewise, when evaluated at the same point but using the boosted coordinates $x^{\overline{\alpha}}$, then

$$\Pi(\mathscr{P}) = B(x^{\overline{\alpha}}), \tag{18.69}$$

with its material time derivative

$$\frac{\mathrm{D}\Pi(\mathscr{P})}{\mathrm{D}t} = (\partial_{\overline{t}} + v^{\overline{m}}\,\partial_{\overline{m}})\,B. \tag{18.70}$$

We provide an explicit example in Exercise 18.5.

18.9.4 Comments

There are many features of geophysical fluid flows that break Galilean invariance. For example, a solid boundary breaks Galilean invariance since it establishes a special reference frame and thus breaks the symmetry of unbounded space. Additionally, a rotating planet distinguishes between longitude and latitude even if the planet is perfectly smooth. Nonetheless, as a starting point in our study of the equations of fluid mechanics, it is useful to establish their properties under a Galilean transformation. In general, if space is Galilean invariant and yet the equations of motion are not, then we question the physical relevance of the equations. Exercise 39.11 provides an example of this reasoning.

There are further symmetries of the equations of fluid mechanics, especially when there is no dissipation (inviscid). Section 2.2 of *Frisch* (1995) and Section 1.4 of *Badin and Crisciani* (2018) provide a discussion of such symmetries.

18.10 Transforming the material time derivative

In the discussion of Galilean invariance in Section 18.9, we showed that the material time derivative operator remains form invariant under changes to the inertial reference frame. Here, we consider an arbitrary transformation, with a focus on its action on a scalar field. The development offers a case study for how to transform from one reference frame to another.

18.10.1 Definition of the material time derivative

We first determine the transformation by focusing on the conceptual definition of the material time derivative. Namely, the material time derivative measures time changes of a fluid property in the reference frame comoving with a fluid particle. The Lagrangian reference frame follows fluid particles, so it is the natural reference frame for measuring material time changes. In contrast, the Eulerian reference frame is fixed in a laboratory. The material time derivative acting on a scalar when computed from the laboratory reference frame consists of an Eulerian time tendency plus an advection operator

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla. \tag{18.71}$$

Importantly, this expression holds regardless the choice of laboratory reference frame, either inertial or non-inertial. The particle reference frame is unconcerned with the subjective choice made by the observer in the laboratory reference frame. Our choice of laboratory frame only impacts on the form of the Eulerian time derivative and on the advection operator. The sum of the two terms returns the same material time derivative operator, no matter what laboratory frame is chosen.

18.10.2 Example: a rotating reference frame

Consider two reference frames. The first is at rest and so serves as an inertial frame, whereas the second is rotating (and thus non-inertial) with rotational axis aligned with the vertical direction as in Figure 10.1. Introduce Cartesian coordinates for the inertial frame, with corresponding basis

vectors $(\hat{\overline{\boldsymbol{x}}}, \hat{\overline{\boldsymbol{y}}}, \hat{\overline{\boldsymbol{z}}})$. Let these inertial frame unit vectors be related to rotating frame unit vectors according to

$$\hat{\overline{\boldsymbol{x}}} = \hat{\boldsymbol{x}} \cos\vartheta - \hat{\boldsymbol{y}} \sin\vartheta \tag{18.72a}$$

$$\hat{\overline{\boldsymbol{y}}} = \hat{\boldsymbol{x}} \sin\vartheta + \hat{\boldsymbol{y}} \cos\vartheta \tag{18.72b}$$

$$\hat{\overline{\boldsymbol{z}}} = \hat{\boldsymbol{z}}, \tag{18.72c}$$

and let time be the same in the two reference frames. The angle ϑ measures the counter-clockwise angle between the inertial frame direction $\hat{\overline{\boldsymbol{x}}}$ and the moving frame direction $\hat{\boldsymbol{x}}$, with this angle a linear function of time

$$\vartheta = \Omega\, t. \tag{18.73}$$

The above relations between the two sets of basis vectors translates into the same relations between the corresponding coordinate representations for an arbitrary vector. Including time, we have the relation between inertial coordinates (the barred frame) and rotating coordinates (unbarred frame)

$$\overline{t} = t \tag{18.74a}$$

$$\overline{x} = x \cos\vartheta - y \sin\vartheta \tag{18.74b}$$

$$\overline{y} = x \sin\vartheta + y \cos\vartheta \tag{18.74c}$$

$$\overline{z} = z. \tag{18.74d}$$

The inverse transformation can be easily found

$$t = \overline{t} \tag{18.75a}$$

$$x = \overline{x} \cos\vartheta + \overline{y} \sin\vartheta \tag{18.75b}$$

$$y = -\overline{x} \sin\vartheta + \overline{y} \cos\vartheta \tag{18.75c}$$

$$z = \overline{z}. \tag{18.75d}$$

We are now prepared to make use of the transformation formalism developed in Section 9.9, and applied for the Galilean transformation in Section 18.9. We include time as part of the formalism by introducing the Greek label $\alpha = 0, 1, 2, 3$ so that the transformation matrix between the inertial frame and rotating frame is given by

$$\frac{\partial x^{\overline{\alpha}}}{\partial x^{\alpha}} = \begin{bmatrix} \partial x^{\overline{0}}/\partial x^0 & \partial x^{\overline{0}}/\partial x^1 & \partial x^{\overline{0}}/\partial x^2 & \partial x^{\overline{0}}/\partial x^3 \\ \partial x^{\overline{1}}/\partial x^0 & \partial x^{\overline{1}}/\partial x^1 & \partial x^{\overline{1}}/\partial x^2 & \partial x^{\overline{1}}/\partial x^3 \\ \partial x^{\overline{2}}/\partial x^0 & \partial x^{\overline{2}}/\partial x^1 & \partial x^{\overline{2}}/\partial x^2 & \partial x^{\overline{2}}/\partial x^3 \\ \partial x^{\overline{3}}/\partial x^0 & \partial x^{\overline{3}}/\partial x^1 & \partial x^{\overline{3}}/\partial x^2 & \partial x^{\overline{3}}/\partial x^3 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -\Omega\,\overline{y} & \cos\vartheta & -\sin\vartheta & 0 \\ \Omega\,\overline{x} & \sin\vartheta & \cos\vartheta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{18.76}$$

Similarly, the inverse transformation is given by

$$\frac{\partial x^{\alpha}}{\partial x^{\overline{\alpha}}} = \begin{bmatrix} \partial x^0/\partial x^{\overline{0}} & \partial x^0/\partial x^{\overline{1}} & \partial x^0/\partial x^{\overline{2}} & \partial x^0/\partial x^{\overline{3}} \\ \partial x^1/\partial x^{\overline{0}} & \partial x^1/\partial x^{\overline{1}} & \partial x^1/\partial x^{\overline{2}} & \partial x^1/\partial x^{\overline{3}} \\ \partial x^2/\partial x^{\overline{0}} & \partial x^2/\partial x^{\overline{1}} & \partial x^2/\partial x^{\overline{2}} & \partial x^2/\partial x^{\overline{3}} \\ \partial x^3/\partial x^{\overline{0}} & \partial x^3/\partial x^{\overline{1}} & \partial x^3/\partial x^{\overline{2}} & \partial x^3/\partial x^{\overline{3}} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ \Omega\, y & \cos\vartheta & \sin\vartheta & 0 \\ -\Omega\, x & -\sin\vartheta & \cos\vartheta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{18.77}$$

The derivative operators transform according to

$$\frac{\partial}{\partial x^\alpha} = \frac{\partial x^{\overline{\alpha}}}{\partial x^\alpha}\,\frac{\partial}{\partial x^{\overline{\alpha}}}, \tag{18.78}$$

in which case

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial \overline{t}} + (\boldsymbol{\Omega}\times\overline{\boldsymbol{x}})\cdot\overline{\nabla} \tag{18.79a}$$

$$\frac{\partial}{\partial x} = \cos\vartheta\,\frac{\partial}{\partial \overline{x}} + \sin\vartheta\,\frac{\partial}{\partial \overline{y}} \tag{18.79b}$$

$$\frac{\partial}{\partial y} = -\sin\vartheta\,\frac{\partial}{\partial \overline{x}} + \cos\vartheta\,\frac{\partial}{\partial \overline{y}} \tag{18.79c}$$

$$\frac{\partial}{\partial z} = \frac{\partial}{\partial \overline{z}}. \tag{18.79d}$$

The velocity vector components transform according to

$$v^\alpha = \frac{\partial x^\alpha}{\partial x^{\overline{\alpha}}}\,v^{\overline{\alpha}}, \tag{18.80}$$

so that

$$v^0 = v^{\overline{0}} \tag{18.81a}$$

$$u = \Omega\,y + \overline{u}\cos\vartheta + \overline{v}\sin\vartheta \tag{18.81b}$$

$$v = -\Omega\,x - \overline{u}\sin\vartheta + \overline{v}\cos\vartheta \tag{18.81c}$$

$$w = \overline{w}, \tag{18.81d}$$

where

$$v^0 = v^{\overline{0}} = 1. \tag{18.82}$$

Bringing these result together leads to the transformation of the horizontal advection operator

$$u\,\frac{\partial}{\partial x} + v\,\frac{\partial}{\partial y} = (\overline{\boldsymbol{u}} - \boldsymbol{\Omega}\times\overline{\boldsymbol{x}})\cdot\overline{\nabla}. \tag{18.83}$$

Combining this result with the transformed Eulerian time derivative leads to the material time derivative

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla \tag{18.84a}$$

$$= \frac{\partial}{\partial t} + u\,\frac{\partial}{\partial x} + v\,\frac{\partial}{\partial y} + w\,\frac{\partial}{\partial z} \tag{18.84b}$$

$$= \frac{\partial}{\partial \overline{t}} + (\boldsymbol{\Omega}\times\overline{\boldsymbol{x}})\cdot\overline{\nabla} + (\overline{\boldsymbol{u}} - \boldsymbol{\Omega}\times\overline{\boldsymbol{x}})\cdot\overline{\nabla} + \overline{w}\,\frac{\partial}{\partial \overline{z}} \tag{18.84c}$$

$$= \frac{\partial}{\partial \overline{t}} + \overline{\boldsymbol{v}}\cdot\overline{\nabla}. \tag{18.84d}$$

As advertised, the operator is form invariant under time dependent transformations to a non-inertial reference frame.

18.10.3 Invariance using space-time tensors

We can generalize the previous result by writing the material time derivative operator using space-time tensor notation from Section 8.5.4, in which case

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla = \frac{\partial}{\partial x^0} + v^m\,\frac{\partial}{\partial x^m} = v^\alpha\,\frac{\partial}{\partial x^\alpha}, \tag{18.85}$$

where we introduced the velocity 4-vector

$$(v^0, v^1, v^2, v^3) = (1, v^1, v^2, v^3). \tag{18.86}$$

All space-time indices are contracted in equation (18.85), which means the material time derivative is a space-time scalar. Consequently, we can change coordinates or change reference frames without changing the material time operator.

We verify the above conclusion via the following manipulations using the chain rule

$$\frac{\mathrm{D}}{\mathrm{D}t} = \partial_0 + v^m\,\partial_m \tag{18.87a}$$

$$= \Lambda^{\overline{\alpha}}{}_0\,\partial_{\overline{\alpha}} + \Lambda^a{}_{\overline{\alpha}}\,v^{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_a\,\partial_{\overline{\beta}} \tag{18.87b}$$

$$= \Lambda^{\overline{\alpha}}{}_0\,\partial_{\overline{\alpha}} + \Lambda^a{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_a\,v^{\overline{\alpha}}\,\partial_{\overline{\beta}}, \tag{18.87c}$$

where we wrote the transformation matrix and its inverse in the form (see Section 9.1.4 for more details)

$$\Lambda^\alpha{}_{\overline{\alpha}} \equiv \frac{\partial x^\alpha}{\partial x^{\overline{\alpha}}} \quad \text{and} \quad \Lambda^{\overline{\alpha}}{}_\alpha \equiv \frac{\partial x^{\overline{\alpha}}}{\partial x^\alpha}. \tag{18.88}$$

Next make use of the identity

$$\Lambda^a{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_a = \Lambda^\alpha{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_\alpha - \Lambda^0{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_0 \qquad a = 1,2,3 \text{ and } \alpha = 0,1,2,3 \tag{18.89a}$$

$$= \delta^{\overline{\beta}}{}_{\overline{\alpha}} - \Lambda^0{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_0 \qquad \Lambda^\alpha{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_\alpha = \delta^{\overline{\beta}}{}_{\overline{\alpha}} \text{ by chain rule} \tag{18.89b}$$

$$= \delta^{\overline{\beta}}{}_{\overline{\alpha}} - \delta^0{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_0 \qquad \Lambda^0{}_{\overline{\alpha}} = \delta^0{}_{\overline{\alpha}} \text{ for Newtonian time.} \tag{18.89c}$$

Use of this identity in equation (18.87c) renders

$$\frac{\mathrm{D}}{\mathrm{D}t} = \Lambda^{\overline{\alpha}}{}_0\,\partial_{\overline{\alpha}} + \left[\delta^{\overline{\beta}}{}_{\overline{\alpha}} - \delta^0{}_{\overline{\alpha}}\,\Lambda^{\overline{\beta}}{}_0\right] v^{\overline{\alpha}}\,\partial_{\overline{\beta}} \tag{18.90a}$$

$$= \Lambda^{\overline{\alpha}}{}_0\,\partial_{\overline{\alpha}} + v^{\overline{\alpha}}\,\partial_{\overline{\alpha}} - v^{\overline{0}}\,\Lambda^{\overline{\beta}}{}_0\,\partial_{\overline{\beta}} \tag{18.90b}$$

$$= v^{\overline{\alpha}}\,\partial_{\overline{\alpha}} \tag{18.90c}$$

$$= \partial_{\overline{t}} + v^{\overline{a}}\,\partial_{\overline{a}}, \tag{18.90d}$$

where we used $v^{\overline{0}} = 1$. This proof means that the material time derivative remains form invariant no matter what coordinate choice is made for the laboratory reference frame.

18.10.4 Comments

As argued at the start of this section, there is no reason for a time derivative computed in a material frame to be concerned with the coordinates chosen for the laboratory frame. Hence, we expect there to be form invariance across all chosen laboratory coordinates. It is satisfying to see the tools of coordinate transformations put to use verifying this result.

18.11 Fluid flow lines

There are three types of flow lines commonly used to visualize fluid motion: *pathlines*, *streamlines*, and *streaklines*. These flow lines are identical for time independent (steady) flow, where steady flow means that all fields are constant in time when observed in the Eulerian reference frame. However, these flow lines differ for unsteady flow. They each offer complementary information about the flow field, and have uses in both theoretical and experimental contexts. We have use for pathlines and streamlines in this book, yet also introduce streaklines for completeness.

18.11.1 Material pathlines from fluid particle trajectories

As introduced in Section 18.5.1, a fluid particle traces out a *trajectory* as it moves through space and time (Figure 18.2). We use the term material *pathline* for a fluid particle trajectory, with a collection of pathlines providing a means to visualize fluid particle motion throughout the flow. In this book we are only concerned with *smooth velocity fields*, which allow for an unambiguous specification of the particle trajectory at each point of the fluid.

Mathematically, a fluid particle trajectory is a curve, $\boldsymbol{\varsigma}(\boldsymbol{a}, T)$, in space that is traced by fixing the material coordinate, $\boldsymbol{a}$, and letting time, T, advance. Trajectories are computed by time integrating the ordinary differential equation

$$\frac{\partial \boldsymbol{\varsigma}(\boldsymbol{a}, T)}{\partial T} = \boldsymbol{v}[\boldsymbol{\varsigma}(\boldsymbol{a}, T), T] \tag{18.91a}$$

$$\boldsymbol{\varsigma}(\boldsymbol{a}, T = 0) = \boldsymbol{a}, \tag{18.91b}$$

where the Lagrangian velocity of the fluid particle (see equation (18.38)) is written as the Eulerian velocity when evaluated on a trajectory

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) = \boldsymbol{v}[\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T), t = T], \tag{18.92}$$

and we have assumed the material coordinates are determined by the initial position. Again, the partial time derivative is computed with the material coordinate held fixed, so that the material coordinate distinguishes between particle trajectories. In a mathematical context we refer to a particle trajectory as the *integral curve* for the velocity vector.

In the laboratory, we can insert tiny particles into the fluid to offer a means for visualizing the flow, with a time exposed photograph providing an estimate of fluid particle pathlines. Experimental particles provide an accurate estimate of fluid particle pathlines if the particles do not disperse through diffusion (see Chapter 64). As another example, consider cars moving at night with a time exposed photograph revealing pathlines formed by car head and tail lights. Like cars, the material pathlines in a fluid can intersect, cross, and become quite complex, particularly when the flow is turbulent.

18.11.2 Fluid streamlines and streamtubes

Streamlines are curves whose tangent is parallel to the instantaneous fluid velocity field. Streamlines can intersect only at a stagnation point; i.e., a point where the fluid is not moving. Let

$$\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{x}}\,\mathrm{d}x + \hat{\boldsymbol{y}}\,\mathrm{d}y + \hat{\boldsymbol{z}}\,\mathrm{d}z \tag{18.93}$$

be an infinitesimal increment along a streamline written using Cartesian coordinates. The family

FIGURE 18.6: This image shows an example streamtube. The side boundaries of a streamtube consist of streamlines. At each point of a streamline, the local tangent vector equals to the velocity field (see equation (18.94)). Streamlines are identical to pathlines only for steady flow; they differ for unsteady flows. Hence, for unsteady flows, particle trajectories generally cross through the streamtube boundary.

of streamlines at a given time, t, satisfy the tangent constraint

$$\boldsymbol{v} \times \mathrm{d}\boldsymbol{x} = 0, \tag{18.94}$$

which is equivalent to

$$\frac{\mathrm{d}x}{u(\boldsymbol{x},t)} = \frac{\mathrm{d}y}{v(\boldsymbol{x},t)} = \frac{\mathrm{d}z}{w(\boldsymbol{x},t)}. \tag{18.95}$$

Alternatively, we can introduce a pseudo-time parameter, s, that determines a position along a streamline. Streamlines are the curves $\boldsymbol{x} = \boldsymbol{\varsigma}(s;\boldsymbol{a},t)$ computed with $(\boldsymbol{a},t)$ held fixed, but with the pseudo-time varied

$$\frac{\partial \boldsymbol{\varsigma}(s;\boldsymbol{a},T)}{\partial s} = \boldsymbol{v}[\boldsymbol{\varsigma}(s;\boldsymbol{a},T),T] \tag{18.96a}$$

$$\boldsymbol{\varsigma}(s=0;\boldsymbol{a},T) = \boldsymbol{a}. \tag{18.96b}$$

Again, both the material coordinate $\boldsymbol{a}$ and time T are held fixed when determining streamlines, so that $(\boldsymbol{a},T)$ act as parameters to distinguish streamlines. Streamlines thus do not know about the time evolution of unsteady flow. Instead, streamlines only sample a snapshot of the velocity field; they are freshly computed at each time instance.

A *streamtube* is a bundle of streamlines crossing through an arbitrary closed curve (see Figure 18.6). Hence, at each time instance, streamtube sides are parallel to the velocity vector. Furthermore, when the flow is steady then streamlines are identical to material particle pathlines. Hence, a streamtube is a material tube for steady flow, in which case no fluid particles cross the streamtube boundary.

18.11.3 Distinguishing streamlines and pathlines

The tangent to a streamline gives the velocity at a single point in time, whereas the tangent to a material pathline (i.e., a trajectory) gives the velocity at subsequent times. These tangents are identical when the flow is steady. However, if the flow is time dependent (unsteady), then streamlines differ from material pathlines. Furthermore, for unsteady flow, the pseudo-time parameter, s, determining the streamlines in equation (18.96a) is not equal to the time, t, used to compute fluid particle trajectories in equation (18.91a). Consequently, the condition $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = 0$ satisfied at each time instance by a streamline still allows fluid particles to cross streamlines. The reason is

FIGURE 18.7: A suite of trajectories emanating from a single point. Common approximate realizations include the paths of fluid particles that leave a chimney, or the smoke from a source like a burning stick or torch. A streakline is defined as the accumulation of positions at time T of particles that passed through the common point at some earlier time $s < T$.

that a material pathline moves with the fluid in such a way that

$$(\boldsymbol{v} - \boldsymbol{v}^{\text{line}}) \cdot \hat{\boldsymbol{n}} = 0 \Longrightarrow \boldsymbol{v} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v}^{\text{line}} \cdot \hat{\boldsymbol{n}} \qquad \text{material lines,} \tag{18.97}$$

where $\boldsymbol{v}^{\text{line}}$ is the velocity of a point on the material pathline. The material pathline thus moves so that no fluid particles cross it. Only when the flow is steady, so that $\boldsymbol{v}^{\text{line}} \cdot \hat{\boldsymbol{n}} = 0$, will material pathlines and streamlines be equal. That is, the streamline constraint $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ is not a material constraint when $\boldsymbol{v}^{\text{line}} \cdot \hat{\boldsymbol{n}} \neq 0$. The key point is that streamlines do not probe the time behavior of the flow, so they do not know whether the velocity is steady or unsteady.

18.11.4 Fluid streaklines

A *streakline* is a curve obtained by connecting the positions for all fluid particles that emanate from a fixed point in space (see Figure 18.7). Streaklines are simple to define conceptually and to realize experimentally. However, they are a bit convoluted to specify mathematically. We present two formulations.

At any time T, the streakline passing through a fixed point $\boldsymbol{y}$ is a curve going from $\boldsymbol{y}$ to $\boldsymbol{\varsigma}(\boldsymbol{y}, T)$, the position reached by the particle initialized at $T = 0$ at the point $\boldsymbol{y}$. A particle is on the streakline if it passed the fixed point $\boldsymbol{y}$ at some time between 0 and T. If this time was s, then the material coordinate of the particle would be given by $\boldsymbol{a}(\boldsymbol{y}, s)$ relating the material coordinate to its corresponding laboratory position). Furthermore, at time T, this particle is at $\boldsymbol{x}$, so that the equation of the streakline at time T is

$$\boldsymbol{x} = \boldsymbol{\varsigma}[\boldsymbol{a}(\boldsymbol{y}, s), T] \qquad 0 \leq s \leq T. \tag{18.98}$$

We can connect the streakline specification to that given for a pathline and streamline through the following. A streakline at some time instance $\tilde{T}$ is a curve defined by fixing $\tilde{T}$ and varying s over $s \leq \tilde{T}$ in the function $\boldsymbol{\varsigma}(s; \boldsymbol{a}, \tilde{T})$. We determine the curves $\boldsymbol{x} = \boldsymbol{\varsigma}(s; \boldsymbol{a}, \tilde{T})$ by solving the following set of initial value problems for trajectories with initial conditions imposed at $T = s$

rather than $T = 0$

$$\frac{\partial \boldsymbol{\varsigma}(s;\boldsymbol{a},T)}{\partial T} = \boldsymbol{v}[\boldsymbol{\varsigma}(s;\boldsymbol{a},T),T] \tag{18.99a}$$

$$\boldsymbol{\varsigma}(T=s;\boldsymbol{a},T) = \boldsymbol{a}. \tag{18.99b}$$

Note that $\boldsymbol{a}$ remains fixed, as we start all trajectories determining a streakline from the same initial point (e.g., the chimney does not move). A streakline can thus be generated by emitting a dye from a point over a time interval equal to the range of s, with the dye following fluid particle trajectories.

18.11.5 An analytic example of flow lines

Consider the following two-dimensional example as taken from Section 4.13 of *Aris* (1962). Let the Eulerian velocity field be given by

$$u = \frac{x}{\tau + t} \quad \text{and} \quad v = \frac{y}{\tau} \quad \text{and} \quad w = 0, \tag{18.100}$$

where $\tau > 0$ is a constant with the dimensions of time. Also write $\boldsymbol{X}(\boldsymbol{a},T) = \boldsymbol{\varsigma}(\boldsymbol{x},T)$ for the trajectories, with $t = T$ the time coordinate.

Pathlines

Pathlines are determined by solving the trajectory equations

$$\frac{\mathrm{d}X(T)}{\mathrm{d}T} = \frac{X(T)}{\tau + T} \quad \text{and} \quad \frac{\mathrm{d}Y(T)}{\mathrm{d}T} = \frac{Y(T)}{\tau} \quad \text{and} \quad \frac{\mathrm{d}Z(T)}{\mathrm{d}T} = 0, \tag{18.101}$$

which are found to be

$$X(T) = X_0\,(1 + T/\tau) \tag{18.102a}$$

$$Y(T) = Y_0\, e^{T/\tau} \tag{18.102b}$$

$$Z(T) = Z_0, \tag{18.102c}$$

where $\boldsymbol{X}(T=0) = \boldsymbol{X}_0$. Sample trajectories are shown in Figure 18.8 over time $T \in [0,2]$. We can eliminate time to yield a curve in the horizontal (x,y) plane

$$y = Y_0\, e^{(x-X_0)/X_0}. \tag{18.103}$$

Streamlines

Streamlines are determined by solving the differential equations

$$\frac{\mathrm{d}X(s;T)}{\mathrm{d}s} = \frac{X(s;T)}{\tau + T} \quad \text{and} \quad \frac{\mathrm{d}Y(s;T)}{\mathrm{d}s} = \frac{Y(s;T)}{\tau} \quad \text{and} \quad \frac{\mathrm{d}Z(s;T)}{\mathrm{d}s} = 0, \tag{18.104}$$

FIGURE 18.8: Left panel: sample pathlines $X(T) = X_0\,(1 + T/\tau)$ and $Y(T) = Y_0\,e^{T/\tau}$ (see equations (18.102a) and (18.102b)) during times $T \in [0, 2\tau]$. The trajectories drawn here all start at $X_0 = 1$ and set the parameter $\tau = 1$. Note that those pathlines with $X_0 = 0$ remain on the y-axis, and those with $Y_0 = 0$ remain on the x-axis. Middle panel: Sample streamlines $X(s;T) = X_0\,e^{s/(\tau+T)}$ and $Y(s;T) = Y_0\,e^{s/\tau}$ (see equations (18.105a) and (18.105b). We set $T = 2$ and let the pseudo-time run from $s \in [0, 4]$. All streamlines shown here start at $X_0 = 1$. Note that those that start with $X_0 = 0$ remain on the y-axis, and those that start with $Y_0 = 0$ remain on the x-axis. Right panel: sample analytic streakline (dark bold line) at $T = 2$ according to equations (18.108a) and (18.108b). This streakline is determined by the position of particles at $T = 2$ that pass through $(X, Y) = (1, 1)$ during times $t \in (-\infty, 2)$. We show three sample trajectories that fall onto the streakline. The longest trajectory starts at $(X, Y) = (1, 1)$ at $T = 0$, whereas the two shorter trajectories pass through $(X, Y) = (1, 1)$ at some time $0 < T < 2$. Notice the distinction between all three flow lines, which is to be expected since the flow field is unsteady.

where time, T, is a fixed parameter whereas the pseudo-time, s, is varied. Integration renders the streamlines

$$X(s;T) = X_0\,e^{s/(\tau+T)} \tag{18.105a}$$

$$Y(s;T) = Y_0\,e^{s/\tau} \tag{18.105b}$$

$$Z(s;T) = Z_0. \tag{18.105c}$$

Sample streamlines are shown in Figure 18.8. Note that we can eliminate the pseudo-time s to render a curve in the horizontal (x, y) plane

$$y = Y_0 \left[\frac{x}{X_0}\right]^{(\tau+T)/\tau} \tag{18.106a}$$

$$z = Z_0. \tag{18.106b}$$

Streaklines

For streaklines, invert the trajectory expressions (18.102a)-(18.102b) to find the material coordinates $\boldsymbol{a}(\boldsymbol{y}, s)$ in the form

$$a_1 = \frac{y_1}{1 + s/\tau} \quad \text{and} \quad a_2 = y_2\,e^{-s/\tau} \quad \text{and} \quad a_3 = y_3. \tag{18.107}$$

We next evaluate the trajectory expressions (18.102a)-(18.102b) with $\boldsymbol{a}$ as the initial positions to find the streaklines

$$X(s;\boldsymbol{a},T) = \frac{y_1\,(1+T/\tau)}{1+s/\tau} \tag{18.108a}$$

$$Y(s;\boldsymbol{a},T) = y_2\,e^{(T-s)/\tau} \tag{18.108b}$$

$$Z(s;\boldsymbol{a},T) = y_3. \tag{18.108c}$$

Figure 18.8 illustrates the streakline for a particular point $(X,Y) = (1,1)$.

18.11.6 Further study

A discussion of flow lines can be found in most books on fluid mechanics. The presentation here borrows from Sections 4.11-4.13 of *Aris* (1962), Section 3.3 of *Kundu et al.* (2016), and online lecture notes on fluid kinematics from Professor McIntyre of Cambridge University.

18.12 Exercises

EXERCISE 18.1: FLUID VELOCITY AND ACCELERATION DERIVED FROM A TRAJECTORY
Following the example in Section 18.8.7, consider the one-dimensional fluid particle trajectory

$$\boldsymbol{X}(T) = \hat{\boldsymbol{x}}\,X(T) = \hat{\boldsymbol{x}}\left[k\,(T-t_0)^2 + x_0^3\right]^{1/3}, \tag{18.109}$$

where k is a constant with dimensions $\mathrm{L}^3\ \mathrm{T}^{-2}$, x_0 is the particle position at time t_0, and $\hat{\boldsymbol{x}}$ is the fixed Cartesian unit vector.

(a) Determine the velocity of the fluid particle.

(b) Determine the acceleration of the fluid particle.

(c) Determine the Eulerian velocity field.

(d) Determine the Eulerian acceleration field and show that it equals to the particle acceleration when evaluated at the spatial point, $\boldsymbol{x} = \boldsymbol{X}(T)$.

EXERCISE 18.2: STREAMLINES AND PATHLINES
Consider the spatially constant oscillating horizontal velocity field

$$\boldsymbol{u} = U\,[\hat{\boldsymbol{x}}\cos(\omega\,t) + \hat{\boldsymbol{y}}\sin(\omega\,t)], \tag{18.110}$$

where U is the constant flow speed and ω is the angular frequency of the oscillating flow. In this example we determine the streamlines and pathlines, which serves to clearly illustrate their distinction for this spatially constant time dependent flow.

(a) Derive the equation $y = y(x)$ for the streamline that passes through the origin at time $t = 0$.

(b) Derive the equation for the pathline that passes through the origin at time $t = 0$. Write the equation in a form that eliminates time, so to reveal the geometric shape of the pathlines.

EXERCISE 18.3: MATERIAL EVOLUTION OF THE PARTIAL DERIVATIVE OF A FUNCTION
In this exercise we establish some properties of the material time derivative operator when acting on spatial derivatives of a scalar field.

(a) If a scalar field Π is materially constant, prove that the material evolution of its spatial derivative is given by

$$\frac{\mathrm{D}(\partial_i \Pi)}{\mathrm{D}t} = -\partial_i \boldsymbol{v} \cdot \nabla \Pi. \tag{18.111}$$

For example, if $\mathrm{D}\Pi/\mathrm{D}t = 0$, then the zonal partial derivative $\partial_x \Pi$ has a material time derivative given by

$$\frac{\mathrm{D}(\partial \Pi/\partial x)}{\mathrm{D}t} = -\frac{\partial \boldsymbol{v}}{\partial x} \cdot \nabla \Pi. \tag{18.112}$$

(b) What is the material time derivative of $\nabla \Pi$ for the case that Π is not materially constant? Write your answer in a manner that clearly shows that the partial space derivative does not commute with the material time derivative. That is,

$$\frac{\mathrm{D}(\partial_i \Pi)}{\mathrm{D}t} \neq \partial_i \frac{\mathrm{D}\Pi}{\mathrm{D}t}. \tag{18.113}$$

Show what term appears on the right hand side to produce an equality.

Hint: Some might find it more suitable to first solve the general case first. Also, use Cartesian tensors for convenience.

EXERCISE 18.4: SURFACE MOVING WITH THE FLUID (EXERCISE Q1.5 OF *Johnson* (1997))
Consider a non-dimensional velocity field

$$\boldsymbol{v}(x, y, z, t) = t\,(2\,x\,\hat{\boldsymbol{x}} - y\,\hat{\boldsymbol{y}} - z\,\hat{\boldsymbol{z}}) \tag{18.114}$$

and a surface defined by the function

$$F(x, y, z, t) = x^2\,\mathrm{e}^{-2\,t^2} + (y^2 + 2\,z^2)\,\mathrm{e}^{t^2} = \text{constant}. \tag{18.115}$$

Show that

$$\frac{\mathrm{D}F}{\mathrm{D}t} = (\partial_t + \boldsymbol{v} \cdot \nabla)F = 0, \tag{18.116}$$

so that surface follows fluid particles.

EXERCISE 18.5: TRACER CONCENTRATION AND A GALILEAN TRANSFORMATION
Consider a tracer concentration[17]

$$\Pi(x, t) = \Pi_0\,\mathrm{e}^{-x^2/(4\,\kappa\,t)}, \tag{18.117}$$

where Π_0 is a constant and where κ is a constant diffusivity with dimensions of $\mathrm{L}^2\ \mathrm{T}^{-1}$.

(a) Compute the material time derivative, $\mathrm{D}\Pi/\mathrm{D}t$, with an assumed zero fluid flow.

(b) Perform a Galilean boost to a reference frame moving with constant velocity, $U\,\hat{\boldsymbol{x}}$. Compute the material time derivative of Π in this reference frame, thus proving that it is the same as in the rest frame from the previous part. Hint: make use of the ideas in Section 18.9

[17] We study tracers in Chapter 21. No prior knowledge of tracers is needed for this exercise.

EXERCISE 18.6: UNSTATED ASSUMPTION IN LUMLEY'S VIDEO

This 27-minute video on Eulerian and Lagrangian descriptions from Prof. Lumley offers a pedagogical discussion of these two perspectives on fluid motion. However, there is one unstated assumption in this video that limits the applicability of his expressions for the material time derivative. What is that assumption? Hint: read Section 18.8.8.

Chapter 19

Strain and rotation

Draw an imaginary geometric object (line, area, volume) within a perfect fluid. Since the fluid is perfect, all fluid particles that start on the geometric object remain on the object, even as the object's shape is deformed by the fluid flow. In this manner, the object is a perfectly *coherent structure*. We study the kinematics of such objects in this chapter by using rudimentary Lagrangian and Eulerian methods. Extra attention is given to the kinematics of two-dimensional flow due to the relative mathematical ease and the associated intuition that proves useful for more general three dimensional flows.

A key goal in this chapter is to develop an understanding of how fluid flow modifies geometric objects placed in the flow. The kinematics of this modification is directly connected to the *deformation* of the flow. There are two general methods to measure deformation. One is based on the motion field, where we see that the *deformation matrix* gives rise to the evolution of a material curve. The second is based on the *velocity gradient tensor*, which can be decomposed into its symmetric component, the *strain rate* tensor, and its anti-symmetric component, the *rotation* tensor.

The ideas developed in this chapter extend to real fluids in the presence of mixing, since we are only concerned with the motion of fluid particles as determined by integral lines of the fluid flow. Hence, perfect fluid kinematics have use in the study of mixing and transport within real fluids (e.g., *Ottino* (1989)). That is, for a real fluid we also find it useful to study geometric objects that follow the flow. However, in a real fluid such objects are not perfectly coherent since matter generally crosses all surfaces through diffusive mixing. The question then becomes whether there are special surfaces where such mixing is suppressed, with this question forming a key part of the study of coherent structures in real fluids (e.g., *Haller* (2015)).

As a basis for the kinematic thinking presented in this chapter, we make extensive use of material fluid particles as introduced in Section 18.3.1. Recall that fluid particles are mathematical points that move with the flow, and there is a continuum of such particles comprising any continuous region of fluid. We do not ask questions about the number of such particles along a curve, nor do we question whether particles are created or destroyed as a material object changes its length, area, or volume. Instead, we make use of fluid particles as a conceptual construct for describing motion of a fluid region, and we use their trajectories to define the Lagrangian reference frame. Importantly, point fluid particles are not approximations to molecules; i.e., they are mathematical constructs rather than physical objects.

READER'S GUIDE FOR THIS CHAPTER

This chapter builds from the kinematics of Chapter 18 and makes some use of Section 3.1 of *Batchelor* (1967). As in Chapter 18, we assign the Latin labels i, j, k for the spatial (Eulerian) description,, $\boldsymbol{x}$, whereas material (Lagrangian) labels use the capital letters, I, J, K.

We start out the chapter with notation from general tensor analysis as per Chapters 8 and 9, with distinctions made between covariant and contra-variant labels. However, we assume Cartesian coordinates to describe the motion field, as doing so allows us to use familiar notions from Cartesian tensor analysis (Chapter 2) when studying how points in the flow move relative to one another. We also move to fully Cartesian tensor notation when connecting the rotation tensor to vorticity. Extending these fundamental kinematic concepts to general manifolds requires more mathematical apparatus than warranted for this chapter.

19.1 Loose threads

- Convert Figure 19.2 into Keynote and gray shade the color.

19.2 Differential increment for $\boldsymbol{a}$-space and $\boldsymbol{x}$-space

We here develop expressions for the differential increment of a function in both position/Eulerian space ($\boldsymbol{x}$-space) and in material/Lagrangian space ($\boldsymbol{a}$-space).[1] These relations are of use for the subsequent development.

19.2.1 Spatial increments

Consider a fluid property, Π, and represent it with the spatial coordinates of an Eulerian description, $\Pi(\boldsymbol{x}, t)$. In Section 18.8.1, we considered the space and time increment of a scalar function. Here we consider just the space increment, as defined by the differential increment of a function evaluated at the same time but at two infinitesimally close points in space. Writing this increment for a scalar renders

$$\mathrm{d}\Pi(\boldsymbol{x}, t) = \Pi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}, t) - \Pi(\boldsymbol{x}, t) \tag{19.1a}$$

$$= (\mathrm{d}\boldsymbol{x} \cdot \nabla)\Pi(\boldsymbol{x}, t). \tag{19.1b}$$

The dimensionless increment operator

$$\mathrm{d}\boldsymbol{x} \cdot \nabla = \mathrm{d}x^i \, \partial_i \tag{19.2}$$

is a scalar since it remains form invariant when switching to another set of spatial coordinates.

19.2.2 Material increments

Consider the same fluid property, Π, now evaluated on a material fluid particle trajectory, and write this Lagrangian function as in Section 18.8.5

$$\Pi^{\mathrm{L}}(\boldsymbol{a}, T) \equiv \Pi[\boldsymbol{x} = \boldsymbol{\varsigma}(\boldsymbol{a}, T), t = T] = \Pi[\boldsymbol{\varsigma}(\boldsymbol{a}, T), T], \tag{19.3}$$

where $\boldsymbol{\varsigma}(\boldsymbol{a}, T)$ is the motion field from Section 18.6, which specifies the trajectories of the continuum of fluid particles. As introduced in Section 18.8.5, the notation $\Pi^{\mathrm{L}}(\boldsymbol{a}, T)$ is a shorthand defined by this equality, with the L superscript *not* a tensor index.

Now consider an infinitesimal increment of $\Pi^{\mathrm{L}}(\boldsymbol{a}, T)$ within material coordinate space. This increment measures the difference of the fluid property, Π, when evaluated on two fluid particles, one labelled by $\boldsymbol{a}$ and the other by $\boldsymbol{a} + \delta\boldsymbol{a}$. Note that we use the δ symbol to signal material increments. Just like when working in $\boldsymbol{x}$-space, we take a Taylor series and truncate to leading order, in which case

$$\delta\Pi^{\mathrm{L}}(\boldsymbol{a}, T) = \Pi[\boldsymbol{\varsigma}(\boldsymbol{a} + \delta\boldsymbol{a}, T), T] - \Pi[\boldsymbol{\varsigma}(\boldsymbol{a}, T), T] \tag{19.4a}$$

$$= \Pi^{\mathrm{L}}(\boldsymbol{a} + \delta\boldsymbol{a}, T) - \Pi^{\mathrm{L}}(\boldsymbol{a}, T) \tag{19.4b}$$

$$= (\delta\boldsymbol{a} \cdot \nabla_{\boldsymbol{a}})\Pi^{\mathrm{L}}(\boldsymbol{a}, T). \tag{19.4c}$$

The dimensionless operator

$$\delta\boldsymbol{a} \cdot \nabla_{\boldsymbol{a}} = \delta a^I \, \partial_I \tag{19.5}$$

is a scalar since it remains form invariant when switching to another set of material coordinates. We sometimes use the notation $\nabla_{\boldsymbol{a}}$ to signal when the partial derivative operator acts on functions on $\boldsymbol{a}$-space rather than $\boldsymbol{x}$-space.

[1] From a mathematical perspective, we develop the exterior derivatives for a selection of scalar functions, and detail their expressions using both Eulerian and Lagrangian coordinates.

FIGURE 19.1: Three time instances of a material curve, highlighting two fluid particles whose trajectories are $\boldsymbol{\varsigma}(\boldsymbol{a},T)$ and $\boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T)$. All points along the curve move through the fluid by following the trajectories of the fluid particles. Kinematics of the relative vector separating two fluid particles is determined by properties of the deformation matrix in Section 19.3, or the deformation rate in Section 19.4.

19.2.3 Duality between Eulerian and Lagrangian perspectives

The value of a fluiid property at a spatial point $\boldsymbol{x}$ (Eulerian perspective) equals to the property evaluated on a moving fluid particle (Lagrangian perspective) at the instance the particle passes through $\boldsymbol{x}$. Mathematically, this identity takes the form

$$\Pi^{\mathrm{L}}(\boldsymbol{a},T) = \Pi[\boldsymbol{\varsigma}(\boldsymbol{a},T),t] = \Pi(\boldsymbol{x},t) \quad \text{if } \boldsymbol{\varsigma}(\boldsymbol{a},T) = \boldsymbol{x}. \tag{19.6}$$

Likewise, if the infinitesimal increment in space, $\delta\boldsymbol{x}$, equals to the vector increment of the two fluid particles,

$$\delta\boldsymbol{\varsigma}(\boldsymbol{a},T) = \boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T) - \boldsymbol{\varsigma}(\boldsymbol{a},T), \tag{19.7}$$

then the functional increments are identical

$$\delta\Pi^{\mathrm{L}}(\boldsymbol{a},T) = \delta\Pi(\boldsymbol{x},t) \quad \text{if } \delta\boldsymbol{\varsigma}(\boldsymbol{a},T) = \delta\boldsymbol{x}, \tag{19.8}$$

where

$$\delta\Pi(\boldsymbol{x},t) = \Pi(\boldsymbol{x}+\delta\boldsymbol{x},t) - \Pi(\boldsymbol{x},t) = (\delta x^i\,\partial_i)\,\Pi(\boldsymbol{x},t) \tag{19.9a}$$

$$\delta\Pi^{\mathrm{L}}(\boldsymbol{a},T) = \Pi^{\mathrm{L}}(\boldsymbol{a}+\delta\boldsymbol{x},T) - \Pi^{\mathrm{L}}(\boldsymbol{a},T) = (\delta a^I\,\partial_I)\,\Pi^{\mathrm{L}}(\boldsymbol{a},T). \tag{19.9b}$$

These identities allow us to develop relations using either a Lagrangian or an Eulerian description, and then to interpret the resulting equations in their complementary perspective.

19.3 The deformation matrix and relative motion

Material curves are one-dimensional geometric objects that follow fluid particles. We initialize a material curve by drawing a line in the fluid and then follow the curve as it deforms according to the trajectories of the fluid particles. The material curve is stretched and folded by the fluid flow as illustrated in Figure 19.1. We here develop the rudimentary kinematics of such motion by considering the evolution of the relative vector connecting two fluid particles. For this purpose we must specialize to Cartesian coordinates in order to compare the position vectors at two points in space. As we will see, the evolution of these two points is determined by the deformation matrix introduced in Section 18.7.2.

19.3.1 Deformation matrix

Consider two fluid particles whose trajectories are $\boldsymbol{\varsigma}(\boldsymbol{a},T)$ and $\boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T)$ (see Figure 19.1). At time T, the vector connecting these two particles (the relative vector) is written

$$\delta\boldsymbol{\varsigma}(\boldsymbol{a},T) = \boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T) - \boldsymbol{\varsigma}(\boldsymbol{a},T). \tag{19.10}$$

Expanding to leading order yields an expression of *Cauchy's solution* (further explored in Section 19.3.4)

$$\delta\boldsymbol{\varsigma}(\boldsymbol{a},T) = \boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T) - \boldsymbol{\varsigma}(\boldsymbol{a},T) \approx (\delta a^I\,\partial_I)\,\boldsymbol{\varsigma}(\boldsymbol{a},T). \tag{19.11}$$

Making use of the assumed Cartesian coordinates for the motion field allows us to write the material increment in terms of the deformation matrix[2]

$$\delta\varsigma^i = \delta a^I\,\partial_I\varsigma^i = \delta a^I\,F^i_{\ I}, \tag{19.12}$$

where

$$F^i_{\ I} \equiv \partial_I\varsigma^i \tag{19.13}$$

are elements of the *deformation matrix* that transforms between the spatial (Eulerian) description in $\boldsymbol{x}$-space to the material (Lagrangian) description in $\boldsymbol{a}$-space. We already encountered the deformation matrix in Section 18.7 (see equation (18.11)).

19.3.2 Cauchy-Green strain tensor

The deformation matrix plays a role in measuring the length of material curves. We see this role by considering the squared length of an infinitesimal portion of a material curve

$$\delta\boldsymbol{\varsigma}\cdot\delta\boldsymbol{\varsigma} = \frac{\partial\boldsymbol{\varsigma}}{\partial a^I}\cdot\frac{\partial\boldsymbol{\varsigma}}{\partial a^J}\,\delta a^I\,\delta a^J \equiv C_{IJ}\,\delta a^I\,\delta a^J. \tag{19.14}$$

Algebraically, this expression is a quadratic form, and the symmetric object

$$C_{IJ} \equiv \frac{\partial\boldsymbol{\varsigma}}{\partial a^I}\cdot\frac{\partial\boldsymbol{\varsigma}}{\partial a^J} = F^i_{\ I}\,F^i_{\ J} \tag{19.15}$$

acts as the metric tensor to measure distance along an infinitesimal material curve. This metric tensor is called the *Cauchy-Green strain* tensor.

19.3.3 Kinematic evolution equation

Now consider the material time derivative of the material increment

$$\frac{\partial[\delta\boldsymbol{\varsigma}(\boldsymbol{a},T)]}{\partial T} = \frac{\partial\boldsymbol{\varsigma}(\boldsymbol{a}+\delta\boldsymbol{a},T)}{\partial T} - \frac{\partial\boldsymbol{\varsigma}(\boldsymbol{a},T)}{\partial T} \tag{19.16a}$$

$$= \boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}+\delta\boldsymbol{a},T) - \boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T) \tag{19.16b}$$

$$\equiv \delta\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T). \tag{19.16c}$$

In these equations, we introduced the Lagrangian velocity

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T) = \boldsymbol{v}[\boldsymbol{x}=\boldsymbol{\varsigma}(\boldsymbol{a},T), t=T] \tag{19.17}$$

as per equation (18.38) and the discussion in Section 19.2.2. As for the manipulations in Section 19.3.1, we can massage the expression (19.16c) by performing a Taylor series expansion and truncating to leading order

$$\frac{\partial[\delta\boldsymbol{\varsigma}(\boldsymbol{a},T)]}{\partial T} = \delta\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T) = (\delta\boldsymbol{a}\cdot\nabla_{\boldsymbol{a}})\,\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T). \tag{19.18}$$

[2]The connection between differential increment and deformation gradient does not hold when using general coordinates for the motion field. The reason is that we cannot naively compare vectors on a general manifold. More work is needed, and that goes beyond our goals for this chapter.

Alternatively, we can choose to evaluate this expression using an Eulerian perspective (see Section 19.2.3), in which case

$$\frac{\mathrm{D}(\delta \boldsymbol{x})}{\mathrm{D}t} = \delta \boldsymbol{v}(\boldsymbol{x}, t) = (\delta \boldsymbol{x} \cdot \nabla)\, \boldsymbol{v}(\boldsymbol{x}, t). \tag{19.19}$$

In Section 19.3.4 we examine this equation according to Cauchy, thus furthering our understanding of how the relative displacement vector evolves.

19.3.4 Cauchy's solution for the relative vector evolution

We can determine a general solution to the kinematic evolution equation (19.19) following the method used by Cauchy[3] to solve the perfect fluid barotropic vorticity equation discussed in Section 41.5. Indeed, we already encountered the Cauchy solution in Section 19.3.1. We rederive it here following a more laborious route. Doing so exposes formalism that can be of general use when working with Lagrangian coordinates, and it offers further insight into the meaning of the solution. For those uninterested in the formalism, then skip to the final few paragraphs of this subsection for a discussion of the solution and extension to vorticity.

Derivation

The derivation that follows involves strategic uses of the transformation between $\boldsymbol{a}$-space and $\boldsymbol{x}$-space. Also, we are mindful to note that $\delta \boldsymbol{x}$ refers to the spatial increment between two material fluid particles, as per equation (19.19). As a result, when we write x^i, it refers to the position of a fluid particle that moves according to the motion, $x^i = \varsigma^i(\boldsymbol{a}, T)$. Likewise, the relative vector increment, δx^i, equals to $\delta x^i = \delta \varsigma^i$. Using equation (19.19) as a starting point leads to

$$\begin{aligned}
\frac{\mathrm{D}(\delta x^i)}{\mathrm{D}t} &= (\delta \boldsymbol{x} \cdot \nabla) v^i && \text{kinematic evolution (19.19)} && (19.20\text{a})\\
&= \delta x^j\, \partial_j \left[\frac{\mathrm{D}x^i}{\mathrm{D}t}\right] && v^i = \mathrm{D}x^i/\mathrm{D}t && (19.20\text{b})\\
&= \delta x^j\, \partial_j a^J \partial_J \left[\frac{\mathrm{D}x^i}{\mathrm{D}t}\right] && \text{chain rule: } \partial_j = (\partial_j a^J)\, \partial_J && (19.20\text{c})\\
&= \delta x^j\, \partial_j a^J \frac{\mathrm{D}}{\mathrm{D}t} \frac{\partial x^i}{\partial a^J} && \text{commute } \partial_J \text{ and } \mathrm{D}/\mathrm{D}t && (19.20\text{d})\\
&= \delta x^j \frac{\mathrm{D}}{\mathrm{D}t} \left[\frac{\partial a^J}{\partial x^j} \frac{\partial x^i}{\partial a^J}\right] - \delta x^j \frac{\mathrm{D}}{\mathrm{D}t} \left[\frac{\partial a^J}{\partial x^j}\right] \frac{\partial x^i}{\partial a^J} && \text{move } \mathrm{D}/\mathrm{D}t && (19.20\text{e})\\
&= -\delta x^j \frac{\mathrm{D}}{\mathrm{D}t} \left[\frac{\partial a^J}{\partial x^j}\right] \frac{\partial x^i}{\partial a^J}. && \frac{\partial a^J}{\partial x^j} \frac{\partial x^i}{\partial a^J} = \delta^i{}_j = \text{constant}. && (19.20\text{f})
\end{aligned}$$

The commutation in equation (19.20d) follows since the material coordinates are fixed on a fluid particle so that

$$\frac{\partial}{\partial a^J} \frac{\mathrm{D}}{\mathrm{D}t} = \frac{\mathrm{D}}{\mathrm{D}t} \frac{\partial}{\partial a^J}. \tag{19.21}$$

[3] See *Frisch and Villone* (2014) for an insightful discussion of the enduring impact of Cauchy's solution.

Contracting the identity (19.20f) with $\partial a^K/\partial x^i$ yields

$$\frac{\partial a^K}{\partial x^i}\,\frac{\mathrm{D}(\delta x^i)}{\mathrm{D}t} = -\delta x^j\,\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\partial a^J}{\partial x^j}\right]\frac{\partial x^i}{\partial a^J}\,\frac{\partial a^K}{\partial x^i} \qquad \text{contraction} \tag{19.22a}$$

$$= -\delta x^j\,\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\partial a^K}{\partial x^j}\right] \qquad \frac{\partial x^i}{\partial a^J}\,\frac{\partial a^K}{\partial x^i} = \delta^K_J \tag{19.22b}$$

$$= -\delta x^i\,\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\partial a^K}{\partial x^i}\right] \qquad \text{change indices from } j \text{ to } i. \tag{19.22c}$$

We can thus identify the material invariant

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\delta x^i\,\frac{\partial a^K}{\partial x^i}\right] = 0 \Longrightarrow (\delta\boldsymbol{x}\cdot\nabla)\,a^K = \text{material invariant}. \tag{19.23}$$

This result follows rather trivially by recognizing the coordinate transformation

$$(\delta\boldsymbol{x}\cdot\nabla)a^K = (\delta x^i\,\partial_i)a^K = (\delta a^J\,\partial_J)a^K = \delta a^K, \tag{19.24}$$

and noting that δa^K is a material invariant, in which case $(\delta\boldsymbol{x}\cdot\nabla)\,a^K$ is also materially invariant. Note that the second equality in equation (19.24) follows from the duality in equation (19.8).

If we choose the material coordinates as the initial positions of fluid particles,

$$\boldsymbol{a} = \boldsymbol{x}(t=0), \tag{19.25}$$

then the inverse transformation matrix element at the initial time is given by the unit tensor

$$\frac{\partial a^K}{\partial x^j} = \delta^K_j \quad \text{at } t=0, \tag{19.26}$$

so that the material invariance in equation (19.23) leads to

$$(\delta\boldsymbol{x}\cdot\nabla)a^K = \delta x^K(t=0) \Longleftrightarrow (\delta x^j\,\partial_j)a^K = \delta x^K(t=0). \tag{19.27}$$

Inverting this equation by contracting with $\partial x^i/\partial a^K$ and using $(\partial x^i/\partial a^K)\,(\partial a^K/\partial x^j) = \delta^i{}_j$ leads to *Cauchy's solution*

$$\delta x^i = \delta x^K(t=0)\,\frac{\partial x^i}{\partial a^K}. \tag{19.28}$$

Reinserting the motion field via $x^i = \varsigma^i(\boldsymbol{a}, T)$ renders

$$\delta x^i = \delta x^K(t=0)\,\frac{\partial \varsigma^i}{\partial a^K} = \delta x^K(t=0)\,F^i{}_K, \tag{19.29}$$

where the final equality introduced the deformation matrix (19.13).

Discussion of Cauchy's solution (19.29)

The Cauchy solution (19.29) says that the increment along a line segment defined by fluid particles, $\delta\boldsymbol{x} = \delta\boldsymbol{\varsigma}$, expands or contracts according to the time and space dependent deformation matrix, $F^i{}_K$. This result follows from our assumption that the increment is defined by fixed $\boldsymbol{a}$-space coordinates, which then constrains the increment's $\boldsymbol{x}$-space evolution. It is also an expression that we wrote down, rather trivially, in Section 19.3.1 when performing a truncated Taylor series expansion of the spatial increment between two material fluid particles that follow the flow. Both

approaches offer distinct insights as well as confidence in the validity of the result.[4] The ability to derive kinematic results using either simple (indeed trivial) methods versus more long-winded methods is somewhat exemplary of fluid kinematics.

Extension to vorticity

As seen in Section 41.3, the relative vorticity, $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$, for a homogeneous inviscid, barotropic fluid satisfies the same kinematic equation (19.19) as for a material line increment

$$\frac{\mathrm{D}\boldsymbol{\omega}}{\mathrm{D}t} = (\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v}(\boldsymbol{x}, t). \tag{19.30}$$

We can thus invoke the Cauchy solution to write the vorticity

$$\omega^i(t) = \omega^K(t=0)\, \frac{\partial x^i}{\partial a^K} = \omega^K(t=0)\, \frac{\partial \varsigma^i}{\partial a^K} = \omega^K(t=0)\, F^i{}_K, \tag{19.31}$$

which is one form of Kelvin's circulation theorem studied in Section 41.2.

19.4 The velocity gradient and relative velocity

In this section we return to the expression (19.11) of the Cauchy solution for the relative position vector between two fluid particles

$$\delta\boldsymbol{\varsigma}(\boldsymbol{a}, T) = \boldsymbol{\varsigma}(\boldsymbol{a} + \delta\boldsymbol{a}, T) - \boldsymbol{\varsigma}(\boldsymbol{a}, T) = (\delta a^I\, \partial_I)\, \boldsymbol{\varsigma}(\boldsymbol{a}, T). \tag{19.32}$$

Rather then developing the solution into the form (19.29), which exposes the deformation matrix, we here take a material time derivative, in which case the deformation rate tensor is seen to determine evolution of the relative velocity.

19.4.1 Evolution of the relative velocity

Taking the material time derivative of the left hand side to equation (19.32) leads to the relative velocity vector

$$\partial_T\, \delta\boldsymbol{\varsigma} = \delta\, \partial_T \boldsymbol{\varsigma} = \delta \boldsymbol{v}^{\mathrm{L}}, \tag{19.33}$$

where we introduced the Lagrangian velocity vector, which is the material time derivative of the motion as evaluated on a fluid particle

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a}, T) = \partial_T \boldsymbol{\varsigma}(\boldsymbol{a}, T). \tag{19.34}$$

Combining equation (19.33) with the material time derivative acting on the right hand side of equation (19.32) renders

$$\delta \boldsymbol{v}^{\mathrm{L}} = (\delta a^I\, \partial_I)\, \partial_T \boldsymbol{\varsigma} = (\delta a^I\, \partial_I)\, \boldsymbol{v}^{\mathrm{L}}, \tag{19.35}$$

where the material time derivative operator commutes with the material increment operator $\delta a^I\, \partial_I$, and with equation (19.35) agreeing with the earlier identity (19.9b). Making use of the deformation matrix (19.13) renders the component form of equation (19.35)

$$\delta v^{\mathrm{L}\, i} = (\delta a^I\, \partial_I)\, \partial_T \varsigma^i = \delta a^I\, \partial_T\, \partial_I \varsigma^i = \delta a^I\, \partial_T F^i{}_I. \tag{19.36}$$

[4] If there is more than one way to solve a problem, then do so, even if one of those ways is much more tedious!

Hence, the relative velocity of two fluid particles is directly determined by the material time derivative of the deformation matrix.

19.4.2 Velocity gradient tensor

We can make use of the duality developed in Section 19.2 to write Lagrangian expression (19.35) in terms of Eulerian position coordinates

$$\delta \boldsymbol{v}(\boldsymbol{x}, t) = (\delta x^j \, \partial_j) \, \boldsymbol{v}(\boldsymbol{x}, t) \Longleftrightarrow \delta v^i = (\delta x^j \, \partial_j) \, v^i. \tag{19.37}$$

Alternatively, we can return to the identity (19.33), and again make use of the duality to write the material time derivative of the position increment

$$\frac{\mathrm{D}(\delta x^i)}{\mathrm{D}t} = \delta v^i = (\delta x^j \, \partial_j) \, v^i. \tag{19.38}$$

This equation says that the material evolution of δx^i is determined by the velocity derivatives, $\partial_j v^i$. These derivatives form elements to the second order *velocity gradient tensor*

$$\mathbb{G}^i{}_j = \partial_j v^i, \tag{19.39}$$

so that equation (19.38) can be written

$$\frac{\mathrm{D}(\delta x^i)}{\mathrm{D}t} = \mathbb{G}^i{}_j \, \delta x^j. \tag{19.40}$$

To help understand the action of the second order velocity gradient tensor on the evolution of $\delta \boldsymbol{x}$, we decompose the tensor into its symmetric and anti-symmetric components, which requires the transposed velocity gradient tensor, $\mathbb{G}^{\mathrm{t}}$. If organized into a matrix, the matrix elements of $\mathbb{G}^{\mathrm{t}}$ are found by transposing the matrix elements of $\mathbb{G}$, so that

$$(\mathbb{G}^{\mathrm{t}})^i{}_j = \mathbb{G}^i_j, \tag{19.41}$$

with the left-most index the row and right-most the column. We can thus write the velocity gradient tensor as

$$\mathbb{G} = (\mathbb{G} + \mathbb{G}^{\mathrm{t}})/2 + (\mathbb{G} - \mathbb{G}^{\mathrm{t}})/2 \equiv \mathbb{S} + \mathbb{R}, \tag{19.42}$$

where

$$\mathbb{S} = (\mathbb{G} + \mathbb{G}^{\mathrm{t}})/2 \qquad \text{strain rate tensor} \tag{19.43a}$$

$$\mathbb{R} = (\mathbb{G} - \mathbb{G}^{\mathrm{t}})/2 \qquad \text{rotation tensor.} \tag{19.43b}$$

As seen in the following, the strain rate and rotation tensors affect the motion of a material fluid object in distinct manners.

19.4.3 Stretching and tilting of material lines

Consider a material line element initially aligned with the vertical axis

$$\delta \boldsymbol{x}_{t=0} = \hat{\boldsymbol{z}} \, \delta Z_0. \tag{19.44}$$

The evolution equation (19.40) means that the initial evolution of this material line element takes on the form

$$\frac{\mathrm{D}(\delta x)}{\mathrm{D}t} = \underbrace{\delta Z_0 \left[\frac{\partial u}{\partial z}\right]}_{\text{tilting}} \quad \text{and} \quad \frac{\mathrm{D}(\delta y)}{\mathrm{D}t} = \underbrace{\delta Z_0 \left[\frac{\partial v}{\partial z}\right]}_{\text{tilting}} \quad \text{and} \quad \frac{\mathrm{D}(\delta z)}{\mathrm{D}t} = \underbrace{\delta Z_0 \left[\frac{\partial w}{\partial z}\right]}_{\text{stretching}}. \tag{19.45}$$

In the presence of a vertical derivative in the horizontal velocity field (vertical shear), the first and second terms create a non-zero projection of the material line element onto the horizontal plane. That is, these terms *tilt* the material line element. Additionally, in the presence of a vertical derivative in the vertical velocity, the material line element is expanded or compressed along its initial axis. This term is called *stretching*. We return to the tilting and stretching mechanisms when discussing the dynamics of vorticity in Chapter 41. There, we see that vortex lines in a perfect fluid flow are material lines. Consequently, vortex lines are also affected by tilting and stretching just like a material line.

19.4.4 Evolution of line element length from the strain rate

Recall the expression (19.14) for the squared length of a material line element

$$\delta\boldsymbol{\varsigma} \cdot \delta\boldsymbol{\varsigma} = (\delta a^I \partial_I)\boldsymbol{\varsigma} \cdot (\delta a^J \partial_J)\boldsymbol{\varsigma}, \tag{19.46}$$

whose material time derivative is given by

$$\partial_T(\delta\boldsymbol{\varsigma} \cdot \delta\boldsymbol{\varsigma}) = 2\,(\delta a^I \partial_I)\boldsymbol{v}^{\mathrm{L}} \cdot (\delta a^J \partial_J)\boldsymbol{\varsigma}. \tag{19.47}$$

We can express this result using Eulerian $\boldsymbol{x}$-space coordinates through the duality in Section 19.2.3, which leads to

$$(\delta a^I\, \partial_I)\boldsymbol{v}^{\mathrm{L}} = (\delta x^i\, \partial_i)\boldsymbol{v} \quad \text{and} \quad (\delta a^I\, \partial_I)\boldsymbol{\varsigma} = \delta\boldsymbol{x}, \tag{19.48}$$

so that

$$\frac{\mathrm{D}(\delta\boldsymbol{x} \cdot \delta\boldsymbol{x})}{\mathrm{D}t} = 2\,\delta x^i\,\delta x^k\,\delta_{jk}\,\partial_i v^j = 2\,\delta x^i\,\delta x^k\,\delta_{jk}\,\mathbb{G}^j{}_i. \tag{19.49}$$

Since the product $\delta x^i\,\delta x^k$ is symmetric on the indices i, k, it projects out the symmetric portion of the velocity gradient tensor, which is the strain rate tensor, thus yielding

$$\frac{1}{2}\frac{\mathrm{D}(\delta\boldsymbol{x} \cdot \delta\boldsymbol{x})}{\mathrm{D}t} = 2\,\delta x^i\,\delta x^k\,\delta_{jk}\,\mathbb{S}^j{}_i. \tag{19.50}$$

Consequently, the strain rate tensor, $\mathbb{S}$, determines the rate at which a material curve changes its length.

To further understand the result (19.50), consider two fluid particles initialized very close together. Equation (19.50) says that the distance between the two particles is modified so long as there are nonzero strain rates in the fluid flow. In the special case of a zero strain rate tensor, then the separation between the two fluid particles is fixed. Evidently, in the absence of a strain rate, the two fluid particles move in a locally and instantaneously rigid manner.

Since the strain rate tensor is symmetric, it has six degrees of freedom. Furthermore, it can be diagonalized, with the diagonal elements equal to the eigenvalues (e.g., see section 2.2 of *Segel* (1987)). Each eigenvalue measures the rate that material lines oriented according to the principle axes (eigenvectors) expand/contract under the impacts of straining motion in the fluid. According to equation (19.50), the expansion/contraction is exponential when aligned along the principle

axes, with the exponential rate determined by the eigenvalues of $\mathbb{S}$. Furthermore, as shown in Section 19.6, the sum of these eigenvalues (given by the trace of the strain rate tensor) measures the rate that a material volume changes through the divergence of the velocity

$$\mathbb{S}^i{}_i = \partial_i v^i = \nabla \cdot \boldsymbol{v}. \tag{19.51}$$

19.4.5 Rigid rotation of the line element

As defined by equation (19.43b), the rotation tensor is given by

$$\mathbb{R} = (\mathbb{G} - \mathbb{G}^{\mathrm{t}})/2. \tag{19.52}$$

Notably, the rotation tensor is anti-symmetric so that

$$\mathbb{R}^{\mathrm{t}} = -\mathbb{R}^{\mathrm{t}}, \tag{19.53}$$

and as such it has three degrees of freedom. At this point we return to the full gamut of Cartesian tensor notation by bringing all indices downstairs.[5] We also introduce the vorticity vector,

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v}, \tag{19.54}$$

which is related to the rotation tensor via

$$2\,\mathbb{R}_{ij} = -\epsilon_{ijk}\,\omega_k \Longleftrightarrow \mathbb{R} = \frac{1}{2}\begin{bmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{bmatrix} \Longleftrightarrow \omega_k = -\epsilon_{kij}\,\mathbb{R}_{ij}, \tag{19.55}$$

where the final expression made use of the identity (1.43) in the form

$$\epsilon_{ijl}\,\epsilon_{ijm} = 2\,\delta_{lm}. \tag{19.56}$$

It is furthermore straightforward to show that the doubly contracted rotation tensor equals to half the squared vorticity

$$\mathbb{R}_{ij}\,\mathbb{R}_{ij} = |\boldsymbol{\omega}|^2/2. \tag{19.57}$$

The contribution of the rotation matrix to evolution of the material line element is given by

$$\left[\frac{\mathrm{D}(\delta x_i)}{\mathrm{D}t}\right]_{\mathrm{rot}} = \mathbb{R}_{ij}\,\delta x_j = -(\epsilon_{ijk}\,\omega_k/2)\,\delta x_j \Longrightarrow \left[\frac{\mathrm{D}(\delta \boldsymbol{x})}{\mathrm{D}t}\right]_{\mathrm{rot}} = \frac{1}{2}\left(\boldsymbol{\omega} \times \delta \boldsymbol{x}\right). \tag{19.58}$$

This relation is in the form of a pure rotation of the material line element, $\delta\boldsymbol{x}$, as generated by the vector, $\boldsymbol{\omega}/2$ (recall the discussion of rigid-body rotations in Section 11.2). We thus conclude that the anti-symmetric rotation tensor, $\mathbb{R}$, provides a rigid rotation to a material line element about the axis defined by the vorticity vector. It rotates the objects without altering the size (length, area, volume).

19.4.6 Cauchy-Stokes decomposition

The above discussion of how fluid motion impacts on a material curve falls under the more general insights from the *Cauchy-Stokes decomposition theorem*. This theorem says that the arbitrary motion of a region in a continuous media can be decomposed into a uniform translation, dilation

[5] To work with general tensors at this stage requires more tools than warranted for this discussion.

FIGURE 19.2: Schematic illustrating the Cauchy-Stokes decomposition of how fluid flow can modify a spherical material region according to equation (19.59). First the sphere can be deformed without rotation, with this process encompassed by the strain rate tensor, $\mathbb{S}_{mn}$. Next it can be rigidly rotated without changing its shape, as encompassed by the rotation tensor, $\mathbb{R}_{mn}$. The axes shown represent the principle axes so that deformation corresponds to expansion or contraction along the principle axes directions.

along three perpendicular axes, plus a rigid body rotation. Mathematically, this decomposition can be written by expanding equation (19.40) to read

$$v_i(\boldsymbol{x}, t) = v_i(\boldsymbol{x}_0, t) + \mathbb{G}_{ij}\,\delta x_j = v_i(\boldsymbol{x}_0, t) + \mathbb{S}_{ij}\,\delta x_j + \mathbb{R}_{ij}\,\delta x_j. \tag{19.59}$$

Figure 19.2 illustrates the deformation and rotation portion of this decomposition. A more thorough discussion of this theorem can be found in Chapter 4 of *Aris* (1962) and Section 3.1 of *Segel* (1987).

19.5 Evolution of material surfaces

We here extend the discussion of the material line element in Sections 19.3 and 19.4 to the case of a material surface such as that shown in Figure 19.3. Considerations are given to both three-dimensional and two-dimensional flows. Furthermore, we retain Cartesian tensor notation throughout this section.

19.5.1 Surfaces in three-dimensional flow

Following from the geometric interpretation of the vector product in Section 1.4.5, we here define a material surface by (see Figure 19.3)

$$\delta\boldsymbol{\mathcal{S}} = \delta\boldsymbol{A} \times \delta\boldsymbol{B} \quad \text{and in components} \quad \delta\mathcal{S}_i = \epsilon_{ijk}\,\delta A_j\,\delta B_k \tag{19.60}$$

where $\delta\boldsymbol{A}$ and $\delta\boldsymbol{B}$ are non-parallel infinitesimal material lines. The surface projected onto the unit normal direction, $\hat{\boldsymbol{n}}$, is given by

$$\hat{\boldsymbol{n}} \cdot \delta\boldsymbol{\mathcal{S}} = \hat{\boldsymbol{n}} \cdot (\delta\boldsymbol{A} \times \delta\boldsymbol{B}). \tag{19.61}$$

The evolution of the material surface is given by

$$\frac{\mathrm{D}(\delta\boldsymbol{\mathcal{S}})}{\mathrm{D}t} = \frac{\mathrm{D}(\delta\boldsymbol{A})}{\mathrm{D}t} \times \delta\boldsymbol{B} + \delta\boldsymbol{A} \times \frac{\mathrm{D}(\delta\boldsymbol{B})}{\mathrm{D}t} \tag{19.62a}$$

$$= [(\delta\boldsymbol{A} \cdot \nabla)\,\boldsymbol{v}] \times \delta\boldsymbol{B} + \delta\boldsymbol{A} \times [(\delta\boldsymbol{B} \cdot \nabla)\,\boldsymbol{v}], \tag{19.62b}$$

FIGURE 19.3: A material surface as defined by the cross product of two material line elements, $\delta\boldsymbol{\mathcal{S}} = \delta\boldsymbol{A}\times\delta\boldsymbol{B}$. In the special case of $\delta\boldsymbol{A} = \hat{\boldsymbol{x}}\,\delta x$ and $\delta\boldsymbol{B} = \hat{\boldsymbol{y}}\,\delta y$, then $\delta\boldsymbol{\mathcal{S}} = \delta x\,\delta y\,\hat{\boldsymbol{z}}$.

where the second equality made use of the material line evolution equation (19.19). To proceed we expose indices and make use of some tensor identities

$$\begin{aligned}
\frac{\mathrm{D}(\delta\mathcal{S}_i)}{\mathrm{D}t} &= \epsilon_{ijk}\left[(\delta A_q\,\partial_q)\,v_j\right]\delta B_k + \epsilon_{ijk}\,\delta A_j\left[(\delta B_q\,\partial_q)\,v_k\right] && (19.63a)\\
&= \epsilon_{ijk}\left[\delta A_q\,\delta B_k\,\partial_q v_j + \delta A_j\,\delta B_q\,\partial_q\,v_k\right] && (19.63b)\\
&= \epsilon_{ijk}\,\partial_q v_j\left[\delta A_q\,\delta B_k - \delta A_k\,\delta B_q\right] && (19.63c)\\
&= \epsilon_{ijk}\,\partial_q v_j\,\epsilon_{rqk}\,\delta\mathcal{S}_r && (19.63d)\\
&= (\delta_{ir}\,\delta_{jq} - \delta_{iq}\,\delta_{jr})\partial_q v_j\,\delta\mathcal{S}_r && (19.63e)\\
&= (\nabla\cdot\boldsymbol{v})\,\delta\mathcal{S}_i - (\partial_i\boldsymbol{v})\cdot\delta\boldsymbol{\mathcal{S}}. && (19.63f)
\end{aligned}$$

To reach this result we made use of the following identities available for the permutation symbol from Chapter 1

$$\delta A_q\,\delta B_k - \delta A_k\,\delta B_q = \epsilon_{rqk}\,\delta\mathcal{S}_r \qquad (19.64a)$$

$$\epsilon_{ijk}\,\epsilon_{rqk} = \delta_{ir}\,\delta_{jq} - \delta_{iq}\,\delta_{kr} \qquad (19.64b)$$

where δ_{ij} is the Kronecker tensor.

19.5.2 Evolution of the area

Now orient the material surface area according to its outward unit normal vector

$$\delta\boldsymbol{\mathcal{S}} = \hat{\boldsymbol{n}}\,\delta\mathcal{S} \quad \text{and in components} \quad \delta\mathcal{S}_i = \hat{n}_i\,\delta\mathcal{S}, \qquad (19.65)$$

where the magnitude of the area element is written

$$\delta\mathcal{S} = |\delta\boldsymbol{\mathcal{S}}|. \qquad (19.66)$$

Doing so brings equation (19.63f) to the form

$$\frac{1}{\delta\mathcal{S}}\,\frac{\mathrm{D}(\hat{n}_i\,\delta\mathcal{S})}{\mathrm{D}t} = (\nabla\cdot\boldsymbol{v})\,\hat{n}_i - (\partial_i\boldsymbol{v})\cdot\hat{\boldsymbol{n}}. \qquad (19.67)$$

Evidently, we can develop evolution equations for the surface area, $\delta\mathcal{S}$, and the unit normal vector, $\hat{\boldsymbol{n}}$.

For the surface area evolution we take the inner product of equation (19.67) with $\hat{n}_i$ to yield

$$\frac{1}{\delta\mathcal{S}}\frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = \nabla\cdot\boldsymbol{v} - [(\hat{\boldsymbol{n}}\cdot\nabla)\boldsymbol{v}]\cdot\hat{\boldsymbol{n}} \tag{19.68}$$

where we set $\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{n}} = 1$ and followed the discussion in Section 2.1.5 to find that

$$\hat{\boldsymbol{n}}\cdot\hat{\boldsymbol{n}} = 1 \Longrightarrow \hat{\boldsymbol{n}}\cdot\frac{\mathrm{D}\hat{\boldsymbol{n}}}{\mathrm{D}t} = 0, \tag{19.69}$$

so that the normal vector is always perpendicular to its material time derivative. Rearrangement of equation (19.68) then leads to the kinematic evolution equation for the area

$$\frac{1}{\delta S}\frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = [\partial_i - \hat{n}_i\,(\hat{\boldsymbol{n}}\cdot\nabla)]\,v_i. \tag{19.70}$$

We next provide some interpretation of this result.

Surface derivative operator

The derivative operator on the right hand side of equation (19.70),

$$\partial_i^{\mathrm{surf}} \equiv \partial_i - \hat{n}_i\,(\hat{\boldsymbol{n}}\cdot\nabla), \tag{19.71}$$

is a *surface derivative operator* since it subtracts from the gradient operator the projection onto the local normal, thus leaving a gradient operator just in the tangent plane of the surface. The area evolution equation (19.70) can thus be written in the tidy form

$$\frac{1}{\delta S}\frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = \nabla^{\mathrm{surf}}\cdot\boldsymbol{v}, \tag{19.72}$$

so that the relative area of the material surface changes according to the surface divergence of the velocity field.

Special case of a horizontal surface

To help understand the kinematic equation (19.72), consider the special case of a horizontal surface with a vertical unit normal vector, $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, so that

$$\frac{1}{\delta S}\frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = \nabla\cdot\boldsymbol{v} - \hat{\boldsymbol{z}}\cdot\partial_z\boldsymbol{v} = \nabla_z\cdot\boldsymbol{u}. \tag{19.73}$$

In this case we see that the area of a horizontal surface increases when the horizontal velocity diverges, and the area decreases when the horizontal velocity converges. We expect this behavior since the surface is material and is thus moving with the flow. We encounter this result again in Section 19.5.4 for two-dimensional flow, in which the area is always horizontal.

As another special case, consider a three dimensional flow that is non-divergent, $\nabla\cdot\boldsymbol{v} = 0$ (see Chapter 22). In this case the area changes are only due to the projection of the normal gradient onto the normal direction. So again considering a horizontal area with $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, the area evolution in a non-divergent flow is given by

$$\frac{1}{\delta S}\frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = -\hat{\boldsymbol{z}}\cdot(\hat{\boldsymbol{z}}\cdot\nabla)\,\boldsymbol{v} = -\partial_z w, \tag{19.74}$$

which follows from equation (19.73) with $\nabla_x u + \partial_y v + \partial_z w = \nabla_z\boldsymbol{u} + \partial_z w = 0$.

FIGURE 19.4: Horizontal shear in the vertical velocity, $\nabla_z w$, creates undulations in an initially horizontal material surface that leads to a horizontal component in the normal vector. We here show the case where $\partial w/\partial x \neq 0$, thus leading to a zonal component to the normal vector according to $\mathrm{D}\hat{n}_x/\mathrm{D}t = -\partial_x w$.

.

19.5.3 Evolution of the normal vector

We make use of the area evolution equation (19.72) within equation (19.67) to derive an evolution equation for the normal vector

$$\frac{\mathrm{D}\hat{n}_i}{\mathrm{D}t} = -\hat{n}_i \frac{1}{\delta\mathcal{S}} \frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} + (\partial_j v_j)\,\hat{n}_i - (\partial_i v_j)\,\hat{n}_j \tag{19.75a}$$

$$= -\hat{n}_i\,[\partial_j v_j - \hat{n}_j\,(\hat{n}_q\,\partial_q)\,v_j] + (\partial_j v_j)\,\hat{n}_i - (\partial_i v_j)\,\hat{n}_j \tag{19.75b}$$

$$= -\hat{n}_j\,[\partial_i - \hat{n}_i\,\hat{n}_q\,\partial_q]\,v_j \tag{19.75c}$$

$$= -\hat{n}_j\,\partial_i^{\mathrm{surf}}\,v_j \tag{19.75d}$$

$$= -\hat{\boldsymbol{n}} \cdot \partial_i^{\mathrm{surf}}\,\boldsymbol{v}. \tag{19.75e}$$

Equation (19.75c) provides a simple means to verify that the kinematic constraint (19.69) is satisfied, in which $\hat{\boldsymbol{n}} \cdot \mathrm{D}\hat{\boldsymbol{n}}/\mathrm{D}t = 0$.

To help understand the evolution equation (19.75e), consider again a horizontal area with its normal vector initially in the vertical. The evolution of this normal vector is thus given by

$$\frac{\mathrm{D}\hat{n}_i}{\mathrm{D}t} = -(\partial_i - \hat{z}_i\,\partial_z)\,w, \tag{19.76}$$

with each component evolving according to

$$\frac{\mathrm{D}\hat{n}_1}{\mathrm{D}t} = -\partial_x w \quad \text{and} \quad \frac{\mathrm{D}\hat{n}_2}{\mathrm{D}t} = -\partial_y w \quad \text{and} \quad \frac{\mathrm{D}\hat{n}_3}{\mathrm{D}t} = 0. \tag{19.77}$$

Hence, an initially vertical normal vector tilts into the horizontal direction according to minus the horizontal shear in the vertical velocity. As illustrated in Figure 19.4, we understand this result by noting that such a shear creates undulations in the initially horizontal surface that render a horizontal component to the normal vector.

19.5.4 Material area in two-dimensional flow

Now consider a material area for two-dimensional fluid flow with velocity, $\boldsymbol{v} = (u, v, 0)$, and $\delta\boldsymbol{A} = \hat{\boldsymbol{x}}\,\delta x$, $\delta\boldsymbol{B} = \hat{\boldsymbol{y}}\,\delta y$, with zero dependence on z. In this case, the area of an infinitesimal material region is

$$\delta\mathcal{S} = (\delta\boldsymbol{A} \times \delta\boldsymbol{B}) \cdot \hat{\boldsymbol{z}} = \delta x\,\delta y, \tag{19.78}$$

FIGURE 19.5: A parallelepiped defined by three material lines with volume (to within a sign) given by $\delta V = (\delta\boldsymbol{A}\times\delta\boldsymbol{B})\cdot\delta\boldsymbol{C}$. See also the discussion surrounding Figure 1.4.

and its evolution is given by

$$\frac{\mathrm{D}(\delta\mathcal{S})}{\mathrm{D}t} = (\delta\boldsymbol{B}\times\hat{\boldsymbol{z}})\cdot(\delta\boldsymbol{A}\cdot\nabla)\,\boldsymbol{u} + (\hat{\boldsymbol{z}}\times\delta\boldsymbol{A})\cdot(\delta\boldsymbol{B}\cdot\nabla)\,\boldsymbol{u} \tag{19.79a}$$

$$= \delta x\,\delta y\,\nabla\cdot\boldsymbol{u}, \tag{19.79b}$$

so that

$$\frac{1}{\delta\mathcal{S}}\frac{\mathrm{D}(\delta\mathcal{S})}{\mathrm{D}t} = \nabla\cdot\boldsymbol{u}. \tag{19.80}$$

Hence, the area of the material region evolves according to the divergence of the horizontal velocity. Correspondingly, the area remains constant in a horizontally non-divergent flow. This result follows from specializing the three-dimensional result (19.63f) to the case of two-dimensional flow by assuming no dependence on the vertical direction.

19.6 Volume, thickness, and the Jacobian

The mass of a material parcel is constant. However, the volume is not generally constant since the fluid density is not generally uniform. We here derive the expression for how volume evolves for a material parcel. We also derive the material evolution equation for the Jacobian of transformation between position space and material space. We find that the relative change for both the parcel volume and the Jacobian are determined by divergence of the velocity field. We retain Cartesian tensor notation throughout this section.

19.6.1 Material parcel volume

Consider a material region with a volume δV spanned by the infinitesimal material lines $\delta\boldsymbol{A}$, $\delta\boldsymbol{B}$, and $\delta\boldsymbol{C}$ (see Figure 19.5). To within a sign the volume is given by

$$\delta V = (\delta\boldsymbol{A}\times\delta\boldsymbol{B})\cdot\delta\boldsymbol{C}. \tag{19.81}$$

Making use of the material line evolution equation (19.19) renders

$$\frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = (\delta\boldsymbol{B}\times\delta\boldsymbol{C})\cdot(\delta\boldsymbol{A}\cdot\nabla)\boldsymbol{v} + (\delta\boldsymbol{C}\times\delta\boldsymbol{A})\cdot(\delta\boldsymbol{B}\cdot\nabla)\boldsymbol{v} + (\delta\boldsymbol{A}\times\delta\boldsymbol{B})\cdot(\delta\boldsymbol{C}\cdot\nabla)\boldsymbol{v}. \tag{19.82}$$

Now specialize to the case where the parcel is a parallepiped oriented according to the coordinate axes

$$\delta\boldsymbol{A} = \hat{\boldsymbol{x}}\,\delta x \quad\text{and}\quad \delta\boldsymbol{B} = \hat{\boldsymbol{y}}\,\delta y \quad\text{and}\quad \delta\boldsymbol{C} = \hat{\boldsymbol{z}}\,\delta z, \tag{19.83}$$

so that

$$\delta V = \delta x \, \delta y \, \delta z. \tag{19.84}$$

Plugging into equation (19.82) leads to

$$\frac{1}{\delta V} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \nabla \cdot \boldsymbol{v}. \tag{19.85}$$

This result is a three-dimensional generalization of the material area equation derived in Section 19.5.4.

We offer an alternative derivation of equation (19.85) in Section 20.2, where no assumptions are made concerning the shape of the material region. That derivation leads us to conclude that the relative volume of a material parcel increases when the parcel moves through a region where the velocity diverges ($\nabla \cdot \boldsymbol{v} > 0$). We think of a diverging velocity field as "spreading out" the material parcel boundary, thus increasing its volume. In contrast, the volume of a material parcel decreases where the fluid velocity converges ($\nabla \cdot \boldsymbol{v} < 0$)

$$\nabla \cdot \boldsymbol{v} > 0 \Rightarrow \text{material volume increases in diverging flow} \Longrightarrow \text{parcel expands} \tag{19.86a}$$

$$\nabla \cdot \boldsymbol{v} < 0 \Rightarrow \text{material volume decreases in converging flow} \Longrightarrow \text{parcel contracts.} \tag{19.86b}$$

19.6.2 Evolution of the column thickness

A material volume, δV, evolves according to the divergence of the velocity (equation (19.85)), whereas the material area, $\delta \mathcal{S}$, evolves according to the surface divergence of the velocity (equation (19.72)). Now consider a material volume whose cross-sectional area is $\delta \mathcal{S}$ and whose thickness is δh, with δh measuring the thickness in a direction defined by the unit normal, $\hat{\boldsymbol{n}}$. That is, the material volume is cylindrical. We can deduce the evolution of the thickness since we know the evolution of the volume and area

$$\frac{1}{\delta V} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \frac{1}{\delta h \, \delta \mathcal{S}} \frac{\mathrm{D}(\delta h \, \delta \mathcal{S})}{\mathrm{D}t} = \frac{1}{\delta h} \frac{\mathrm{D}(\delta h)}{\mathrm{D}t} + \frac{1}{\delta \mathcal{S}} \frac{\mathrm{D}(\delta \mathcal{S})}{\mathrm{D}t}. \tag{19.87}$$

Use of equations (19.85) and (19.72) render

$$\frac{1}{\delta h} \frac{\mathrm{D}(\delta h)}{\mathrm{D}t} = \nabla \cdot \boldsymbol{v} - \nabla^{\mathrm{surf}} \cdot \boldsymbol{v} = \hat{n}_i \, (\hat{\boldsymbol{n}} \cdot \nabla) \, v_i. \tag{19.88}$$

For example, consider the special case with $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, in which

$$\frac{1}{\delta h} \frac{\mathrm{D}(\delta h)}{\mathrm{D}t} = \frac{\partial w}{\partial z}, \tag{19.89}$$

so that the column thickness evolves according to the vertical derivative of the vertical velocity. This result accords with our discussion of stretching in Section 19.4.3.

19.6.3 Evolution of the Jacobian of transformation

Recall the discussion in Section 18.7.4, where we showed that the Jacobian of transformation between material space ($\boldsymbol{a}$-space) and position space ($\boldsymbol{x}$-space) is related to the ratio of the volume elements written in the two coordinate systems. In particular, equation (18.24) is given by

$$\delta V(\boldsymbol{x}) = \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} \, \delta V^{\mathrm{L}}(\boldsymbol{a}) \Longrightarrow \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} = \frac{\delta V(\boldsymbol{x})}{\delta V^{\mathrm{L}}(\boldsymbol{a})}. \tag{19.90}$$

The material coordinate volume $\delta V^{\mathrm{L}}(\boldsymbol{a})$ is time independent when following the flow. Consequently, the material evolution of the Jacobian is given by

$$\frac{\mathrm{D}}{\mathrm{D}t}\frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} = \frac{1}{\delta V^{\mathrm{L}}(\boldsymbol{a})}\frac{\mathrm{D}(\delta V(\boldsymbol{x}))}{\mathrm{D}t} \tag{19.91a}$$

$$= \frac{\delta V(\boldsymbol{x})}{\delta V^{\mathrm{L}}(\boldsymbol{a})}\,\nabla\cdot\boldsymbol{v} \tag{19.91b}$$

$$= \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}}\,\nabla\cdot\boldsymbol{v}. \tag{19.91c}$$

The second equality made use of the equation (19.85), which expresses the material time change for the volume of a material fluid parcel, as measured in position space, in terms of the velocity divergence. We thus see that the relative change of the Jacobian is determined by the divergence of the velocity

$$\left[\frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}}\right]^{-1}\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}}\right] = \nabla\cdot\boldsymbol{v}. \tag{19.92}$$

This equation is identical to the parcel volume equation (19.85), which is expected given the relation between the Jacobian and the parcel volume. In Exercise 19.5, we derive this result using the explicit expression for the Jacobian in terms of the permutation symbol, ϵ.

19.7 Kinematics of two-dimensional flow

In this section we consider the rudiments of two-dimensional flow as a venue to illustrate topics presented earlier in this chapter such as dilation, rotation, and strains. In so doing we expose kinematic properties commonly used to characterize two-dimensional flow, with generalizations to three-dimensions available with a bit more maths. We retain Cartesian tensor notation throughout this section.

The starting point is Figure 19.6, which shows a square region of fluid exposed to a variety of flow regimes. We can kinematically describe these changes by making use of the velocity gradient tensor introduced in Section 19.4, here written for the two-dimensional flow with horizontal velocity components, (u, v)

$$[\partial_j v_i] = \begin{bmatrix} \partial u/\partial x & \partial u/\partial y \\ \partial v/\partial x & \partial v/\partial y \end{bmatrix} \tag{19.93a}$$

$$= \begin{bmatrix} \partial u/\partial x & (1/2)\left(\partial u/\partial y + \partial v/\partial x\right) \\ (1/2)\left(\partial u/\partial y + \partial v/\partial x\right) & \partial v/\partial y \end{bmatrix} + \frac{\zeta}{2}\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \tag{19.93b}$$

$$= \mathbb{S} + \mathbb{R}, \tag{19.93c}$$

where

$$\zeta = \hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{v} = \partial v/\partial x - \partial u/\partial y \tag{19.94}$$

is the vertical component to the vorticity.

19.7.1 Diverging flow

Recall from Section 19.5.4 that a material surface in two-dimensional flow changes its area according to the divergence. The upper left panel of Figure 19.6 thus illustrates equation (19.80)

$$\frac{1}{\delta\mathcal{S}}\frac{\mathrm{D}(\delta\mathcal{S})}{\mathrm{D}t} = \nabla\cdot\boldsymbol{u} = \mathbb{S}_{ii} = \mathbb{S}_{11} + \mathbb{S}_{22}, \tag{19.95}$$

FIGURE 19.6: Illustrating the varieties of changes for an initially square material fluid region in two-dimensional flow. Upper left: purely divergent flow, whereby $\nabla \cdot \boldsymbol{u} > 0$ yet with zero vorticity, thus leading to an increase in the area. An example flow generating this motion is realized by $\boldsymbol{u} = \gamma\,(x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}) = \gamma\,\boldsymbol{x}$ (with $\gamma > 0$ a constant of dimensions inverse time) so that the divergence is $\nabla \cdot \boldsymbol{u} = 2\,\gamma$. Upper right: rotational flow with nonzero vertical vorticity component, $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u})$, yet zero divergence, thus leading to a pure rotation of the square patch. An example flow generating this motion is realized by $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi = \gamma\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}) = -\gamma\,\hat{\boldsymbol{z}} \times \boldsymbol{x}$ with streamfunction $\psi = (\gamma/2)\,(x^2 + y^2)$ and vorticity $\zeta = \nabla^2\psi = 2\,\gamma$. Lower left: result of a pure tension/compression straining flow (also called a deformation flow) with zero divergence and zero vorticity, leading to compression in one direction and dilation in the orthogonal direction. An example flow is given by $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi = \gamma\,(x\,\hat{\boldsymbol{x}} - y\,\hat{\boldsymbol{y}})$ with streamfunction $\psi = -\gamma\,x\,y$. The deformation of the region is measured by the tension strain, $\partial_x u - \partial_y v = 2\,\gamma$. Lower right: pure shearing strain flow with zero divergence and zero vorticity. An example flow is given by $\boldsymbol{u} = -\gamma\,(y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}})$ with streamfunction $\psi = -(\gamma/2)\,(x^2 - y^2)$. The deformation of the region is measured by the shearing strain, $\partial_y u + \partial_x v = -2\,\gamma$. This figure is adapted from Figure 2.4 of *Hoskins and James* (2014).

FIGURE 19.7: Two-dimensional horizontally non-divergent and irrotational flow with nonzero deformation/strain. Left panel: pure tension strain as determined by the streamfunction, $\psi = -\gamma\, x\, y$, so that the velocity $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi = \gamma\,(x\,\hat{\boldsymbol{x}} - y\,\hat{\boldsymbol{y}})$. The y-axis orients the direction along which flow contracts (compression) whereas the x-axis is the dilation axis (tension). Right panel: pure shearing flow as determined by the streamfunction $\psi = -(\gamma/2)\,(x^2 - y^2)$ so that the velocity is $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi = \gamma\,(-y\,\hat{\boldsymbol{x}} - x\,\hat{\boldsymbol{y}})$. We set $\gamma = 1$ for both examples.

where $\delta\mathcal{S}$ is the area and $\mathbb{S}_{ii}$ is the trace of the strain rate tensor. That is, a diverging flow as depicted by this figure, with $\nabla\cdot\boldsymbol{u} > 0$, leads to an expansion of the area. The opposite occurs for a converging flow, where the area compresses.

19.7.2 Flow with nonzero deformation

The lower left panel of Figure 19.6 shows the square within a deformational flow whereby it contracts along the y-axis and dilates along the x-axis. This flow is non-divergent, $\nabla\cdot\boldsymbol{u} = 0$, and has zero vorticity, $\zeta = 0$, so that the area remains constant and the orientation is fixed. However, it has shear that acts to deform the area. This particular non-divergent deformational flow is determined by

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi, \tag{19.96}$$

with the streamfunction, $\psi = -\gamma\, x\, y$ where γ is a constant inverse time scale and hence the strength of the strain. The resulting velocity components are $u = -\partial\psi/\partial y = \gamma\, x$ and $v = \partial\psi/\partial x = -\gamma\, y$.

19.7.3 Rotational flow with nonzero vorticity

The upper right panel of Figure 19.6 illustrates the effects from flow with a non-zero vorticity, $\zeta = \partial v/\partial x - \partial u/\partial y$. We provide extensive discussion of vorticity in Part VII of this book, with vorticity measuring the spin of a fluid particle within the flow. The nonzero spin imparts a rotation to an area element, with the flow in the upper right panel of Figure 19.6 bringing about a counter-clockwise rotation. All components of the strain tensor vanish for a purely rotational flow, so that there is no deformation of the square as it rotates.

There are two combinations of the strain rate tensor elements that are useful in describing deformational flows:

$$\text{tension strain} = S_{\mathrm{T}} = \mathbb{S}_{11} - \mathbb{S}_{22} = \partial u/\partial x - \partial v/\partial y \tag{19.97a}$$

$$\text{shearing strain} = S_{\mathrm{S}} = 2\,\mathbb{S}_{12} = \partial u/\partial y + \partial v/\partial x. \tag{19.97b}$$

The tension strain and shearing strain are also known as tension and shearing *deformation rates*. Note that negative tension is known as *compression*. For the deformation flow with streamfunction $\psi = -\gamma\, x\, y$, we have

$$S_{\mathrm{T}} = 2\,\gamma \qquad \text{and} \qquad S_{\mathrm{S}} = 0, \tag{19.98}$$

so that this velocity leads to a purely tension straining flow. In contrast, the following non-divergent irrotational flow is a purely shearing strain flow

$$\psi = -(\gamma/2)\,(x^2 - y^2) \qquad u = -\gamma\, y \qquad v = -\gamma\, x \qquad S_{\mathrm{T}} = 0 \qquad S_{\mathrm{S}} = -2\,\gamma, \tag{19.99}$$

as depicted by the right panel of Figure 19.7. This pure shearing flow leads to the deformation of the fluid square shown in the lower right panel of Figure 19.6.

19.7.4 Further study

Elements of this section can be found in Section 2.3 of *Hoskins and James* (2014). More detailed examinations of two-dimensional flow kinematics are offered by *Weiss* (1991) and *Lilly* (2018). Furthermore, we here introduced the streamfunction, ψ, for non-divergent two-dimensional flow, yet provide a more thorough discussion in Section 22.4.

19.8 Exercises

EXERCISE 19.1: MATERIAL EVOLUTION OF THE ACCELERATION DIVERGENCE
This exercise is based on problem 10(a) from Section 3.1 of *Segel* (1987). Here, we derive the relation

$$\nabla \cdot \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \frac{\mathrm{D}(\nabla \cdot \boldsymbol{v})}{\mathrm{D}t} + \mathbb{S}_{ij}\,\mathbb{S}_{ij} - \mathbb{R}_{ij}\,\mathbb{R}_{ij}, \tag{19.100}$$

where $\mathbb{S}_{ij}\,\mathbb{S}_{ij}$ and $\mathbb{R}_{ij}\,\mathbb{R}_{ij}$ are the doubly contracted strain rate tensor and squared rotation tensor (Sections 19.4.4 and 19.4.5). Make use of Cartesian tensors for your solution.

EXERCISE 19.2: VELOCITY FIELD WITH ZERO STRAIN (*Aris* (1962) EXERCISE 4.41.1)
If the strain rate tensor vanishes, show that the velocity field can be written

$$\boldsymbol{v} = \boldsymbol{U} + \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{19.101}$$

where $\boldsymbol{\Omega}$ is a constant angular rotation rate and $\boldsymbol{U}$ is a constant velocity. That is, a fluid velocity equal to a constant rotation plus translation renders zero strain. Hint: if $\mathbb{S}_{mn} = 0$, what does that imply about the velocity field? You may also wish to make use of the general decomposition (19.59).

EXERCISE 19.3: STRAIN RATE TENSOR AND ROTATION TENSOR (*Aris* (1962) EXERCISE 4.43.3)
Consider a two-dimensional flow with horizontal velocity

$$\boldsymbol{u} = (F/r)\,(\hat{\boldsymbol{x}}\, y - \hat{\boldsymbol{y}}\, x), \tag{19.102}$$

where $F = F(r)$ is an arbitrary function of the radial distance $r = \sqrt{x^2 + y^2}$ and with dimensions of L T^{-1}. Throughout this exercise, be sure your solution is dimensionally consistent.

(a) Show that the velocity field is non-divergent.

(b) Determine an analytic expression for the streamlines and draw a picture.

(c) Determine the elements to the strain rate tensor, $\mathbb{S}$, given by equation (19.93c). Write the expression using polar coordinates $x = r\cos\varphi$ and $y = r\sin\varphi$ (see Section 10.3) and the

structure function

$$G(r) = r\,\frac{\mathrm{d}(F/r)}{\mathrm{d}r} = (F' - F/r)/2 \quad \text{with } F' = \mathrm{d}F/\mathrm{d}r. \tag{19.103}$$

(d) Determine elements to the rotation tensor, $\mathbb{R}$, given by equation (19.93c), also written in polar coordinates.

EXERCISE 19.4: STRAIN RATE TENSOR AND ROTATION TENSOR FOR PARALLEL SHEAR FLOW
Consider a two-dimensional parallel shear flow with horizontal velocity

$$\boldsymbol{u} = a\,x\,\hat{\boldsymbol{y}}, \tag{19.104}$$

where a is a constant with dimension inverse time.

(a) Compute the strain rate tensor, $\mathbb{S}$ (equation (19.93c)) for this velocity field.

(b) Compute the rotation tensor, $\mathbb{R}$ (equation (19.93c)) for this velocity field.

(c) Decompose the velocity field according to equation (19.59), and show that each of the velocity components is non-divergent. That is, write

$$\boldsymbol{u} = \boldsymbol{u}^0 + \boldsymbol{u}^{(\mathrm{S})} + \boldsymbol{u}^{(\mathrm{A})} \qquad \text{with} \qquad \nabla\cdot\boldsymbol{u}^{(\mathrm{S})} = \nabla\cdot\boldsymbol{u}^{(\mathrm{A})} = 0, \tag{19.105}$$

with u_i^0 the velocity at the point where $\delta x_i = x_i - x_i^0 = 0$. The velocity $\boldsymbol{u}^{(\mathrm{S})}$ has a constant strain but no vorticity whereas $\boldsymbol{u}^{(\mathrm{A})}$ has a constant vorticity but no strain. Hint: both $\boldsymbol{u}^{(\mathrm{S})}$ and $\boldsymbol{u}^{(\mathrm{A})}$ have nonzero $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$ components.

(d) Determine the streamfunctions for $\boldsymbol{u}^{(\mathrm{S})}$ and $\boldsymbol{u}^{(\mathrm{A})}$.

(e) Sketch the velocity vectors $\boldsymbol{u}^{(\mathrm{S})}$ and $\boldsymbol{u}^{(\mathrm{A})}$.

EXERCISE 19.5: EVOLUTION OF THE JACOBIAN USING ϵ-TENSOR GYMNASTICS
There is another way to derive the identity (19.92) for the evolution of the Jacobian. This other method is somewhat more tedious. However, it exercises some useful methods of index gymnastics involving the ϵ-tensor. It also has a natural generalization to curved spaces. This exercise is only for aficionados of tensor analysis.

An explicit expression for the Jacobian of transformation is given by

$$\frac{\partial \boldsymbol{X}}{\partial \boldsymbol{a}} = \frac{1}{3!}\,\epsilon_{mnp}\,\epsilon_{IJK}\,\frac{\partial X_m}{\partial a_I}\,\frac{\partial X_n}{\partial a_J}\,\frac{\partial X_p}{\partial a_K}. \tag{19.106}$$

Take the material derivative of this expression and show that we get the same expression as equation (19.92). Hint: make use of the identity

$$\frac{\mathrm{D}}{\mathrm{D}t}\,\frac{\partial X_m}{\partial a_I} = \frac{\partial V_m}{\partial a_I}, \tag{19.107}$$

which holds since the material time derivative is taken with the material coordinates, $\boldsymbol{a}$, held fixed.

Chapter 20

Mass conservation

Throughout this book, we assume that matter is neither created nor destroyed anywhere within the continuous fluid domain, and that the fluid remains in a single phase.[1] These assumptions hold independently of the forces acting on the fluid, and they offer constraints on the fluid motion so they comprise topics in fluid kinematics. In this chapter, we derive a variety of mathematical expressions for mass conservation in a single component fluid (materially homogeneous fluid), along with associated kinematic constraints placed on fluid motion. These constraints are examined both in the fluid interior and at fluid boundaries, and from both the Eulerian and Lagrangian viewpoints.

READER'S GUIDE TO THIS CHAPTER

In this chapter we are concerned with single-component fluids, with generalizations to multiple-component fluids given in Chapter 21. Spatial positions and trajectories are represented using Cartesian coordinates to simplify the maths, with generalizations following the tensor analysis methods of Chapter 9. We build on the understanding of the Eulerian and Lagrangian kinematic descriptions developed in Chapters 18 and 19.

20.6 Exercises **496**

20.1 Eulerian fluid regions

We here develop expressions for the mass budget within an Eulerian region, both infinitesimal and finite. Recall that Eulerian regions are fixed in space and thus have constant volumes.

20.1.1 Finite volume expression

Consider a finite sized cubic region that is fixed in space as shown in Figure 20.1. The mass contained within the cube is given by

$$\Delta M = \rho\,\Delta V = \rho\,\Delta x\,\Delta y\,\Delta z, \tag{20.1}$$

where the cube volume,

$$\Delta V = \Delta x\,\Delta y\,\Delta z, \tag{20.2}$$

is constant in time as per an Eulerian region. Since we will be taking the limit as the size of the cube becomes infinitesimal, it is sufficient to approximate the mass density as that at the cube center, $\rho = \rho(x, y, z, t)$. In the absence of mass sources within the fluid, the mass within the cube changes only through the accumulation or depletion of mass transported across the six cube faces.

Focusing on the mass transport in the meridional direction as illustrated in Figure 20.1, the accumulation of mass within the cube through this transport is determined by the difference in mass transport crossing the two adjacent cell faces

$$\text{mass change from meridional transport} = (\Delta x\,\Delta z)\,[(v\,\rho)_{y-\Delta y/2} - (v\,\rho)_{y+\Delta y/2}]. \tag{20.3}$$

Expanding the difference into a Taylor series and truncating after leading order yields

$$\text{mass change from meridional transport} \approx -(\Delta x\,\Delta y\,\Delta z)\,\frac{\partial(v\,\rho)}{\partial y}. \tag{20.4}$$

The same analysis for the zonal and vertical directions leads to the mass budget for the cube

$$\frac{\partial(\rho\,\Delta V)}{\partial t} = -\Delta V\left[\frac{\partial(u\,\rho)}{\partial x} + \frac{\partial(v\,\rho)}{\partial y} + \frac{\partial(w\,\rho)}{\partial z}\right]. \tag{20.5}$$

Hence, the cube mass changes according to convergence of mass across the cube boundaries. Cancelling the constant volume ΔV (again, the volume is assumed fixed as per an Eulerian region) renders the *flux-form* Eulerian mass continuity equation

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\,\boldsymbol{v}) = 0. \tag{20.6}$$

The mass continuity equation (20.6) is in the form of a *flux-form conservation law*, in which the local time tendency of a field is determined by the convergence of a flux

$$\frac{\partial\rho}{\partial t} = -\nabla\cdot(\rho\,\boldsymbol{v}). \tag{20.7}$$

The *mass flux*, $\rho\,\boldsymbol{v}$, with dimensions $M\,L^{-2}\,T^{-1}$, measures the mass per time of matter crossing a unit area oriented with an outward normal in each of the three Cartesian directions. If more mass

FIGURE 20.1: A finite sized cube or cell region with fixed dimensions and position (an Eulerian region) used to formulate the Eulerian form of mass conservation. We highlight two cell faces with area $\Delta x\,\Delta z$ and with meridional mass transport crossing the faces given by $\Delta x\,\Delta z\,(v\,\rho)_{y-\Delta y/2}$ and $\Delta x\,\Delta z\,(v\,\rho)_{y+\Delta y/2}$. To establish signs we assume the meridional velocity is positive, $v > 0$, so that mass enters the face at $y - \Delta y/2$ and leaves the face at $y + \Delta y/2$. Differences between these two transports leads to an accumulation of mass within the cell. The resulting mass budget holds regardless the direction of the flow velocity.

is transported into a region than leaves (i.e., mass converges), then the mass density increases, and vice versa for a mass flux that diverges from a region. It is notable that the mass flux also serves as a measure of the *momentum flux*, which we discuss in Chapter 25.

20.1.2 Arbitrary Eulerian region

The discussion for the infinitesimal cube can be generalized by making use of Gauss's divergence theorem from Section 2.7. For that purpose, consider an arbitrary static and simply closed region within the fluid such as in Figure 20.2. Integrating the continuity equation (20.6) over that region leads to

$$\int_{\mathcal{R}} \frac{\partial \rho}{\partial t}\,\mathrm{d}V = -\int_{\mathcal{R}} \nabla\cdot(\rho\,\boldsymbol{v})\,\mathrm{d}V. \tag{20.8}$$

Since the region is static we can move the partial time derivative outside on the left hand side. Furthermore, the divergence theorem can be applied to the right hand side to convert the volume integral to a surface integral over the boundaries of the static domain. The resulting mass budget is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho\,\mathrm{d}V = -\oint_{\partial\mathcal{R}} \rho\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{20.9}$$

where $\hat{\boldsymbol{n}}$ is the outward unit normal vector along the closed boundary of the region, and $\mathrm{d}\mathcal{S}$ is the surface area element along that boundary. This equation says that the mass within a fixed region of the fluid changes in time (left hand side) according to the accumulation of mass crossing the region boundary (right hand side). The minus sign means that the mass decreases in the region if there is a net mass transport leaving the domain in the direction of the outward normal.

20.2 Material fluid parcels

We here derive the differential expressions for mass conservation of a constant mass fluid parcel within a Lagrangian reference frame. The differential expressions for volume and density arise as a corollary. This discussion complements the Eulerian discussion from Section 20.1. To motivate

FIGURE 20.2: An arbitrarily shaped simply closed region, $\mathcal{R}$, within the fluid. If the region is fixed in space, then it represents a general Eulerian region for considering mass budgets. A surface area element, $\mathrm{d}\mathcal{S}$, is oriented according to the outward normal, $\hat{\boldsymbol{n}}$.

the derivations we expand the flux-form mass continuity equation (20.6) to have

$$\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{v}, \tag{20.10}$$

where $\mathrm{D}/\mathrm{D}t = \partial_t + \boldsymbol{v}\cdot\nabla$ is the material time derivative operator from Section 18.8.4. We now derive this form of the mass continuity using Lagrangian methods.

20.2.1 Lagrangian expression for mass conservation

The mass of an infinitesimal fluid parcel that moves with the fluid flow is written[2]

$$\delta M = \rho\,\delta V, \tag{20.11}$$

where δV is the volume and

$$\rho = \frac{\delta M}{\delta V} \tag{20.12}$$

is the mass density of the parcel. By definition, the fluid parcel has a constant mass as it moves with the flow, so that its material time derivative vanishes

$$\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = 0. \tag{20.13}$$

Equation (20.13) is the most basic form of mass conservation for a fluid parcel. However, one often has need to express this result in terms of parcel density and parcel volume

$$\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = \frac{\mathrm{D}\left(\rho\,\delta V\right)}{\mathrm{D}t} \tag{20.14a}$$

$$= \delta M\left[\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} + \frac{1}{\delta V}\frac{\mathrm{D}(\delta V)}{\mathrm{D}t}\right]. \tag{20.14b}$$

[2]Recall that we use the δ symbol to signal a property measured in the Lagrangian reference frame.

Comparing to the mass continuity equation (20.10) leads to[3]

$$\frac{1}{\delta M}\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = \frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} + \nabla\cdot\boldsymbol{v}. \tag{20.15}$$

Setting $\mathrm{D}(\delta M)/\mathrm{D}t = 0$ renders the continuity equation (20.10) derived from the Eulerian expression

$$\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{v}. \tag{20.16}$$

The parcel volume contracts in regions where the velocity converges (we prove that property in Sections 19.6.1 and 20.3.1). The continuity equation (20.16) then says that regions of volume contraction are where the parcel density increases whereas the opposite occurs for regions where the velocity diverges.

20.2.2 Alternative derivation based on the Jacobian

An alternative approach to deriving the mass conservation equation makes use of the material time evolution of the Jacobian. We detail this approach for integrals in Section 20.3.3, and discussed it for fluid parcels in Section 19.6.3. Making use of those results, in particular equation (19.92), allows us to write the material evolution for the fluid parcel mass in the form

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\rho\,\delta V(\boldsymbol{x})\right] = \frac{\mathrm{D}}{\mathrm{D}t}\left[\rho\,\frac{\partial\boldsymbol{\varsigma}}{\partial\boldsymbol{a}}\,\delta V^{\mathrm{L}}(\boldsymbol{a})\right] \tag{20.17a}$$

$$= \left[\frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho\,\nabla\cdot\boldsymbol{v}\right]\left[\frac{\partial\boldsymbol{\varsigma}}{\partial\boldsymbol{a}}\right]\delta V^{\mathrm{L}}(\boldsymbol{a}) \tag{20.17b}$$

$$= \left[\frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho\,\nabla\cdot\boldsymbol{v}\right]\delta V(\boldsymbol{x}). \tag{20.17c}$$

We recover the mass conservation equation (20.16) when noting that the mass of a material parcel is constant so that $\mathrm{D}\rho/\mathrm{D}t = -\rho\,\nabla\cdot\boldsymbol{v}$.

20.2.3 Summary of material kinematic equations

Let us now summarize the variety of differential evolution equations for mass, volume, and density as viewed from a material reference frame

$$\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = 0 \qquad \text{parcel mass is constant} \tag{20.18}$$

$$\frac{1}{\delta V}\frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \nabla\cdot\boldsymbol{v} \qquad \text{parcel volume increases in divergent flow} \tag{20.19}$$

$$\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{v} \qquad \text{parcel density increases in convergent flow.} \tag{20.20}$$

To help remember the signs on the right hand side, recall that as the fluid diverges from a point ($\nabla\cdot\boldsymbol{v} > 0$), it expands the boundaries of the material parcel and so increases the parcel volume as per equation (20.19). Since the parcel has a fixed mass, the diverging velocity field causes the material parcel density to decrease ($-\nabla\cdot\boldsymbol{v} < 0$) as per equation (20.20).

[3] In Section 19.6.1 we derived the material evolution of volume, and will again see this result in equation (20.26).

20.3 Material fluid regions

We now extend the kinematics of material fluid parcels in Section 20.2 to finite sized material fluid regions. Just as for material fluid parcels, the finite sized material fluid region retains the same matter content, and thus maintains a constant mass.[4] We contrast the discussion here with that for Eulerian regions (fixed in space) considered in Section 20.1. One key operational distinction between the Eulerian and Lagrangian domains is that partial time derivative operators commute with integration over a fixed Eulerian domain, whereas material time derivative operators commute with integration over a Lagrangian domain as per Reynolds transport theorem derived in Section 20.3.4.

20.3.1 Evolution of volume

Consider a finite material region, $\mathcal{R}(\boldsymbol{v})$, whose volume is given by the integral

$$V = \int_{\mathcal{R}(\boldsymbol{v})} \mathrm{d}V, \tag{20.21}$$

with $\mathrm{d}V$ the volume element. The region changes its shape according to motion of the fluid particles fixed to the boundary of the material region. We designate this volume as

$$\mathcal{R}(\boldsymbol{v}) = \text{region following flow}, \tag{20.22}$$

with the $\boldsymbol{v}$ argument emphasizing that the volume moves with the flow velocity. The material region expands when the flow moves outward and contracts when the flow moves inward. These statements take on the following mathematical expression

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \mathrm{d}V = \oint_{\partial\mathcal{R}(\boldsymbol{v})} \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{20.23}$$

where $\hat{\boldsymbol{n}}$ is the outward normal on the region's closed boundary, $\mathrm{d}\mathcal{S}$ is the area element on the boundary, and

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \text{volume transport (volume per time) at the boundary } \partial\mathcal{R}. \tag{20.24}$$

Use of the divergence theorem then leads to the equivalent expression

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \nabla \cdot \boldsymbol{v} \, \mathrm{d}V. \tag{20.25}$$

We now take the limit as the material region becomes a material parcel, in which case we recover the differential expression

$$\frac{1}{\delta V} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \nabla \cdot \boldsymbol{v}, \tag{20.26}$$

where we make use of $\mathrm{D}/\mathrm{D}t$ since the infinitesimal volume is moving with the fluid. This equation is also derived in Section 19.6.1 using different methods.

[4] Recall that throughout this chapter we are focused on single-component fluids, so there is no diffusion of matter considered here. We relax this restriction in Chapter 21.

20.3.2 Mass conservation

The mass of fluid contained in a finite material region is given by

$$M = \int_{\mathcal{R}(\boldsymbol{v})} \rho \, \mathrm{d}V. \tag{20.27}$$

As a material fluid region, it maintains a constant mass as it moves through the fluid so that

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \rho \, \mathrm{d}V = 0. \tag{20.28}$$

Just as for the volume in Section 20.3.1, taking the limit as the material region becomes infinitesimally small, the region mass conservation statement (20.28) becomes the parcel mass conservation statement (20.13)

$$\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = \frac{\mathrm{D}(\rho \, \delta V)}{\mathrm{D}t} = 0. \tag{20.29}$$

20.3.3 Mass conservation using Lagrangian methods

Rather than take the limit as the finite material region $\mathcal{R}(\boldsymbol{v})$ becomes infinitesimal, we develop a formalism for moving the time derivative across an integral of the mass within a finite sized material region, as in equation (20.28). As part of this discussion we introduce two coordinate representations of the mass within a material region. The first is the Cartesian $\boldsymbol{x}$-space representation

$$\int_{\mathcal{R}(\boldsymbol{v})} \rho \, \mathrm{d}V = \int\limits_{x_1(t)}^{x_2(t)} \int\limits_{y_1(t)}^{y_2(t)} \int\limits_{z_1(t)}^{z_2(t)} \rho \, \mathrm{d}x \, \mathrm{d}y \, \mathrm{d}z \equiv \int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{x},t)]} \rho \, \mathrm{d}V(\boldsymbol{x}). \tag{20.30}$$

The first equality expresses the integral with bounds that are functions of time, with the time dependence needed since the material region is moving with the fluid. The second equality uses a notation that emphasizes the region bounds and volume element are moving with the fluid velocity, $\boldsymbol{v}$, as specified using the $\boldsymbol{x}$-space representation, $\boldsymbol{v}(\boldsymbol{x}, t)$.

An alternative representation of mass in a material fluid region makes use of $\boldsymbol{a}$-space material coordinates. For this representation we perform a coordinate transformation from the $\boldsymbol{x}$-space representation to the $\boldsymbol{a}$-space representation, with this coordinate transformation requiring the Jacobian of transformation. To capture the gist of this transformation let us consider the one-dimensional case in which

$$\int\limits_{x_1(t)}^{x_2(t)} \rho \, \mathrm{d}x = \int\limits_{a[x_1(t)]}^{a[x_2(t)]} \rho \, \frac{\partial \varsigma}{\partial a} \, \mathrm{d}a = \int\limits_{a_1}^{a_2} \rho \, \frac{\partial \varsigma}{\partial a} \, \mathrm{d}a. \tag{20.31}$$

The first equality introduced the Jacobian, $\partial \varsigma / \partial a$, for the one-dimensional coordinate transformation from $\boldsymbol{x}$-space to $\boldsymbol{a}$-space, with corresponding changes to the limits of integration. We can make this coordinate transformation since there is a 1-to-1 relation between the $\boldsymbol{a}$-space and $\boldsymbol{x}$-space representation of a material fluid parcel. The second equality wrote the integral bounds in terms of the material coordinate. Since we are considering a material region that follows fluid particles, the integral bounds have fixed material coordinate values, $a[x_1(t)] = a_1$ and $a[x_2(t)] = a_2$.

Generalizing to three dimensions then renders

$$\int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{x},t)]} \rho \, \mathrm{d}V(\boldsymbol{x}) = \int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{a})]} \rho \, \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} \, \mathrm{d}V^{\mathrm{L}}(\boldsymbol{a}). \tag{20.32}$$

Again, we distinguish the $\boldsymbol{x}$ and $\boldsymbol{a}$ arguments for the material region, with the $\boldsymbol{x}$ representation also requiring a time argument whereas the material $\boldsymbol{a}$ representation has no time dependence since it is attached to the moving fluid particles.

We now make use of the equality (20.32) to take the time derivative of the mass contained in the material region. Since the time derivative follows the material region, we can make use of the material space coordinate representation as part of the manipulations

$$\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{x},t)]} \rho \, \mathrm{d}V(\boldsymbol{x}) \right] = \frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{a})]} \rho \, \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} \, \mathrm{d}V^{\mathrm{L}}(\boldsymbol{a}) \right] \tag{20.33a}$$

$$= \int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{a})]} \frac{\mathrm{D}}{\mathrm{D}t} \left[\rho \, \frac{\partial \boldsymbol{\varsigma}}{\partial \boldsymbol{a}} \mathrm{d}V^{\mathrm{L}}(\boldsymbol{a}) \right] \tag{20.33b}$$

$$= \int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{x},t)]} \left[\frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho \, \nabla \cdot \boldsymbol{v} \right] \mathrm{d}V(\boldsymbol{x}) \tag{20.33c}$$

$$= \int_{\mathcal{R}[\boldsymbol{v}(\boldsymbol{x},t)]} \left[\frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} + \nabla \cdot \boldsymbol{v} \right] \rho \, \mathrm{d}V(\boldsymbol{x}), \tag{20.33d}$$

where we used equation (19.92) for the equality (20.33c). When expressing the integral bounds using $\boldsymbol{a}$-space coordinates, the integral bounds have no time dependence since they are fixed on fluid particles. We can thus move the time derivative inside of the integral sign to reach the second equality. Upon entering the integral, the time derivative is written as a material time derivative, $\mathrm{D}/\mathrm{D}t$, since it is a time derivative computed by following the fluid particles that define the material region. The third equality made use of equation (20.17c) and converted back to $\boldsymbol{x}$-space. As the material region $\mathcal{R}$ has a materially constant mass, we recover the mass continuity equation (20.16) by setting the integrand in equation (20.33d) to zero.

20.3.4 Reynolds transport theorem

On first encounter, the method from Section 20.3.3 that involves moving between Eulerian ($\boldsymbol{x}$-space) and Lagrangian ($\boldsymbol{a}$-space) representations is clumsy at best and a black box at worse. However, with some practice it becomes an elegant means to study the time evolution of fluid properties integrated over a material region. The method is formalized by the *Reynolds transport theorem*.

Manipulations leading to the mass conservation statement (20.33d) can be generalized by considering the material time derivative of a mass-weighted field ψ (e.g., a tracer concentration as in Section 21.1)

$$\frac{\mathrm{D}(\psi \, \rho \, \delta V)}{\mathrm{D}t} = \frac{\mathrm{D}\psi}{\mathrm{D}t} \, \rho \, \delta V + \psi \, \frac{\mathrm{D}(\rho \, \delta V)}{\mathrm{D}t} \tag{20.34a}$$

$$= \rho \, \delta V \left[\frac{\mathrm{D}\psi}{\mathrm{D}t} + \frac{\psi}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} + \psi \, \nabla \cdot \boldsymbol{v} \right] \tag{20.34b}$$

$$= \delta V \left[\frac{\partial(\rho \, \psi)}{\partial t} + \nabla \cdot (\rho \, \psi \, \boldsymbol{v}) \right]. \tag{20.34c}$$

The first equality used the product rule, which holds for material time derivatives. Mass conser-

vation means that the material derivative $\mathrm{D}(\rho\,\delta V)/\mathrm{D}t = 0$. However, we choose to write mass conservation in the form of equation (20.17c), which allows us to introduce the flux-form Eulerian expression after replacing the material time derivative with its Eulerian form from equation (18.31). Another means to derive this result is to write

$$\rho\,\frac{\mathrm{D}\psi}{\mathrm{D}t} = \rho\left[\frac{\partial\psi}{\partial t} + \boldsymbol{v}\cdot\nabla\psi\right] \tag{20.35a}$$

$$= \rho\left[\frac{\partial\psi}{\partial t} + \boldsymbol{v}\cdot\nabla\psi\right] + \psi\left[\frac{\partial\rho}{\partial t} + \nabla\cdot(\boldsymbol{v}\,\rho)\right] \tag{20.35b}$$

$$= \frac{\partial(\rho\,\psi)}{\partial t} + \nabla\cdot(\rho\,\boldsymbol{v}\,\psi). \tag{20.35c}$$

Following the discussion in Section 20.3.3, we can extend the material parcel result (20.34c) to a finite size material region. Again, each point in the material region is following a fluid particle. The result is known as the *Reynolds transport theorem*, which can be written in the following equivalent manners

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}(\boldsymbol{v})}\psi\,\rho\,\mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})}\frac{\mathrm{D}\psi}{\mathrm{D}t}\rho\,\mathrm{d}V \qquad \text{material region} \tag{20.36a}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})}\left[\frac{\partial(\rho\,\psi)}{\partial t} + \nabla\cdot(\rho\,\psi\,\boldsymbol{v})\right]\mathrm{d}V \qquad \text{identity (20.35c)} \tag{20.36b}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})}\frac{\partial(\rho\,\psi)}{\partial t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}(\boldsymbol{v})}\rho\,\psi\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \qquad \text{divergence theorem (2.68).} \tag{20.36c}$$

Note that we returned to the notation $\mathcal{R}(\boldsymbol{v})$ for material region as introduced in Section 20.3.1. This notation is sufficient to designate that the region is following fluid particles whose velocity is the fluid velocity, $\boldsymbol{v}$. The surface integral term, $\boldsymbol{v}\cdot\hat{\boldsymbol{n}}$, generally does not vanish. Rather, it is given by $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = \boldsymbol{v}^{(s)}\cdot\hat{\boldsymbol{n}}$, where $\boldsymbol{v}^{(s)}$ is the velocity of a point on the boundary of the material region. Only when the material boundary is static can we set $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = 0$. We further consider this issue in Section 20.4 when studying kinematic boundary conditions.

20.3.5 Comments on notation for the time derivative

In this book we write $\mathrm{d}/\mathrm{d}t$ for the time derivative operator acting on an integral. Furthermore, when the domain is specialized to follow fluid particles, we identify the special nature of such domains by introducing the fluid velocity argument to the domain name, $\mathcal{R}(\boldsymbol{v})$. This notation designates that all points in the domain, $\mathcal{R}$, move with the fluid velocity, $\boldsymbol{v}$, since all points have fluid particles attached. However, many authors choose an alternative notation by using the material time derivative, $\mathrm{D}/\mathrm{D}t$, when acting on an integral over a material region. We thus have the following equality across the two notational conventions

$$\frac{\mathrm{D}}{\mathrm{D}t}\int_{\mathcal{R}}\psi\,\rho\,\mathrm{d}V = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}(\boldsymbol{v})}\psi\,\rho\,\mathrm{d}V. \tag{20.37}$$

The use of one convention versus the other is a matter of taste. We follow Section 2.1 of *Batchelor* (1967) by restricting the $\mathrm{D}/\mathrm{D}t$ operator to act only on space-time fields, such as $\psi(\boldsymbol{x},t)$. Hence, the $\mathrm{D}/\mathrm{D}t$ operator is not used when acting on integrals over spatial regions. Following this convention leads us to write $\mathcal{R}(\boldsymbol{v})$ for a region that moves with the fluid flow and to retain $\mathrm{d}/\mathrm{d}t$ when acting on the integral over that region.

The $\mathcal{R}(\boldsymbol{v})$ notation is not generally used in the literature, with many authors dropping the

FIGURE 20.3: Illustrating the no-normal flow boundary condition maintained for a solid material boundary, on which $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ (equation (20.38)). When the solid boundary denotes the solid-earth (ground or ocean bottom), and when the boundary does not overturn (i.e., $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}}$ is single-signed), then the position of the interface can be written $s(x, y, z) = z - \eta_b(x, y) = 0$ (equation (20.39)). Correspondingly, the outward unit normal is given by $\hat{\boldsymbol{n}} = -\nabla s/|\nabla s| = -(\hat{\boldsymbol{z}} - \nabla \eta_b)/\sqrt{1 + |\nabla \eta_b|^2}$ as given by equation (20.40).

$\boldsymbol{v}$ and thus letting words designate whether a region follows the flow or otherwise. As we have occasion in this book to consider a variety of fluid regions, we find it essential to introduce the somewhat more explicit notation, $\mathcal{R}(\boldsymbol{v})$, to denote a region moving with the flow velocity, $\boldsymbol{v}$. This usage aims to help the reader freely swim along with the mathematical flow rather than struggling to stay afloat in an ocean of confused or non-specific notation.

20.4 Kinematic boundary conditions

When a fluid encounters a boundary, either at the edge of the fluid region or an imaginary boundary within the fluid itself, the flow must accommodate the boundary. Conversely, the boundary must accommodate the flow. Some boundaries are impermeable, so that they do not allow matter to cross. For material boundaries, any fluid originally in contact with the boundary stays in contact; at most the fluid can move tangential to the boundary without leaving it. We can understand this rather remarkable constraint placed on material boundaries by noting that no two fluid particles can occupy the same point along the material boundary, nor can there be a cavity next to the boundary as the boundary moves through the fluid. Other boundaries are permeable, thus allowing matter to cross. In this section we develop kinematic boundary conditions appropriate for the variety of cases encountered in fluid mechanics.

20.4.1 Static material surface

Consider a moving fluid that encounters a static material surface, such as the solid-earth. At the boundary, we can decompose the fluid velocity into a component that moves in the plane locally tangent to the boundary and another component that is normal to the boundary. To ensure that no fluid crosses the static boundary, the normal component must vanish at the boundary surface. Hence, the kinematic boundary condition for a moving fluid that encounters a static material boundary is (see Figure 20.3)

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{no-normal flow condition on static material boundary.} \tag{20.38}$$

Recall our discussion of streamlines in Section 18.11.2, where $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ along a streamline. Evidently, the static material boundary is a flow streamline so that fluid that is in contact with the boundary remains in contact. This result holds even in the case of a time dependent flow.[5]

For many cases in practice, the material surface is monotonic in the vertical, meaning there are no overturns. In this case, it is useful to introduce some differential geometry (at the level of introductory calculus) to unpack the boundary condition (20.38). Doing so helps to develop

[5]Specification of the tangential velocity along a material boundary requires dynamical information, such as the no-slip boundary from Section 26.8.7, that is unavailable from purely kinematic considerations.

a geometric formalism especially useful for the more complicated moving boundary conditions in Sections 20.4.2 and 20.4.3. For this purpose, introduce a coordinate expression for the boundary according to

$$s(x, y, z) = z - \eta_{\mathrm{b}}(x, y) = 0 \qquad \text{static material boundary,} \tag{20.39}$$

with $z = \eta_{\mathrm{b}}(x, y)$ the vertical position of the boundary. The outward unit normal vector at the boundary is thus given by

$$\hat{\boldsymbol{n}} = -\frac{\nabla s}{|\nabla s|} = -\frac{\nabla(z - \eta_{\mathrm{b}})}{|\nabla(z - \eta_{\mathrm{b}})|} = -\frac{\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{b}}}{\sqrt{1 + |\nabla\eta_{\mathrm{b}}|^2}}. \tag{20.40}$$

Consequently, the no-flux boundary condition (20.38) takes the form

$$\nabla(z - \eta_{\mathrm{b}}) \cdot \boldsymbol{v} = w - \boldsymbol{u} \cdot \nabla\eta_{\mathrm{b}} = 0 \qquad \text{at } z = \eta_{\mathrm{b}}(x, y), \tag{20.41}$$

where the velocity is decomposed into its horizontal and vertical components, $\boldsymbol{v} = (\boldsymbol{u}, w)$. Hence, to maintain the no-flux boundary condition requires the vertical velocity component to precisely balance the projection of the horizontal velocity onto the slope of the material surface. If the material surface is flat, so that $\nabla\eta_{\mathrm{b}} = 0$, then the kinematic boundary condition reduces to $w = 0$. Alternatively, if the flow is purely horizontal and thus moves along a constant η_{b} isoline, then $\boldsymbol{u} \cdot \nabla\eta_{\mathrm{b}} = 0$ so that $w = 0$.

20.4.2 Moving (free) material surface

We next consider the kinematic constraints imposed by a moving surface that does not allow matter to cross the surface.[6]

General expression of the kinematic boundary condition

To ensure that no matter crosses the surface, the normal component of the velocity for a point on the surface must match the normal component of the fluid at the surface. We are thus led to the kinematic boundary condition for a moving material surface

$$(\boldsymbol{v} - \boldsymbol{v}^{(s)}) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{moving material boundary condition.} \tag{20.42}$$

We illustrate this boundary condition in Figure 20.4, where $\boldsymbol{v}^{(s)}$ is the velocity of a point fixed on the moving material surface and $\boldsymbol{v}$ is the velocity of the fluid particles.

As for the static material boundary, there is no constraint on the tangential component of the velocities, since it is only the normal component that measures the flow of matter across the boundary. Hence, the boundary condition (20.42) does not mean $\boldsymbol{v}$ and $\boldsymbol{v}^{(s)}$ are identical. It only says that their normal components are the same when evaluated on the material surface. As a Corollary, we see that $\boldsymbol{v} \cdot \hat{\boldsymbol{n}}$ is not generally zero so that a moving material boundary does *not* coincide with a flow streamline (see discussion in Sections 18.11.2 and 18.11.3).

[6] As we discuss in Chapter 21, with multiple matter components a surface that follows the barycentric velocity and so allows for zero net mass to cross it can still allow for the exchange of component matter in the presence of matter diffusion. In the current chapter, we are only considering a single matter constituent, so that zero mass crossing a surface also means there are no fluid particles crossing the surface.

FIGURE 20.4: Illustrating the boundary condition for a moving material surface, on which $\hat{\boldsymbol{n}}\cdot(\boldsymbol{v}-\boldsymbol{v}^{(s)}) = 0$ (equation (20.42)), so that no fluid particles cross the surface. The boundary condition means that the velocity of the surface, $\boldsymbol{v}^{(s)}$, has the same normal component as the velocity of a fluid particle, $\boldsymbol{v}$. The material nature of the surface is not compromised if $\boldsymbol{v}\neq\boldsymbol{v}^{(s)}$, so long as their normal components are identical, $\hat{\boldsymbol{n}}\cdot\boldsymbol{v} = \hat{\boldsymbol{n}}\cdot\boldsymbol{v}^{(s)}$. For many cases, we can specify the surface by the value of a function that is a constant on the surface: $s(\boldsymbol{x},t) = s_0$ for some constant s_0 (equation (20.43)), in which case the unit normal direction is given by $\hat{\boldsymbol{n}} = |\nabla s|^{-1}\nabla s$ (equation (20.44)). For example, s could represent a surface of constant temperature, or a constant Archimedean buoyancy (Chapter 31) in a buoyancy stratified fluid.

Specialized expression of the boundary condition

Now specialize the kinematic condition (20.42) to the case of a material surface, $\mathcal{S}$, as specified by a scalar function whose value remains a fixed constant when it is evaluated on the surface

$$s(\boldsymbol{x},t) = s_0 \quad \text{when } \boldsymbol{x}\in\mathcal{S}. \tag{20.43}$$

An example of such a function is the Archimedean buoyancy (Chapter 31) or the Conservative Temperature (Section 27.11). Correspondingly, the surface unit normal vector is given by

$$\hat{\boldsymbol{n}} = |\nabla s|^{-1}\nabla s. \tag{20.44}$$

From Section 18.8.6, we know that a point fixed on an arbitrary surface has a velocity that satisfies (see equation (18.46))

$$\frac{\partial s}{\partial t} + \boldsymbol{v}^{(s)}\cdot\nabla s = 0 \qquad \text{on an iso-surface } s(\boldsymbol{x},t) = s_0. \tag{20.45}$$

Note that we offer another derivation of this equation later in this subsection. Use of the identity

$$\frac{\partial s}{\partial t} = \frac{\mathrm{D}s}{\mathrm{D}t} - \boldsymbol{v}\cdot\nabla s \tag{20.46}$$

renders

$$\frac{\mathrm{D}s}{\mathrm{D}t} - \boldsymbol{v}\cdot\nabla s + \boldsymbol{v}^{(s)}\cdot\nabla s = \frac{\mathrm{D}s}{\mathrm{D}t} + (\boldsymbol{v}^{(s)}-\boldsymbol{v})\cdot\nabla s = 0. \tag{20.47a}$$

Since $(\boldsymbol{v}^{(s)}-\boldsymbol{v})\cdot\nabla s = 0$ from the boundary condition (20.42), we are left with the material constancy condition

$$\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\partial s}{\partial t} + \boldsymbol{v}\cdot\nabla s = 0 \qquad \text{on material surface } s(\boldsymbol{x},t) = s_0. \tag{20.48}$$

Consequently, matter does not cross a surface of constant s as long as s is materially constant. This is an important kinematic property that reappears in many forms throughout fluid mechanics.[7]

[7] As noted on page 137 of *Serrin* (1959), the kinematic condition (20.48) originates from Kelvin in 1848 and Lagrange in 1781.

FIGURE 20.5: A surface within a fluid at two time instants, along with the position of a fluid particle on the surface at $\boldsymbol{X}(t)$ and $\boldsymbol{X}(t+\delta t)$. The velocity of a point on the surface is given by $\boldsymbol{v}^{(s)} = [\boldsymbol{X}(t+\delta t)-\boldsymbol{X}(t)]/\delta t = \delta\boldsymbol{X}/\delta t$. The equation $s(\boldsymbol{x},t) = z-\eta(x,y,t) = s_0$ specifies the vertical position for points on the surface as a function of horizontal position and time. At both time instances the vertical position is determined by $s(\boldsymbol{x},t) = s(\boldsymbol{x}+\delta\boldsymbol{x},t+\delta t) = s_0$.

Boundary condition for a material interface

Consider the interface between two immiscible fluids. Assume this interface has an outward normal that has a nonzero vertical component, so that there are no breaking waves, for example. In this case we can express the vertical position of a point on the interface as

$$s(x,y,z,t) = z - \eta(x,y,t) = s_0. \tag{20.49}$$

The function $\eta(x,y,t)$ is the vertical deviation of the interface relative to the horizontal. The kinematic boundary condition (20.48) thus takes the form

$$\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\mathrm{D}(z-\eta)}{\mathrm{D}t} = 0. \tag{20.50}$$

Hence, the vertical velocity component at the interface equals to the material time derivative of the interface displacement

$$\frac{\mathrm{D}z}{\mathrm{D}t} = \frac{\mathrm{D}\eta}{\mathrm{D}t} \Longrightarrow w = \frac{\partial\eta}{\partial t} + \boldsymbol{u}\cdot\nabla\eta \qquad \text{material b.c. at interface } z=\eta(x,y,t). \tag{20.51}$$

This boundary condition can be equivalently written in the form

$$\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = \frac{\partial\eta/\partial t}{\sqrt{1+|\nabla\eta|^2}}, \tag{20.52}$$

where

$$\hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{-\nabla\eta+\hat{\boldsymbol{z}}}{\sqrt{1+|\nabla\eta|^2}} \tag{20.53}$$

is the outward unit normal at the material surface. These equations provide kinematic relation for the motion of an surface within a perfect fluid. It also provides the kinematic relation for the interface separating two immiscible fluid layers. A particular example concerns the boundary condition placed on the ocean free surface in the special case of no water penetrating the surface (i.e., no rain or evaporation).

A geometric derivation of the material boundary condition

The material invariance condition $\mathrm{D}s/\mathrm{D}t = 0$ is a key kinematic result. We thus offer an alternative derivation to help solidify its meaning. As before, define the surface according to

$$s(\boldsymbol{x},t) = z - \eta(x,y,t) = s_0, \tag{20.54}$$

which specifies the vertical position of a point on the surface at time t. Now consider the position of the surface after a small time interval, $t + \delta t$ (see Figure 20.5). The vertical position of the surface at the new time is determined by the same condition

$$s(\boldsymbol{x} + \delta\boldsymbol{x}, t + \delta t) = s_0, \tag{20.55}$$

where $\boldsymbol{\varsigma}(t+\delta t) = \boldsymbol{x}+\delta\boldsymbol{x}$ is the displaced position of a point on the surface that started at $\boldsymbol{\varsigma}(t) = \boldsymbol{x}$, and

$$\boldsymbol{v}^{(s)} = [\boldsymbol{\varsigma}(t + \delta t) - \boldsymbol{\varsigma}(t)]/\delta t = \delta\boldsymbol{x}/\delta t \tag{20.56}$$

is the velocity of a point stuck to the surface. Expanding equation (20.55) in a Taylor series to leading order yields

$$s(\boldsymbol{x}, t) + \delta\boldsymbol{x} \cdot \nabla s + \delta t\, \partial_t s = s_0. \tag{20.57}$$

Since $s(\boldsymbol{x}, t) = s_0$ from equation (20.54) we thus have

$$\frac{\partial s}{\partial t} + \frac{\delta\boldsymbol{x}}{\delta t} \cdot \nabla s = \frac{\partial s}{\partial t} + \frac{\delta\boldsymbol{x}}{\delta t} \cdot \hat{\boldsymbol{n}}\, |\nabla s| = 0, \tag{20.58}$$

where $\hat{\boldsymbol{n}} = |\nabla s|^{-1}\, \nabla s$ is the surface unit normal direction. This result means that when positioned at a fixed point in space, it is the normal component of the displacement that corresponds to a temporal modification of $s(\boldsymbol{x}, t)$

$$\frac{\partial s}{\partial t} = -\boldsymbol{v}^{(s)} \cdot \hat{\boldsymbol{n}}\, |\nabla s|. \tag{20.59}$$

In contrast, any tangential displacement along an s-isosurface leaves $s(\boldsymbol{x}, t)$ unchanged. Hence, when following motion of points on the surface, we are only concerned with motion along the direction set by the normal component of the velocity of that point, $\hat{\boldsymbol{n}}\, (\boldsymbol{v}^{(s)} \cdot \hat{\boldsymbol{n}})$. It is this velocity component that corresponds to movement of the surface normal to itself, thus leading to nonzero motion through space.

Writing equation (20.59) in a more conventional form leads to the differential equation satisfied by a point fixed on the moving surface

$$\frac{\partial s}{\partial t} + \boldsymbol{v}^{(s)} \cdot \nabla s = 0. \tag{20.60}$$

Again, assuming the surface is material means that

$$\boldsymbol{v}^{(s)} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v} \cdot \hat{\boldsymbol{n}}, \tag{20.61}$$

so that motion of the surface normal to itself is identical to that of the fluid in the same direction. Use of the boundary condition (20.61) in equation (20.60) renders the material invariance condition

$$\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\partial s}{\partial t} + \boldsymbol{v} \cdot \nabla s = 0. \tag{20.62}$$

20.4.3 Dynamic and permeable surface

We now consider the kinematic boundary condition for a moving permeable surface that separates two fluid media (e.g., ocean and atmosphere) or two regions within a single media (e.g., surface of constant buoyancy within the ocean or within the atmosphere). As before, the kinematic boundary condition is a statement about the mass transport through the boundary. Whereas the previous conditions enforced a zero mass transport through the boundary at each point of the boundary, here we allow for a generally non-zero transport (mass per time). We write this

FIGURE 20.6: Illustrating the boundary condition for a moving permeable surface, such as the interface between two miscible fluid layers. On this surface, the boundary condition states that $\rho\left(\boldsymbol{v}-\boldsymbol{v}^{(s)}\right)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}=-\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S}$ (as per equation (20.63)). In the special case of an ocean free surface with no overturns, this boundary condition reduces to the surface kinematic boundary condition (20.79).

transport condition as

$$\rho\left(\boldsymbol{v}-\boldsymbol{v}^{(s)}\right)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}=-\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S}\qquad\text{moving non-material boundary condition.}\tag{20.63}$$

In this equation, $\mathrm{d}\mathcal{S}$ is an infinitesimal area element on the surface, and $\mathcal{Q}_{\mathrm{m}}$ measures the mass per time per surface area (mass flux) crossing the boundary. The minus sign is a convention to be motivated in the following. We now massage this kinematic boundary condition into alternative forms.

Coordinate representation of the permeable surface

The expression (20.45) for $\boldsymbol{v}^{(s)}\cdot\hat{\boldsymbol{n}}$ holds for a point on an arbitrary surface, even if that surface is permeable, so that

$$\boldsymbol{v}^{(s)}\cdot\hat{\boldsymbol{n}}=-\frac{\partial s/\partial t}{|\nabla s|}.\tag{20.64}$$

Furthermore, the projection of the fluid velocity onto the normal direction can be written

$$\frac{\mathrm{D}s}{\mathrm{D}t}=\frac{\partial s}{\partial t}+\boldsymbol{v}\cdot\nabla s\Longrightarrow\boldsymbol{v}\cdot\hat{\boldsymbol{n}}=\frac{1}{|\nabla s|}\left[\frac{\mathrm{D}s}{\mathrm{D}t}-\frac{\partial s}{\partial t}\right].\tag{20.65}$$

Bringing these results together leads to

$$\rho\left(\boldsymbol{v}-\boldsymbol{v}^{(s)}\right)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}=\frac{\rho\,\mathrm{d}\mathcal{S}}{|\nabla s|}\frac{\mathrm{D}s}{\mathrm{D}t}\Longrightarrow\mathcal{Q}_{\mathrm{m}}=-\frac{\rho}{|\nabla s|}\frac{\mathrm{D}s}{\mathrm{D}t}.\tag{20.66}$$

This equation says that the mass transport crossing the surface is proportional to the material time derivative of the surface coordinate. The material time derivative vanishes when there is no mass transport across the surface, which is a result already seen in Section 20.4.2.

In terms of the horizontal projection of the surface area

Assume that the surface is not vertical, so that its normal direction has a nonzero component in the vertical (e.g., waves that do not overturn). This assumption means that

$$\frac{\partial s}{\partial z}\neq 0,\tag{20.67}$$

so that we can further massage the boundary condition (20.66) by writing the area factor in the form

$$\frac{\mathrm{d}\mathcal{S}}{|\nabla s|} = \frac{\mathrm{d}\mathcal{S}}{\sqrt{(\partial s/\partial x)^2 + (\partial s/\partial y)^2 + (\partial s/\partial z)^2}} \tag{20.68a}$$

$$= \frac{\mathrm{d}\mathcal{S}}{|\partial s/\partial z|\,\sqrt{[(\partial s/\partial x)/(\partial s/\partial z)]^2 + [(\partial s/\partial y)/(\partial s/\partial z)]^2 + 1}} \tag{20.68b}$$

$$= \frac{\mathrm{d}\mathcal{S}}{|\partial s/\partial z|\sqrt{1+\tan^2\vartheta}} \tag{20.68c}$$

$$= \left|\frac{\partial z}{\partial s}\right| |\cos\vartheta|\,\mathrm{d}\mathcal{S} \tag{20.68d}$$

$$= \left|\frac{\partial z}{\partial s}\right| \mathrm{d}A. \tag{20.68e}$$

The equality (20.68c) introduced the angle, ϑ, between the boundary surface and the horizontal plane. The squared slope of this surface is given by

$$\tan^2\vartheta = \frac{\nabla_z s\cdot\nabla_z s}{(\partial s/\partial z)^2} = \nabla_s z\cdot\nabla_s z \tag{20.69}$$

with

$$\nabla_z = \hat{\boldsymbol{x}}\left[\frac{\partial}{\partial x}\right]_{y,z} + \hat{\boldsymbol{y}}\left[\frac{\partial}{\partial y}\right]_{x,z} \tag{20.70}$$

the horizontal gradient operator on constant z surfaces, and

$$\nabla_s = \hat{\boldsymbol{x}}\left[\frac{\partial}{\partial x}\right]_{y,s} + \hat{\boldsymbol{y}}\left[\frac{\partial}{\partial y}\right]_{x,s} \tag{20.71}$$

the horizontal gradient operator on constant s surfaces, along with $z(x,y,s,t)$ for the vertical position of the constant s surface.[8] The equality (20.68d) made use of a trigonometric identity, and the equality (20.68e) introduced the horizontal projection of the area,

$$\mathrm{d}A = |\cos\vartheta|\,\mathrm{d}\mathcal{S}. \tag{20.72}$$

See Figure 20.7 for an illustration.

These results bring the kinematic boundary condition (20.66) into the form

$$\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(s)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S} \tag{20.73a}$$

$$= \rho\,\frac{\mathrm{D}s}{\mathrm{D}t}\left|\frac{\partial z}{\partial s}\right|\mathrm{d}A \tag{20.73b}$$

$$\equiv -Q_{\mathrm{m}}\,\mathrm{d}A. \tag{20.73c}$$

As defined, the flux Q_{m} is the net mass per time per horizontal area crossing the boundary surface

$$Q_{\mathrm{m}} = -\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(s)})\cdot\hat{\boldsymbol{n}}\,\frac{\mathrm{d}\mathcal{S}}{\mathrm{d}A} = -\rho\,\frac{\mathrm{D}s}{\mathrm{D}t}\left|\frac{\partial z}{\partial s}\right|. \tag{20.74}$$

We motivate the minus sign through the ocean free surface case in the following.

[8] We study in detail such operators in Chapter 59 when developing the mathematics of generalized vertical coordinates.

FIGURE 20.7: Illustrating the relation between an infinitesimal area element on a surface, $\mathrm{d}\mathcal{S}$, to its horizontal projection, $\mathrm{d}A = |\cos\vartheta|\,\mathrm{d}\mathcal{S}$, according to equation (20.72). The angle, φ, must be bounded away from $\pm\pi/2$, thus enabling a nonzero horizontal area projection. For the specific case of a surface defined by $s = z - \eta(x, y, t)$, then $\partial s/\partial z = 1$ and $\mathrm{d}A = \sqrt{1 + (\nabla\eta)^2}\,\mathrm{d}\mathcal{S}$.

Kinematic boundary condition at the ocean free surface

Consider the ocean free surface located at

$$s(x, y, z, t) = z - \eta(x, y, t) = 0 \qquad \text{ocean free surface.} \tag{20.75}$$

For this boundary, $\partial s/\partial z = 1$ so that the area elements are related by

$$\mathrm{d}\mathcal{S} = |\nabla(z - \eta)|\,\mathrm{d}A = \sqrt{1 + |\nabla\eta|^2}\,\mathrm{d}A. \tag{20.76}$$

The normal projection for the velocity of a point fixed on the free surface is given by

$$\boldsymbol{v}^{(\eta)} \cdot \hat{\boldsymbol{n}} = -\frac{\partial s/\partial t}{|\nabla s|} = \frac{\partial\eta/\partial t}{|\nabla(z-\eta)|} = \frac{\partial\eta/\partial t}{\sqrt{1 + |\nabla\eta|^2}} \Longrightarrow \boldsymbol{v}^{(\eta)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \partial_t\eta\,\mathrm{d}A, \tag{20.77}$$

so that the mass flux crossing the free surface is

$$-\mathcal{Q}_{\mathrm{m}} = \rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}}. \tag{20.78}$$

The boundary condition (20.74) thus takes the form

$$\rho\,(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \cdot \hat{\boldsymbol{n}}\,\frac{\mathrm{d}\mathcal{S}}{\mathrm{d}A} = \rho\left[\frac{\mathrm{D}(z-\eta)}{\mathrm{D}t}\right] = -Q_{\mathrm{m}} \Longrightarrow w + \rho^{-1}\,Q_{\mathrm{m}} = \frac{\partial\eta}{\partial t} + \boldsymbol{u}\cdot\nabla\eta. \tag{20.79}$$

We now motivate the sign convention chosen for equation (20.73c) by considering the special case of a flat free surface and a resting fluid with $\boldsymbol{v} = 0$. Adding mass to the ocean raises the free surface, so that $\partial\eta/\partial t > 0$. Hence, the chosen sign convention means that $Q_{\mathrm{m}} > 0$ corresponds to mass added to the ocean.

Kinematic boundary condition on a buoyancy surface

Now consider the interface to be a surface of constant potential density in the ocean (or analogously a surface of constant specific entropy in the atmosphere). These buoyancy isosurfaces are also known as isopycnals, and we use the symbol[9]

$$s = \sigma(x, y, z, t) \tag{20.80}$$

[9]In this book, we use σ as an arbitrary generalized vertical coordinate, here chosen to be an isopycnal.

for a particular isopycnal, σ. The mass transport crossing the isopycnal is written

$$Q_{\mathrm{m}} = \rho \frac{\mathrm{D}\sigma}{\mathrm{D}t} \left| \frac{\partial z}{\partial \sigma} \right| \equiv \rho \, w^{(\dot{\sigma})}, \tag{20.81}$$

where we introduced the *diapycnal transport velocity*

$$w^{(\dot{\sigma})} \equiv \frac{\mathrm{D}\sigma}{\mathrm{D}t} \left| \frac{\partial z}{\partial \sigma} \right|. \tag{20.82}$$

A key aspect of physical oceanography concerns the development of theories for processes that cause a non-zero diapycnal transport. Examples include breaking waves, which act to mix matter across density surfaces; i.e., to *entrain* water from one density class to another.

20.5 Volume and mass budgets for an ocean column

We close this chapter by deriving the budget for the volume per horizontal area in a column of ocean fluid such as that shown in Figure 20.8, as well as the budget for the mass per horizontal area in this column. Since the upper boundary of the domain is the free surface, and since the free surface is a function of time, the region is not strictly Eulerian even though the sides are fixed in space. Furthermore, the free surface is permeable, as are the sides, so that the region is not material. Hence, the discussion offers experience working with the kinematic boundary conditions, as well as some exposure to the use of Leibniz's rule from calculus.

20.5.1 Kinematic free surface equation

We here derive an equation for the free surface evolution, with this equation providing a budget for the volume per horizontal area in the column. The derivation proceeds by vertically integrating the mass continuity equation (20.16) over the depth of an ocean column, from $z = \eta_{\mathrm{b}}(x, y)$ at the bottom to $z = \eta(x, y, t)$ at the free surface. Use of the bottom and surface kinematic boundary conditions renders a kinematic expression for the free surface time tendency.

Vertically integrating the continuity equation (20.16) for a compressible fluid renders

$$-\int_{\eta_{\mathrm{b}}}^{\eta} \frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} \, \mathrm{d}z = \int_{\eta_{\mathrm{b}}}^{\eta} \nabla \cdot \boldsymbol{v} \, \mathrm{d}z \tag{20.83a}$$

$$= w(\eta) - w(\eta_{\mathrm{b}}) + \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z \cdot \boldsymbol{u} \, \mathrm{d}z \tag{20.83b}$$

$$= w(\eta) - w(\eta_{\mathrm{b}}) + \nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \right] - \boldsymbol{u}(\eta) \cdot \nabla_z \eta + \boldsymbol{u}(\eta_{\mathrm{b}}) \cdot \nabla_z \eta_{\mathrm{b}} \tag{20.83c}$$

$$= [w(\eta) - \boldsymbol{u}(\eta) \cdot \nabla_z \eta] - [w(\eta_{\mathrm{b}}) - \boldsymbol{u}(\eta_{\mathrm{b}}) \cdot \nabla_z \eta_{\mathrm{b}}] + \nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \right], \tag{20.83d}$$

where we made use of *Leibniz's rule* from calculus in order to move the horizontal divergence outside of the integral. Also note that $\nabla \cdot \boldsymbol{u} = \nabla_z \cdot \boldsymbol{u}$ since $\boldsymbol{u}$ is the horizontal velocity, and likewise for $\nabla \eta_{\mathrm{b}}$ and $\nabla \eta$ since η_{b} and η are both functions of horizontal space and time, and so have no z dependence.

Use of the surface kinematic boundary condition (20.79) and no-normal flow bottom boundary condition yield

$$\frac{\partial \eta}{\partial t} = \frac{Q_{\mathrm{m}}}{\rho(\eta)} - \nabla \cdot \boldsymbol{U} - \int_{\eta_{\mathrm{b}}}^{\eta} \frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} \, \mathrm{d}z \tag{20.84}$$

FIGURE 20.8: A longitudinal-vertical slice of ocean fluid from the surface at $z = \eta(x, y, t)$ to bottom at $z = \eta_{\mathrm{b}}(x, y)$. The horizontal boundaries of the column at $x - \Delta x/2$ and $x + \Delta x/2$ are static and are penetrated by zonal mass transport, $F^{(x)}$. The zonal mass transport is computed by integrating the zonal mass flux, $\rho\, u$ over the area of the column sides. A similar transport acts in the meridional direction as well. The ocean bottom at the solid-earth boundary, $z = \eta_{\mathrm{b}}(x, y)$, is static with no mass crossing this interface. The ocean surface at $z = \eta(x, y, t)$ is time dependent with mass flux, Q_{m}, crossing this interface.

where

$$\boldsymbol{U} = \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u}\, \mathrm{d}z \tag{20.85}$$

is the depth integrated horizontal transport. Hence, as deduced from the mass continuity equation, the ocean free surface time tendency is affected by the passage of mass across the surface boundary (as normalized by the surface density), the convergence of depth integrated flow, and the depth integral of the material changes in density. The density term contributes to a positive sea surface height tendency when density decreases, and vice versa when density increases. *Griffies and Greatbatch* (2012) provide a more complete analysis of the sea surface height budget (20.84) by unpacking the physical processes leading to the material evolution of density, which they refer to as the *non-Boussinesq steric effect*.

20.5.2 Budget for mass per horizontal area

The mass per horizontal area in the fluid column is given by $\int_{\eta_{\mathrm{b}}}^{\eta} \rho\, \mathrm{d}z$. Use of Leibniz's rule, the bottom kinematic boundary condition, (20.41), surface kinematic boundary condition (20.79),

and the mass continuity equation (20.6), leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\eta_\mathrm{b}}^{\eta} \rho\,\mathrm{d}z\right] = \rho(\eta)\,\frac{\partial\eta}{\partial t} + \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial\rho}{\partial t}\,\mathrm{d}z \tag{20.86a}$$

$$= \rho(\eta)\,\frac{\partial\eta}{\partial t} - \int_{\eta_\mathrm{b}}^{\eta} \nabla\cdot(\rho\,\boldsymbol{v})\,\mathrm{d}z \tag{20.86b}$$

$$= \rho(\eta)\left[\frac{\partial\eta}{\partial t} - w(\eta)\right] + \rho(\eta_\mathrm{b})\,w(\eta_\mathrm{b}) - \int_{\eta_\mathrm{b}}^{\eta} \nabla_z\cdot(\rho\,\boldsymbol{u})\,\mathrm{d}z \tag{20.86c}$$

$$= \rho(\eta)\left[\frac{\partial\eta}{\partial t} + \boldsymbol{u}\cdot\nabla\eta - w(\eta)\right] + \rho(\eta_\mathrm{b})\left[w(\eta_\mathrm{b}) - \boldsymbol{u}(\eta_\mathrm{b})\cdot\nabla\eta_\mathrm{b}\right] - \nabla_z\cdot\boldsymbol{U}^\rho \tag{20.86d}$$

$$= Q_\mathrm{m} - \nabla_z\cdot\boldsymbol{U}^\rho, \tag{20.86e}$$

where

$$\boldsymbol{U}^\rho = \int_{\eta_\mathrm{b}}^{\eta} \rho\,\boldsymbol{u}\,\mathrm{d}z. \tag{20.87}$$

Hence, the mass per horizontal area within a column evolves according to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\eta_\mathrm{b}}^{\eta} \rho\,\mathrm{d}z\right] = Q_\mathrm{m} - \nabla\cdot\boldsymbol{U}^\rho, \tag{20.88}$$

with terms on the right hand side representing the convergence of mass onto the column either through the sides or upper surface. We consider an alternative derivation of this budget in Exercise 20.3.

20.6 Exercises

EXERCISE 20.1: VELOCITY THAT DOES NOT PENETRATE A CURVE
Consider a static curve defined by

$$s(x,y) = x\,y = \text{constant}. \tag{20.89}$$

Provide an example velocity, $\boldsymbol{v} = u\,\hat{\boldsymbol{x}} + v\,\hat{\boldsymbol{y}} + w\,\hat{\boldsymbol{z}}$, that has nonzero horizontal components and that satisfies $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = 0$, where $\hat{\boldsymbol{n}}$ is the unit normal to the curve. Be sure that your answer has the proper dimensions for a velocity. Hint: see Section 39.4.5.

EXERCISE 20.2: CENTER OF MASS MOTION
Consider a material fluid region, $\mathcal{R}(\boldsymbol{v})$, with constant mass written as

$$M = \int_{\mathcal{R}(\boldsymbol{v})} \rho\,\mathrm{d}V. \tag{20.90}$$

Assume Cartesian coordinates throughout this exercise.[10]

(a) Show mathematically that the center of mass for the region moves with the region's total

[10] Note the for a general manifold, the addition of vectors is only defined locally within a tangent space. This limitation prevents us from integrating general tensors over a volume. However, for Cartesian tensors we can perform integration in a naive manner just as for scalars.

linear momentum

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{1}{M}\int_{\mathcal{R}(\boldsymbol{v})}\boldsymbol{x}\,\rho\,\mathrm{d}V\right]=\frac{1}{M}\int_{\mathcal{R}(\boldsymbol{v})}\frac{\mathrm{D}\boldsymbol{x}}{\mathrm{D}t}\,\rho\,\mathrm{d}V=\frac{1}{M}\int_{\mathcal{R}(\boldsymbol{v})}\boldsymbol{v}\,\rho\,\mathrm{d}V. \tag{20.91}$$

Precisely describe the reasoning behind each step. Note: a brief solution is sufficient, so long as the reasoning is sound.

(b) Show mathematically (or precisely describe why) that the time change in the linear momentum for the region is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(\boldsymbol{v})}\rho\,\boldsymbol{v}\,\mathrm{d}V\right]=\int_{\mathcal{R}(\boldsymbol{v})}\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t}\,\rho\,\mathrm{d}V. \tag{20.92}$$

Precisely describe the reasoning behind each step. Note: a brief solution is sufficient, so long as the reasoning is sound.

EXERCISE 20.3: MASS BUDGET FOR A FLUID COLUMN

We here provide an alternative derivation of equation (20.88), the budget for the mass per horizontal area over a column of fluid.

The mass within an arbitrary fluid region is given by

$$M=\int_{\mathcal{R}}\rho\,\mathrm{d}V. \tag{20.93}$$

Consider the fluid mass within the column shown in Figure 20.8. In this column, the vertical side-walls are fixed in time, the bottom surface, $z=\eta_{\mathrm{b}}(x,y)$, is at the solid-earth boundary, and the top, $z=\eta(x,y,t)$, is the fluctuating ocean free surface. Convince yourself that the mass for this column can be written

$$M=\iint\left[\int_{\eta_{\mathrm{b}}(x,y)}^{\eta(x,y,t)}\rho\,\mathrm{d}z\right]\mathrm{d}x\,\mathrm{d}y, \tag{20.94}$$

where the horizontal (x,y) integrals extend over the horizontal extent of the column. Mass conservation for this column means that the change in mass arises just through boundary fluxes, so that

$$\frac{\mathrm{d}M}{\mathrm{d}t}=-\int\rho\,\Delta\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{20.95}$$

where $\hat{\boldsymbol{n}}$ is the outward normal to the surface of the fluid region, $\mathrm{d}\mathcal{S}$ is the area of an infinitesimal element on the surface, and the minus sign means that fluid leaving the region contributes to a reduction in mass within the region. The term

$$\Delta\boldsymbol{v}=\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{s})} \tag{20.96}$$

is the velocity of the fluid relative to the velocity of the boundary; e.g., see the kinematic boundary condition discussion in Section 20.4.3. We also derive a general form of this relation in equation (21.50), though this exercise can be solved without knowing the details of that derivation.

(a) Mass transported in the zonal direction ($\hat{\boldsymbol{x}}$) that crosses the column's vertical boundary at

x is given by

$$F^{(x)}(x,y,t) = \int_{y-\Delta y/2}^{y+\Delta y/2} \left[\int_{\eta_{\rm b}(x,y')}^{\eta(x,y',t)} u(x,y',z',t)\, \rho(x,y',z',t)\, \mathrm{d}z' \right] \mathrm{d}y' \tag{20.97a}$$

$$\equiv \int_{y-\Delta y/2}^{y+\Delta y/2} U^{\rho}(x,y',t)\, \mathrm{d}y', \tag{20.97b}$$

and similarly for mass transport in the meridional direction

$$F^{(y)}(x,y,t) = \int_{x-\Delta x/2}^{x+\Delta x/2} \left[\int_{\eta_{\rm b}(x',y)}^{\eta(x',y,t)} v(x',y,z',t)\, \rho(x',y,z',t)\, \mathrm{d}z' \right] \mathrm{d}x' \tag{20.98a}$$

$$\equiv \int_{x-\Delta x/2}^{x+\Delta x/2} V^{\rho}(x',y,t)\, \mathrm{d}x', \tag{20.98b}$$

where

$$\boldsymbol{U}^{\rho}(x,y,t) = \int_{\eta_{\rm b}(x,y)}^{\eta(x,y,t)} \boldsymbol{u}(x,y,z',t)\, \rho(x,y,z',t)\, \mathrm{d}z' = \hat{\boldsymbol{x}}\, U^{\rho} + \hat{\boldsymbol{y}}\, V^{\rho}. \tag{20.99}$$

What are the physical dimensions [in terms of length (L), mass (M), and time (T)] for the mass transports, $F^{(x)}$ and $F^{(y)}$?

(b) Using these expressions for the mass crossing the vertical side boundaries of a fluid column, take the limit as the horizontal cross-sectional area of the column becomes infinitesimally small to show that the evolution equation for the mass per unit area of the column is given by

$$\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\eta_{\rm b}}^{\eta} \rho\, \mathrm{d}z \right] = -\nabla \cdot \boldsymbol{U}^{\rho} + Q_{\rm m}, \tag{20.100}$$

where $Q_{\rm m}$ is the mass transport entering the ocean through the surface, per horizontal area, as defined by equation (20.73c), so that

$$\int Q_{\rm m}\, \mathrm{d}A = -\int \rho\, \Delta \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{at } z = \eta. \tag{20.101}$$

The derivation of equation (20.100) is part of this exercise, using methods distinct from those used in Section 20.5.2.

(c) In words, the mass budget in equation (20.100) says that mass changes in a column of fluid if there is a convergence of mass into the column across its vertical boundaries (first term on right hand side), and a mass flux entering the column across the ocean surface (second term on right hand side). What are the physical dimensions of all terms in equation (20.100)?

EXERCISE 20.4: CHANGE IN LINEAR MOMENTUM OF A FLUID REGION

Consider a closed ocean basin with zero boundary fluxes of matter; i.e., zero precipitation/evaporation and zero mass fluxes through the solid-earth bottom. Consequently, this region is bounded by material surfaces and so it maintains constant matter content with fixed mass

$$M = \int_{\mathcal{R}} \rho\, \mathrm{d}V. \tag{20.102}$$

FIGURE 20.9: Cross-section of the integration region for Exercise 20.4, with the region extending from the ocean bottom at $z = \eta_\mathrm{b}(x, y)$ and the free surface at $z = \eta(x, y, t)$. The sides are assumed to be vertical and rigid. An infinitesimal column is shown with cross-sectional area $\mathrm{d}A$, extending from the bottom to the surface. The cross-sectional area for the column is time independent, so that a time derivative passes across the area integral to act only on the upper limit $z = \eta$ and the integrand in equation (20.104).

Show that the time change in the linear momentum for this ocean basin is given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\boldsymbol{v}\,\mathrm{d}V\right] = \int_{\mathcal{R}} \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t}\,\rho\,\mathrm{d}V. \tag{20.103}$$

This result is identical to that derived in Exercise 20.2. Rather than just repeating the solution method used there, make use of Leibniz's rule, the kinematic boundary condition detailed in Section 20.4.2, and mass conservation.

As noted in the footnote for Exercise 20.2, addition of vectors is only defined locally within a tangent space when working on a general manifold. This limitation prevents us from integrating vectors over an arbitrary manifold. However, for Cartesian tensors in Euclidean space, we can perform integration in a naive manner just as for scalars, thus enabling us to perform the integration in equation (20.103). Hence, throughout this exercise we use Cartesian tensors in Euclidean space.

Hint: Refer to Figure 20.9 for a schematic of the integration where we have expanded the volume integral into the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\boldsymbol{v}\,\mathrm{d}V\right] = \frac{\mathrm{d}}{\mathrm{d}t}\left[\int \left(\int_{\eta_\mathrm{b}}^{\eta} \rho\,\boldsymbol{v}\,\mathrm{d}z\right)\mathrm{d}A\right], \tag{20.104}$$

where the horizontal integral extends over the rigid and fixed horizontal area of the basin, $\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y$ is the time independent horizontal area element, $z = \eta_\mathrm{b}(x, y)$ is the solid-earth bottom and $z = \eta(x, y, t)$ is the ocean free surface. Time dependence appears in the upper boundary at $z = \eta$ and within the integrand. Perform the time derivative operation and make use of mass continuity and the kinematic boundary condition. Also make use of the trigonometry presented in Section 20.4.3 (in particular equation (20.72)). Unlike the formulation in Exercise 20.2, there is no use of a material time derivative in this approach. Rather, it is a straightforward (albeit tedious) use of integration over a domain with fixed horizontal/bottom boundaries and a time dependent free surface boundary.

Chapter 21

Tracer conservation

As seen in Chapter 20, the assumption of *mass conservation* has many implications for the motion of single-component fluids. In this chapter we extend that discussion to the case of a fluid comprised of multiple matter constituents (e.g., seawater comprised of fresh water, salt, nitrogen, oxygen, carbon, nutrients, biogeochemicals). In so doing we develop differential and integral budget equations for extensive properties, such as mass or tracer content, along with *continuity equations* for intensive properties, such as mass density and tracer concentration. The Leibniz-Reynolds transport theorem provides the link between the differential and integral formulations.

A key element in the formulation of mass budgets concerns the *barycentric velocity*, which is the center of mass velocity for a fluid element. The barycentric velocity is the extension to multi-component fluids of the fluid parcel velocity used in single-component fluids. Differences between the barycentric velocity and the velocity of a specific fluid constituent lead to the diffusion of matter constituents across the boundary of the fluid element.

READER'S GUIDE TO THIS CHAPTER

The formulation pursued in this chapter is inspired by similar treatments in the chemical physics literature (e.g., Chapter 11 of *Aris* (1962), Chapter II of *DeGroot and Mazur* (1984), or Section 2.1 of *Kreuzer* (1981)), who develop a theory for transport processes in multi-component fluids. For this chapter, we assume an understanding of the Eulerian and Lagrangian kinematic descriptions detailed in Chapter 18 and the mass conservation analysis in Chapter 20. Much of the material from this chapter is used for the study of scalar fields such as potential enthalpy and material tracers. Furthermore, the Leibniz-Reynolds transport theorem of Section 21.2.4 is a kinematic result central to all finite volume budgets in fluid mechanics.

21.1 The tracer equation

As defined in Section 18.3, a fluid element is an infinitesimal region of constant mass within the fluid continuum. Although possessing a constant mass, it generally has a non-constant material composition. That is, a fluid element is a non-material fluid parcel. Fluid element boundaries are open to the exchange of matter (i.e., tracers) with adjacent fluid elements. They are also open to the exchange of thermodynamic properties such as temperature and specific entropy.

The kinematics of fluid elements share certain features with material fluid parcels. For example, we can uniquely specify the position of a fluid element's center of mass by providing a material coordinate and time. Correspondingly, we can generalize the Reynolds transport theorem for integration over a constant mass fluid region (Section 21.2.4). We make use of fluid elements to develop the mass budgets for multi-component fluids such as the ocean and atmosphere. The constituent mass budgets are commonly referred to as *tracer equations*.

21.1.1 Mass conservation for each constituent

In this subsection we formulate the mass conservation equation for each constituent within the fluid. The mass equation is formulated by taking an integral (or weak formulation) approach over a fixed (Eulerian) region.

Density and velocity for each matter constituent

Consider a fluid with $n = 1, N$ matter constituents. For example, seawater has $N = 2$ when concerned just with its freshwater and salt content, whereas $N > 2$ when also concerned with other material constituents such as CO_2 and biogeochemical species. Now focus on a fixed (Eulerian) region of the fluid with volume V and total mass M. Inside of the region, count the number of molecules of each constituent and determine (at least, in principle) their corresponding velocities. This information can be used to construct the molecular center of mass velocity for each constituent, $\boldsymbol{v}^{(n)}$, as well as the mass density,

$$\rho^{(n)} = V^{-1} M^{(n)}. \tag{21.1}$$

In the continuum limit, the volume and mass in the region get tiny ($V \to \mathrm{d}V$ and $M \to \mathrm{d}M$), yet the mass density remains smooth and finite (see Figure 17.2). Correspondingly, the constituent velocity and mass density are continuous fields whose values are available at each point within the continuum fluid.

Integral formulation of the constituent mass budget

Consider an arbitrary region, $\mathcal{R}$, assumed to be fixed in space (an Eulerian region). The mass of component n within $\mathcal{R}$ is given by the integral

$$M^{(n)} = \int_{\mathcal{R}} \rho^{(n)} \, \mathrm{d}V, \tag{21.2}$$

and it changes in time according to the finite volume budget equation (there is no implied summation on the right hand side)

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} \rho^{(n)} \, \mathrm{d}V = - \oint_{\partial\mathcal{R}} \rho^{(n)} \, \boldsymbol{v}^{(n)} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{21.3}$$

This equation is a constituent form of the finite volume mass budget given for a single-component fluid by equation (20.9). Since the region, $\mathcal{R}$, is assumed to be fixed in space, we can move the time derivative across the integral to reveal

$$\int_{\mathcal{R}} \left[\frac{\partial \rho^{(n)}}{\partial t} + \nabla \cdot (\rho^{(n)} \, \boldsymbol{v}^{(n)}) \right] \mathrm{d}V = 0, \tag{21.4}$$

where we also used the divergence theorem to convert the surface integral to a volume integral. Arbitrariness of the region means that this integral expression must be satisfied at each point of the continuum, thus leading to the Eulerian form of the constituent mass continuity equation

$$\frac{\partial \rho^{(n)}}{\partial t} + \nabla \cdot (\rho^{(n)} \, \boldsymbol{v}^{(n)}) = 0. \tag{21.5}$$

This equation can also be written using a material time derivative

$$\frac{\mathrm{D}^{(n)} \rho^{(n)}}{\mathrm{D}t} = -\rho^{(n)} \, \nabla \cdot \boldsymbol{v}^{(n)} \qquad \text{for each of the } n = 1, N \text{ constituents}, \tag{21.6}$$

where the constituent material time derivative is given by

$$\frac{\mathrm{D}^{(n)}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}^{(n)} \cdot \nabla. \tag{21.7}$$

We thus have N statements of mass conservation corresponding to each constituent material fluid parcel moving according to the velocity, $\boldsymbol{v}^{(n)}$.

21.1.2 Total mass conservation

Summing the Eulerian mass continuity equation (21.5) over all constituents leads to the continuity equation for the total mass

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \, \boldsymbol{v}) = 0, \tag{21.8}$$

where the total mass density and *barycentric velocity* are given by

$$\rho = \sum_{n=1}^{N} \rho^{(n)} \qquad \text{and} \qquad \boldsymbol{v} = \rho^{-1} \sum_{n=1}^{N} \rho^{(n)} \, \boldsymbol{v}^{(n)}. \tag{21.9}$$

Introducing the material time derivative following the barycentric velocity, $\mathrm{D}/\mathrm{D}t = \partial/\partial t + \boldsymbol{v}\cdot\nabla$, leads to the equivalent material form for the mass conservation equation

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho\,\nabla\cdot\boldsymbol{v}. \tag{21.10}$$

The *barycenter* of a distribution of matter is the center of inertia for that matter. We choose the term barycentric velocity for $\boldsymbol{v}$ to distinguish it from the molecular *center of mass velocity*, $\boldsymbol{v}^{(n)}$, of each material constituent. The barycentric velocity plays a key role the conservation laws for multi-component fluids, largely since equations (21.8) and (21.10) are identical to the mass conservation equations holding for the homogeneous fluid derived in Section 20.2.

21.1.3 The tracer equation

Rather than keep track of each constituent velocity, $\boldsymbol{v}^{(n)}$, and the corresponding material parcels, it is generally more convenient to focus on the fluid element that moves with the barycentric velocity. For this purpose, we consider again the constituent mass continuity equation (21.5)

$$\left[\frac{\partial}{\partial t} + \boldsymbol{v}^{(n)}\cdot\nabla\right]\rho^{(n)} = -\rho^{(n)}\nabla\cdot\boldsymbol{v}^{(n)} \tag{21.11}$$

and insert the barycentric velocity to both sides by adding $0 = \boldsymbol{v} - \boldsymbol{v}$

$$\left[\frac{\partial}{\partial t} + (\boldsymbol{v} - \boldsymbol{v} + \boldsymbol{v}^{(n)})\cdot\nabla\right]\rho^{(n)} = -\rho^{(n)}\nabla\cdot[\boldsymbol{v} - \boldsymbol{v} + \boldsymbol{v}^{(n)}]. \tag{21.12}$$

Rearrangment leads to

$$\left[\frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla\right]\rho^{(n)} = -\rho^{(n)}\nabla\cdot\boldsymbol{v} - \nabla\cdot[\rho^{(n)}\,(\boldsymbol{v}^{(n)} - \boldsymbol{v})], \tag{21.13}$$

which can be written

$$\frac{\mathrm{D}\rho^{(n)}}{\mathrm{D}t} = -\rho^{(n)}\,\nabla\cdot\boldsymbol{v} - \nabla\cdot\boldsymbol{J}^{(n)}, \tag{21.14}$$

where we defined the constituent *tracer mass flux*

$$\boldsymbol{J}^{(n)} = \rho^{(n)}\,(\boldsymbol{v}^{(n)} - \boldsymbol{v}), \tag{21.15}$$

which arises from the difference between the constituent velocity and the barycentric velocity. The dimensions of $\boldsymbol{J}^{(n)}$ are mass of constituent n per time per area.

The material mass conservation equation (21.14) takes on the Eulerian form

$$\frac{\partial\rho^{(n)}}{\partial t} + \nabla\cdot(\boldsymbol{v}\,\rho^{(n)}) = -\nabla\cdot\boldsymbol{J}^{(n)}. \tag{21.16}$$

Introducing the tracer concentration $C^{(n)}$ according to

$$C^{(n)} = \frac{\rho^{(n)}}{\rho} = \frac{\delta M^{(n)}}{\delta M} = \frac{\text{mass of constituent } n \text{ in fluid element}}{\text{mass of fluid element}}, \tag{21.17}$$

leads to the tracer flux

$$\boldsymbol{J}^{(n)} = \rho\,C^{(n)}\,(\boldsymbol{v}^{(n)} - \boldsymbol{v}), \tag{21.18}$$

FIGURE 21.1: A finite sized cube as in Figure 20.1, here used to illustrate the budget of tracer mass over an Eulerian region. In addition to the advective flux of tracer moving with the barycentric velocity, $\boldsymbol{v}$, there is a flux, $\boldsymbol{J}$, that arises from differences between the barycentric velocity and the constituent velocity. Note that we here only show fluxes in the $\hat{\boldsymbol{y}}$ direction, with corresponding fluxes in the $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{z}}$ also contributing to the tracer budget.

and the flux-form tracer budget

$$\frac{\partial(\rho\, C^{(n)})}{\partial t} + \nabla \cdot [\boldsymbol{v}\,\rho\, C^{(n)} + \boldsymbol{J}^{(n)}] = 0. \tag{21.19}$$

In Figure 21.1 we illustrate the contributions to the tracer evolution according to equation (21.19).

Eulerian and Lagrangian forms of the tracer equation

The flux-form equation (21.19) has a corresponding material time derivative form derived by expanding the derivatives

$$\begin{aligned} C^{(n)}\,\frac{\partial \rho}{\partial t} + \rho\,\frac{\partial C^{(n)}}{\partial t} + \rho\,\boldsymbol{v}\cdot\nabla C^{(n)} + C^{(n)}\,\nabla\cdot(\rho\,\boldsymbol{v}) \\ = C^{(n)}\left[\frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\,\boldsymbol{v})\right] + \rho\left[\frac{\partial C^{(n)}}{\partial t} + \boldsymbol{v}\cdot\nabla C^{(n)}\right]. \end{aligned} \tag{21.20}$$

The first term on the right hand side vanishes through mass continuity in the form of equation (21.8). The second term on the right hand side is the material time derivative of the tracer concentration. We are thus led to the equivalent forms for the tracer equation[1]

$$\frac{\partial(\rho\, C^{(n)})}{\partial t} + \nabla\cdot[\boldsymbol{v}\,\rho\, C^{(n)}] = \rho\,\frac{\mathrm{D}C^{(n)}}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}^{(n)}. \tag{21.21}$$

Advective plus non-advective (diffusive) tracer fluxes

The above definitions allow us to decompose an advective tracer flux defined according to the tracer velocity into an advective flux based on the barycentric velocity plus a *non-advective flux*

$$\rho\, C^{(n)}\,\boldsymbol{v}^{(n)} = \rho\, C^{(n)}\,(\boldsymbol{v}^{(n)} - \boldsymbol{v} + \boldsymbol{v}) = \boldsymbol{J}^{(n)} + \rho\, C^{(n)}\,\boldsymbol{v}. \tag{21.22}$$

The non-advective flux vanishes when the tracer velocity equals to the barycentric velocity. Correspondingly, the non-advective flux also vanishes for a single-component fluid, since in that case

[1] The same result was also derived in equation (20.35c) when discussing Reynolds transport theorem for a single-component fluid.

there is only one matter component and so the constituent velocity equals to the barycentric velocity. We sometimes refer to the non-advective flux as a *diffusive flux* since it is common in practice to parameterize this term as a downgradient diffusive flux. However, as seen in Section 27.10.2, not all non-advective processes are downgradient. We also offer further discussion of diffusion due to turbulent processes in Chapter 66.

21.1.4 Compatibility between total mass and tracer mass

By construction, the flux-form of the tracer equation (21.19) is compatible with the flux-form continuity equation

$$\frac{\partial(\rho\, C^{(n)})}{\partial t} + \nabla\cdot[\rho\, \boldsymbol{v}\, C^{(n)} + \boldsymbol{J}^{(n)}] = 0 \Longleftrightarrow \frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\, \boldsymbol{v}) = 0. \tag{21.23}$$

Compatibility is manifest by summing the tracer equation over all constituents and using the identities

$$\sum_{n=1}^{N} C^{(n)} = 1 \qquad \text{and} \qquad \sum_{n=1}^{N} \boldsymbol{J}^{(n)} = 0. \tag{21.24}$$

Furthermore, through use of the barycentric velocity (21.9), we are ensured that the continuity equation (21.8) for the total density of a fluid element is only transported by the barycentric velocity. There is no contribution from $\boldsymbol{J}^{(n)}$ since $\sum_{n=1}^{N} \boldsymbol{J}^{(n)} = 0$.

21.1.5 Passive tracers

As defined in equation (21.17), the concentration of a material tracer is the mass of the trace constituent per mass of a fluid element. Such material tracers modify the barycentric velocity (21.9) since they carry mass and thus affect the mass density. We here define the idealized construct known as a *passive tracer*. A passive tracer satisfies the advection-diffusion equation, but it has zero impact on the velocity and is thus dynamically passive. The passive tracer is thus analogous to the massless fluid particle of Section 18.3 whose trajectories define the Lagrangian reference frame. However, the passive tracer is transported both via advection and diffusion. Hence, we make use of passive tracers to probe the advective and diffusive features of the flow without modifying the flow. For example, a passive tracer can be used to define tracer pathways and time scales for transport between fluid regions, such as reviewed by *Haine et al.* (2024) for ocean applications.

In Chapter 19 and Section 20.4.2, we discussed the notion of a material fluid object, which is an object comprised of fluid particles that follow the velocity, $\boldsymbol{v}$. In a single-component fluid, such material objects are impenetrable to matter, by construction. For a multi-component fluid, trace matter will generally cross the material object through diffusion since $\boldsymbol{v}^{(n)} \neq \boldsymbol{v}$. Hence, there is no perfectly impenetrable fluid object in a fluid with any form of diffusion, including molecular diffusion. However, we can conceive of a passive tracer that follows the barycentric velocity and is either acted on by diffusion or is unaffected by diffusion. Again, these features are afforded the passive tracer given that it is a conceptual idealization used to probe the fluid flow properties. Hence, the passive tracer is not subject to the same physical constraints as a material tracer.

21.1.6 Summary of some conceptual points

What is a fluid element? How does it maintain constant mass but not constant matter? Here we aim to review some of the conceptual points to help answer these puzzles, building from our initial specification of fluid elements and fluid parcels in Section 18.3.

Revisiting a fluid element

The mass continuity equation (21.10) motivates us to define a fluid element as an infinitesimal fluid parcel that moves with barycentric velocity, $\boldsymbol{v}$, and maintains a constant total mass

$$\delta M = \sum_{n=1}^{N} \delta M^{(n)}. \tag{21.25}$$

The fluid element does not maintain a constant mass for each constituent, since the fluid element moves at the barycentric velocity, $\boldsymbol{v}$, which generally differs from the constituent velocities $\boldsymbol{v}^{(n)}$. Consequently, a fluid element boundary is permeable to matter transport that leaves its mass constant but allows for exchanges of matter constituents with adjacent fluid elements. Hence, if some matter leaves the fluid element, then an equal amount must enter the element in order to maintain a constant mass.

The exchange of matter across a fluid element's boundary can arise from the direct motion of matter crossing the boundary, or from the motion of the fluid element boundary relative to the matter. This point is central to resolving conundrums associated with the notion of matter exchange constrained to retain constant mass.

Conceptual summary of the formulation

The formulation pursued in this section is based on considering the multi-component fluid to be a continuum with distinct matter constituents (e.g., salt and freshwater for the ocean or water vapor and dry air for the atmosphere). Furthermore, the mass concentration for each constituent is represented by a scalar field whose value at any point in space-time gives the mass of tracer per mass of fluid. We then formulate mass conservation equations (i.e., continuity equations) for each matter constituent following methods used for the single-component fluid in Chapter 20. By choosing to use the *barycentric* (center of mass) velocity for describing fluid flow, the mass continuity equation for the total mass in a fluid element takes on the same form as for a single-component fluid. The resulting constituent mass budgets (i.e., tracer equations) have non-advective (diffusive) fluxes since the velocity of each matter constituent is generally distinct from the barycentric velocity.

To expose a bit of the details, we saw in this section that the tracer equation expresses the balance of mass for each trace constituent in the fluid. Furthermore, a nonzero tracer flux, $\boldsymbol{J}^{(n)} = \rho\, C^{(n)}\, (\boldsymbol{v}^{(n)} - \boldsymbol{v})$, arises when the barycentric velocity, $\boldsymbol{v}$, differs from the constituent velocity, $\boldsymbol{v}^{(n)}$. In that case, matter and thermodynamic properties are exchanged between fluid elements, with the exchange made without altering the mass of a fluid element. In the presence of random motion within a turbulent fluid, or in the presence of random interactions with molecular degrees of freedom, tracer exchange is akin to a random walk. Such exchange is commonly parameterized by a diffusion process (see Section 64.3). Correspondingly, the mass of tracers in a fluid element is altered in the presence of differences in tracer concentration between fluid elements (i.e., tracer concentration gradients). However, the total mass of the element remains fixed.

How to maintain constant mass

As defined, a fluid element provides a generalization to multi-component fluids of the notion of a constant mass material fluid parcel that we used in describing a single-component fluid (see Section 18.3). Later in this chapter we encounter a finite volume extension of the fluid element, which we refer to as a *Lagrangian region*. A Lagrangian region has boundaries that follow the barycentric

velocity, $\boldsymbol{v}$, so that the region maintains constant mass as per our discussion of Reynolds transport theorem in Section 21.2.6.

To maintain constant mass, any matter that leaves the fluid element by crossing its boundary is compensated by an equal mass that enters the boundary. Kinematically, there are two means for matter to cross a boundary. First, the matter itself can move across the boundary, with the limiting case being a stationary boundary with matter moving across. Second, the boundary can move relative to the matter, with the limiting case being stationary matter with the boundary moving. In either case, by choosing to follow the barycentric velocity, a fluid element's boundary (or a corresponding Lagrangian region's boundary) adjusts so that mass remains constant.

The strategic choice to formulate the kinematics of multi-component fluids using the barycentric velocity is directly analogous to the choice in Newtonian mechanics to describe motion relative to the center of mass for a system of many moving objects such as planets or point particles (see Section 11.5). In particular, by describing the motion of a multi-component fluid using the barycentric velocity, we simplify the kinematics by linking to the kinematics of single-component fluids while also supporting a generalization in the form of constituent tracer equations. As seen in Part V of this book, a dynamical description of fluid motion is also facilitated by working with constant mass fluid elements/regions.

The importance of compatibility

In Section 21.1.4, we introduced the notion of compatibility between the tracer equation and mass continuity equation. On first encounter, one might consider it a rather trivial consequence of the formulation. Indeed, mathematically it is rather trivial, as it directly follows from our choice to describe motion according to the barycentric velocity. However, it is a notion that can sometimes be overlooked when in the midst of a formulation that decomposes the flow into mean components and deviations, as occurs with studies of turbulent flows. The key point to remember is that whatever form the mean-field mass continuity equation takes, one must retain a clear formulation of mass conservation. Doing so may require modification of the effective barycentric velocity in the presence of turbulent fluctuations.

As an example, let $\overline{\rho}$ and $\overline{\boldsymbol{v}}$ be the mean density and mean velocity, where "mean" can represent any number of averaging operators, and let primes denote deviations from the means. The mass continuity equation for the mean density thus takes the form

$$\partial_t \overline{\rho} + \nabla \cdot (\overline{\rho}\, \overline{\boldsymbol{v}}) = 0. \tag{21.26}$$

Introducing the density-weighted velocity

$$\boldsymbol{v}^{\mathrm{H}} \equiv \overline{\rho\, \boldsymbol{v}}/\overline{\rho} = \overline{\boldsymbol{v}} + \overline{\rho'\, \boldsymbol{v}'}/\overline{\rho} \tag{21.27}$$

renders the mean continuity equation

$$\partial_t \overline{\rho} + \nabla \cdot (\overline{\rho}\, \boldsymbol{v}^{\mathrm{H}}) = 0. \tag{21.28}$$

The density-weighted velocity, $\boldsymbol{v}^{\mathrm{H}}$, is motivated by the work of *Hesselberg* (1926) and *Favre* (1965), with further details for its use in the full suite of dynamical equations summarized in Chapter 8 of *Griffies* (2004). Rather than pursue details here, we use it simply to illustrate how one may choose to work with averaged equations in a manner that retains a clear sense for mass conservation. Namely, by introducing $\boldsymbol{v}^{\mathrm{H}}$, which can be considered a modified barycentric velocity, the mean mass conservation equation (21.28) takes on the same form as the un-averaged mass equation (21.8). In this manner we see that $\boldsymbol{v}^{\mathrm{H}}$, rather than $\overline{\boldsymbol{v}}$, advects the mean fluid mass density.

21.1.7 Further study

We used many words in this section to develop the mass budget for fluid elements in a multi-component fluid. The reason for such verbosity is that the formulation can be confusing on first encounter. Even so, it is important to keep in mind that the basic notions are quite simple. Further extension of these ideas incorporates chemical reactions that transfer mass from one matter constituent to others, while retaining fixed net mass. This extension is relevant for studies of atmospheric chemistry and ocean bioegeochemistry. Development of these extensions, using nomenclature similar to that used here, is provided in Chapter 11 of *Aris* (1962), Chapter II of *DeGroot and Mazur* (1984), and Section 2.1 of *Kreuzer* (1981).

The tracer fluxes introduced when formulating the tracer equation are typically parameterized by downgradient diffusion. However, as discussed in our study of the ocean entropy budget in Section 27.10, the transport of a scalar field can arise both from spatial gradients in that field as well as gradients in other fluid properties. These fluxes arise as a result of fundamental constraints from the second law of thermodynamics, and as such they are part of the suite of processes contributing to the transport of scalar properties in a multi-component fluid.

21.2 Budgets for arbitrary fluid regions

Thus far in this chapter we have considered the evolution of mass within a variety of fluid regions, including infinitesimal and finite domains either moving with the fluid or fixed in space. We have also considered similar domains in Chapter 20 where the fluid domains were typically material regions. In this section we synthesize these presentations by considering mass budgets over an arbitrary finite sized domain within multi-component fluids. The resulting mass equations form the basis for matter budgets used in geophysical fluid mechanics.

21.2.1 Extensive and intensive fluid properties

Consider a bucket of seawater that has homogeneous temperature and salinity. Removing a cup of water from this bucket does not alter the temperature or salinity, but it does alter the enthalpy, salt mass, and freshwater mass. We are thus motivated to characterize physical properties as *extensive* or *intensive*. For the bucket of seawater, temperature and salinity are intensive quantities, whose value does not change when removing seawater from the bucket. Further intensive properties include number density (number of particles per volume), mass density (mass of substance per volume), tracer concentration (mass of tracer per mass of fluid), temperature, velocity (linear momentum per mass), kinetic energy per mass, entropy per mass, and enthalpy per mass. An extensive property changes when the size of the sample changes, with examples including particle number, mass, length, volume, kinetic energy, entropy, enthalpy, and linear momentum.[2]

We are concerned in this section with how scalar extensive properties change as a function of time.[3] Determining the evolution of such properties constitutes a budget analysis for the scalar property. What are the processes responsible for these changes? Where are the changes coming from? Those are basic questions asked when performing a budget analysis. In addition to physical and biogeochemical processes active within the fluid, details of the region over which one performs a budget have an important impact on the budget. Is the region open to matter and energy transport, or is it closed? Is the region static (Eulerian) or do boundaries move? If the boundaries move, do they move with fluid elements (Lagrangian) or are they moving in some other manner (arbitrary)?

[2] We again encounter intensive and extensive properties when studying thermodynamics in Chapter 23.

[3] We consider budget equations for vector linear momentum in Chapter 25.

In the following, let Π represent an intensive scalar property of a fluid element so that $\Pi\,\rho\,\delta V$ is the corresponding extensive property

$$\Pi = \text{intensive fluid property such as tracer concentration} \tag{21.29a}$$

$$\Pi\,\rho\,\delta V = \text{extensive fluid property such as tracer mass.} \tag{21.29b}$$

For example, if Π is the tracer concentration in a fluid element (i.e., mass of tracer per mass of fluid), then the corresponding extensive property, $\Pi\,\rho\,\delta V$, is the mass of tracer in the fluid element. Anticipating our discussion in Section 27.11, then if Π is the Conservative Temperature, Θ, of a fluid element, then the corresponding extensive property, $\Theta\,c_{\mathrm{p}}\,\rho\,\delta V$, is the potential enthalpy with c_{p} the specific heat capacity.

We furthermore assume that Π satisfies the scalar conservation equation, written here in both its material (or advective) form and flux-form

$$\rho\,\frac{\mathrm{D}\Pi}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J} \qquad \Longleftrightarrow \qquad \frac{\partial(\rho\,\Pi)}{\partial t} + \nabla\cdot(\rho\,\Pi\,\boldsymbol{v} + \boldsymbol{J}) = 0, \tag{21.30}$$

where $\boldsymbol{J}$ is a flux such as that associated with the tracer equation derived in Section 21.1.3. Depending on the context, the budget equation (21.30) is sometimes referred to as a *conservation law* for Π. Notably, satisfaction of a conservation law does not mean that Π is constant either at a point in space nor following a fluid particle. Instead, there are two cases of "constancy" that naturally arise. First, with $-\nabla\cdot\boldsymbol{J} = 0$, the scalar field is constant following a material fluid particle

$$-\nabla\cdot\boldsymbol{J} = 0 \Longrightarrow \frac{\mathrm{D}\Pi}{\mathrm{D}t} = 0. \tag{21.31}$$

In this case we say that Π is a *material invariant* or a *material constant*. Second, if the Eulerian time derivative vanishes, $\partial_t\Pi = 0$, then Π remains constant at a fixed spatial point in the fluid and we say that Π is in a *steady state*. Furthermore, recall that the Eulerian reference frame is stationary with respect to a laboratory frame, with the laboratory frame inertial when connected by a Galilean transformation to the universal Newtonian reference frame (Section 18.4). Hence, if the flow in one laboratory frame is steady, then flow in all laboratory frames is steady so long as the laboratory frames are connected by a Galilean transformation (see Section 18.9).

21.2.2 General form of the finite domain integral

We are concerned here with the evolution of extensive fluid properties integrated over an arbitrary region. Let us make use of the following notation for such integrals

$$\mathcal{I}[\mathcal{R}(t), t] = \int_{\mathcal{R}(t)} \Pi\,\rho\,\mathrm{d}V \equiv \int_{\mathcal{R}(t)} \varphi\,\mathrm{d}V, \tag{21.32}$$

where we introduced the shorthand

$$\varphi = \rho\,\Pi. \tag{21.33}$$

The integrand in equation (21.32) is a function of space and time, $\varphi = \varphi(\boldsymbol{x}, t)$, and the integration region is generally a function of time, $\mathcal{R}(t)$. In previous sections, $\mathcal{R}$ was a material region of fixed matter content (Section 20.3) or a constant mass fluid region open to the exchange of matter with the surroundings (Section 21.1). In both of these cases the region was denoted by $\mathcal{R}(\boldsymbol{v})$ since it moved with the fluid flow. Here we make no *a priori* assumption about the region.

The total time derivative of $\mathcal{I}$ can be written as

$$\frac{\mathrm{d}\mathcal{I}}{\mathrm{d}t} = \left[\frac{\partial \mathcal{I}}{\partial t}\right]_{\mathcal{R}} + \frac{\mathrm{d}\mathcal{R}}{\mathrm{d}t}\left[\frac{\partial \mathcal{I}}{\partial \mathcal{R}}\right]_t . \tag{21.34}$$

The first term on the right hand side is the time derivative of the integral when holding the region fixed in space as per an Eulerian time derivative. The second term accounts for changes due to evolution of the region as weighted by dependence of the integral on the region itself. How the integral changes in time depends on both the evolution of the fluid property relative to the chosen region and evolution of the fluid region itself. Equation (21.34) is directly analogous to the total time derivative of a field in a moving fluid as given by equation (18.29).

21.2.3 Eulerian (static) domain

We first consider an Eulerian domain, which is fixed in space and thus static so that

$$\frac{\mathrm{d}\mathcal{I}}{\mathrm{d}t} = \left[\frac{\partial \mathcal{I}}{\partial t}\right]_{\mathcal{R}} = \frac{\partial}{\partial t}\left[\int_{\mathcal{R}} \Pi\,\rho\,\mathrm{d}V\right] = \int_{\mathcal{R}}\left[\frac{\partial(\rho\,\Pi)}{\partial t}\right]\mathrm{d}V. \tag{21.35}$$

Movement of the time derivative across the integral sign is available since the domain boundaries are static; i.e., the second term on the right hand side of equation (21.34) vanishes. Furthermore, since the domain is static, the volume element, $\mathrm{d}V$, provides a static partition of the total domain volume so that $\mathrm{d}V$ does not appear inside the time derivative. This case corresponds to the Eulerian budgets depicted in Figures 20.1, 20.2, and 21.1.

21.2.4 Deriving the Leibniz-Reynolds transport theorem

We now allow the domain boundaries to be time dependent so that both terms in the total time derivative (21.34) contribute. The resulting *Leibniz-Reynolds transport theorem* is a general expression of conservation over an arbitrary region. We derive this theorem here using two methods, one naive and another a bit more rigorous. Interpretation and application of this theorem are then presented in Section 21.2.5.

A rectangular region

Consider a one-dimensional domain with time dependent endpoints. Integrals of this type commonly arise when integrating over the depth of the atmosphere or ocean, in which case the boundary terms are replaced by the kinematic boundary conditions studied in Section 20.4. The chain rule for differentiating integrals is known as *Leibniz's rule*. It results in the time derivative acting on the upper integral limit, the lower limit, and the integrand

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{x_1(t)}^{x_2(t)} \varphi(x,t)\,\mathrm{d}x\right] = \int_{x_1(t)}^{x_2(t)} \frac{\partial \varphi}{\partial t}\,\mathrm{d}x + \frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{x_1(t)}^{x_2(t)}\right]\varphi(x,t)\,\mathrm{d}x \tag{21.36a}$$

$$= \int_{x_1(t)}^{x_2(t)} \frac{\partial \varphi}{\partial t}\,\mathrm{d}x + \frac{\mathrm{d}x_2(t)}{\mathrm{d}t}\varphi(x_2,t) - \frac{\mathrm{d}x_1(t)}{\mathrm{d}t}\varphi(x_1,t), \tag{21.36b}$$

with the terms $\mathrm{d}x_{1,2}/\mathrm{d}t$ the velocities of the endpoints.

We can generalize the one-dimensional result (21.36b) to three dimensions by assuming the three dimensional domain is expressible by Cartesian coordinates whose extents are mutually independent. That is, we assume the domain, $\mathcal{R}(t)$, is rectangular. In this case we can immediately

generalize equation (21.36b) to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \varphi \,\mathrm{d}V\right] = \int_{\mathcal{R}} \frac{\partial \varphi}{\partial t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \varphi\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{21.37}$$

where we introduced the shorthand for the velocity of a point on the region boundary

$$\boldsymbol{v}^{(b)} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t}. \tag{21.38}$$

The identity (21.37) is the *Leibniz-Reynolds transport theorem.*

An arbitrary simply connected region

We now present the derivation for an arbitrary simply connected domain, $\mathcal{R}(t)$, thus generalizing the domain geometry while offering further insight into the transport theorem. For this purpose, again let the region boundary, $\partial\mathcal{R}$, have an outward unit normal, $\hat{\boldsymbol{n}}$, and let points on the boundary move with the velocity, $\boldsymbol{v}^{(b)}$. In Figure 21.2 we depict the region geometry as it evolves over a time step of size, Δt. In particular, this figure illustrates the identity[4]

$$\mathcal{R}(t+\Delta t/2) = \mathcal{R}(t-\Delta t/2) + [\mathcal{R}(t+\Delta t/2) - \mathcal{R}(t-\Delta t/2)], \tag{21.39}$$

with the corresponding equation for the region volume given by

$$\int_{\mathcal{R}(t+\Delta t/2)} \mathrm{d}V = \int_{\mathcal{R}(t-\Delta t/2)} \mathrm{d}V + \int_{\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)} \mathrm{d}V. \tag{21.40}$$

From Figure 21.2 we see that the volume of the time incremented region, $\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)$, in the limit $\Delta t \to 0$, is given by

$$\lim_{\Delta t\to 0} \frac{1}{\Delta t}\int_{\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)} \mathrm{d}V = \lim_{\Delta t\to 0} \frac{1}{\Delta t}\left[\int_{\mathcal{R}(t+\Delta t/2)} \mathrm{d}V - \int_{\mathcal{R}(t-\Delta t/2)} \mathrm{d}V\right] \tag{21.41a}$$

$$= \frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(t)} \mathrm{d}V\right] \tag{21.41b}$$

$$= \oint_{\partial\mathcal{R}(t)} \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{21.41c}$$

The final equality follows since $\boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}$ measures the rate that the boundary is moving normal to itself, so that its area integral over $\partial\mathcal{R}(t)$ measures the rate that the volume of $\mathcal{R}(t)$ changes. It is the analog to the Lagrangian result (20.23) measuring the change in volume of a material region following the fluid flow.

The above ideas used to derive the volume budget equation (21.41c) are now applied when

[4]For those familiar with numerical methods, note that we make use of centered finite time differences in this discussion. Doing so offers a second order accurate expression of the finite difference approximations to the time derivative, whereas forward or backward differences are only first order accurate. Central differences also provides an intuitive centering of the time differences around the central time, t.

FIGURE 21.2: Illustrating the geometry of the Leibniz-Reynolds transport theorem. The region at time $t+\Delta t/2$, is written as $\mathcal{R}(t+\Delta t/2)$, which results from changing $\mathcal{R}(t-\Delta t/2)$ by the increment $\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)$. We here depict the case with an expanding boundary that renders a larger volume at $t+\Delta t/2$. At each point along the boundary the velocity of the boundary, $\boldsymbol{v}^{(b)}$, has an outward normal projection, $\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}$. The product $\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\,\Delta t$ measures the distance that the boundary moves over the time increment, Δt. Hence, area integrating $\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}$ over the boundary yields the rate that the region volume changes.

$\varphi(\boldsymbol{x},t)$ is included within the integral, in which case we consider

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(t)}\varphi(t)\,\mathrm{d}V\right]=\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left[\int_{\mathcal{R}(t+\Delta t/2)}\varphi(t+\Delta t/2)\,\mathrm{d}V-\int_{\mathcal{R}(t-\Delta t/2)}\varphi(t-\Delta t/2)\,\mathrm{d}V\right]. \tag{21.42}$$

Note that for brevity we suppressed the $\boldsymbol{x}$ functional dependence of $\varphi(\boldsymbol{x},t)$. Expanding the first integral on the right hand side around the central time leads to the expression, which is accurate to $\mathcal{O}(\Delta t)^2$,

$$\begin{aligned}\int_{\mathcal{R}(t+\Delta t/2)}&\varphi(t+\Delta t/2)\,\mathrm{d}V\\ &=\int_{\mathcal{R}(t)}\left[\varphi(t)+\frac{\Delta t}{2}\frac{\partial\varphi(t)}{\partial t}\right]\mathrm{d}V+\int_{\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t)}\left[\varphi(t)+\frac{\Delta t}{2}\frac{\partial\varphi(t)}{\partial t}\right]\mathrm{d}V.\end{aligned} \tag{21.43}$$

We have a similar expansion for the second integral in equation (21.42)

$$\begin{aligned}\int_{\mathcal{R}(t-\Delta t/2)}&\varphi(t-\Delta t/2)\,\mathrm{d}V\\ &=\int_{\mathcal{R}(t)}\left[\varphi(t)-\frac{\Delta t}{2}\frac{\partial\varphi(t)}{\partial t}\right]\mathrm{d}V+\int_{\mathcal{R}(t-\Delta t/2)-\mathcal{R}(t)}\left[\varphi(t)-\frac{\Delta t}{2}\frac{\partial\varphi(t)}{\partial t}\right]\mathrm{d}V,\end{aligned} \tag{21.44}$$

thus leading to the finite difference

$$\begin{aligned}\int_{\mathcal{R}(t+\Delta t/2)}\varphi(t+\Delta t/2)\,\mathrm{d}V-\int_{\mathcal{R}(t-\Delta t/2)}&\varphi(t-\Delta t/2)\,\mathrm{d}V\\ &=\Delta t\int_{\mathcal{R}(t)}\frac{\partial\varphi(t)}{\partial t}\,\mathrm{d}V+\int_{\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)}\varphi(t)\,\mathrm{d}V,\end{aligned} \tag{21.45}$$

which is again accurate to $\mathcal{O}(\Delta t)^2$. Following our derivation of equation (21.41c) leads us to

$$\int_{\mathcal{R}(t+\Delta t/2)-\mathcal{R}(t-\Delta t/2)}\varphi(t)\,\mathrm{d}V=\Delta t\oint_{\partial\mathcal{R}(t)}\varphi\,\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{21.46}$$

where all terms on the right hand side surface integral are evaluated at the central time, t.

Bringing the pieces together, and taking the limit as $\Delta t \to 0$, leads to the Leibniz-Reynolds transport theorem

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(t)} \varphi(t)\,\mathrm{d}V\right] = \int_{\mathcal{R}(t)} \frac{\partial \varphi}{\partial t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}(t)} \varphi\,\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{21.47}$$

which agrees with the earlier result given by equation (21.37).

21.2.5 Interpreting the Leibniz-Reynolds transport theorem

The Leibniz-Reynolds transport theorem (21.37) is a central kinematic result in fluid mechanics since it forms the starting point for all finite volume budgets. Although we made use of Cartesian coordinates for both derivations, the result is a coordinate invariant measure of how an extensive fluid property evolves within a region. Hence, by the rules of tensor analysis from Chapter 9, the result holds for arbitrary coordinates. Furthermore, we can extend it to multiply connected domains for which one sums over the distinct sub-domains to render the complete budget. These results confirm our notions regarding extensive properties, such as fluid mass, tracer mass, and enthalpy, and how they are budgeted throughout the fluid. Namely, these quantities are simply counted over the various regions of the fluid.

Comments on the boundary velocity

The appearance of the boundary velocity, $\boldsymbol{v}^{(b)}$, warrants some comment. As defined by equation (21.38), it measures the velocity of a point on the domain boundary. Notably, the resulting budget only requires information about the normal component to that velocity, $\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}$. For example, the domain boundary could be exhibiting arbitrary motion in the direction tangent to the bounding surface. Yet such tangential motion is of no concern for a budget developed over the domain since we are only concerned with transport across the boundary. Indeed, information concerning the tangential component is not available without making dynamical assumptions that go beyond the kinematics considered here. We encountered the same ideas when studying the kinematic boundary conditions in Section 20.4.

Transport theorem for region volume

As part of the general derivation, we derived the expression (21.41c) for the volume changes of the region, which is recovered by setting $\varphi = 1$ in the transport theorem (21.37)

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \mathrm{d}V\right] = \oint_{\partial\mathcal{R}} \boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{21.48}$$

This result says that the volume for an arbitrary region changes in time so long as there is motion of the region boundary normal to itself. As noted above, we can compare this expression to that for a material region given by equation (20.23), with the expressions identical when $\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}} = \boldsymbol{v}\cdot\hat{\boldsymbol{n}}$ for a material region. Note that the general volume budget (21.48) holds for both divergent and non-divergent flows, with further specialization to the non-divergent (incompressible) case considered in Section 22.6.2.

Transport theorem for a scalar field

We can derive a corollary to the transport theorem (21.37) that proves useful for budget analyses over moving regions. For this purpose, make use of the flux-form of the scalar conservation

equation (21.30) so that the transport theorem is written

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \left[\rho\,\Pi\,(\boldsymbol{v}-\boldsymbol{v}^{(b)}) + \boldsymbol{J}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{21.49}$$

Setting $\Pi = 1$ gives an expression for the change in mass for the region

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \rho\,(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{21.50}$$

The transport theorem (21.49) has a straightforward interpretation. Namely, the left hand side is the time tendency for the total Π-stuff within the moving region. The right hand side is the surface area integral of the flux of Π-stuff through the boundary of the region. The first right hand side term arises from the difference between the barycentric fluid velocity and the velocity of the boundary, and the second term arises from the non-advective (e.g., diffusive) flux. Both fluxes are projected onto the outward normal at the boundary and then integrated over the surface area. Hence, the budget is not affected by fluxes tangential to the boundary. Finally, for the mass budget (21.50), the non-advective flux vanishes since the mass of a fluid element moves according to the barycentric velocity of Section (21.1.2).

In Figure 21.3 we illustrate the transport theorem (21.49) for the special case of a discrete numerical model grid cell. This cell has fixed positions for the vertical sides whereas the top and bottom interfaces are time dependent. This application of the transport theorem provides the framework for finite volume methods in numerical models (e.g., *Griffies et al.* (2020)). We offer further discussion of the kinematics of such *general vertical coordinate* models in Chapter 60 and their dynamics in Chapter 61.

21.2.6 Revisiting Reynolds transport theorem

Consider the special case of a region that is moving with the fluid flow, in which case we provide a more general derivation of the *Reynolds transport theorem* than originally given for material regions in Section 20.3.4. The following results are special cases of the general expression (21.49).

Reynolds Transport Theorem

Let us apply the result (21.37) to a region that follows the fluid flow as defined by the barycentric velocity, $\boldsymbol{v}$. For this moving region, the time derivative of the region boundaries in equation (21.37) is given by the fluid velocity thus leading to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(\boldsymbol{v})} \varphi\,\mathrm{d}V\right] = \int_{\mathcal{R}(\boldsymbol{v})} \left[\frac{\partial\varphi}{\partial t} + \nabla\cdot(\boldsymbol{v}\,\varphi)\right]\mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \left[\frac{\mathrm{D}\varphi}{\mathrm{D}t} + \varphi\,\nabla\cdot\boldsymbol{v}\right]\mathrm{d}V. \tag{21.51}$$

This result is the Reynolds transport theorem. The derivation given here is more general than that in Section 20.3.4, with that derivation assuming the region to be material (i.e., no matter crosses the region boundary). For the present derivation we only assumed that the region boundaries move so that $(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}} = 0$, where again $\boldsymbol{v}$ is the barycentric velocity. We did not assume the region boundaries are material. We can thus make use of Reynolds transport theorem (21.51) for constant mass regions of a multi-component fluid so long as $(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}} = 0$. Furthermore, the region boundary is generally permeable via the non-advective (diffusive) tracer fluxes.

FIGURE 21.3: This figure depicts the contributions to the Leibniz-Reynolds transport theorem (21.49). The theorem is applied to a domain corresponding to a numerical model grid cell with the top and bottom interfaces defined by generalized vertical coordinates of Chapters 59, 60, and 61. In particular, the vertical cell faces are assumed to have fixed positions, so that $(\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} = \boldsymbol{v} \cdot \hat{\boldsymbol{n}}$ for these cell faces. Hence, the fluxes crossing these faces are due to advection by the barycentric velocity plus and contributions from non-advective (e.g., diffusive) fluxes. However, the top and bottom faces of the cell are allowed to move according to the generalized vertical coordinate surfaces. Hence, transport through these faces must take into account the nonzero velocity of the boundaries. Note that numerical models generally assume the top and bottom interfaces have a nonzero projection in the vertical direction so that they never overturn (e.g., *Griffies et al.* (2020)).

Alternative form of Reynolds Transport Theorem

We can put the Reynolds Transport Theorem (21.51) into another useful form by reintroducing $\varphi = \rho\, \Pi$ and making use of mass continuity

$$\frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{v}. \tag{21.52}$$

Doing so yields the rather tidy result

$$\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\mathcal{R}(\boldsymbol{v})} \Pi\, \rho\, \mathrm{d}V \right] = \int_{\mathcal{R}(\boldsymbol{v})} \left[\frac{\mathrm{D}\varphi}{\mathrm{D}t} + \varphi\, \nabla \cdot \boldsymbol{v} \right] \mathrm{d}V \qquad \text{Reynolds (21.51)} \tag{21.53a}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})} \left[\frac{\mathrm{D}(\rho\, \Pi)}{\mathrm{D}t} + \rho\, \Pi\, \nabla \cdot \boldsymbol{v} \right] \mathrm{d}V \qquad \varphi = \rho\, \Pi \tag{21.53b}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})} \left[\Pi \left(\frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho\, \nabla \cdot \boldsymbol{v} \right) + \rho\, \frac{\mathrm{D}\Pi}{\mathrm{D}t} \right] \mathrm{d}V \qquad \text{product rule} \tag{21.53c}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})} \frac{\mathrm{D}\Pi}{\mathrm{D}t}\, \rho\, \mathrm{d}V. \qquad \text{mass continuity (21.10)} \tag{21.53d}$$

Heuristically, this result follows since $\rho\, \mathrm{d}V$ is a constant when following the flow, so that passage of the time derivative across the material integral only picks up the material derivative of Π.

We can take the result (21.53d) one more step by inserting the material form of the scalar

conservation equation (21.30) so that

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(\boldsymbol{v})} \Pi\,\rho\,\mathrm{d}V\right] = -\oint_{\partial\mathcal{R}(\boldsymbol{v})} \boldsymbol{J}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{21.54}$$

which is a special case of the general transport theorem (21.49) found by setting $(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}}=0$ along the region boundary. This result says that the change in Π-stuff within a region moving with the barycentric velocity arises only from the area integrated non-advective flux crossing normal to the boundary. It is a finite volume generalization of the mass conservation statement for a fluid element as discussed in Section 21.1.3. We can set $\Pi = 1$ to render a statement of mass conservation for a Lagrangian region

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(\boldsymbol{v})} \rho\,\mathrm{d}V\right] = 0, \tag{21.55}$$

where the non-advective flux, $\boldsymbol{J}$, vanishes for the mass.

21.2.7 Summary of the time derivatives acting on integrals

We here summarize the variety of time derivatives acting on integrals of scalar fields

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V = \begin{cases} \int_{\mathcal{R}} \frac{\partial(\rho\,\Pi)}{\partial t}\,\mathrm{d}V = -\oint_{\partial\mathcal{R}} (\rho\,\boldsymbol{v}\,\Pi + \boldsymbol{J})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} & \text{Eulerian } \mathcal{R} \\ \int_{\mathcal{R}(\boldsymbol{v})} \rho\,\frac{\mathrm{D}\Pi}{\mathrm{D}t}\,\mathrm{d}V = -\oint_{\partial\mathcal{R}(\boldsymbol{v})} \boldsymbol{J}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} & \text{Lagrangian } \mathcal{R}(\boldsymbol{v}) \\ -\oint_{\partial\mathcal{R}} \left[\rho\,\Pi\,(\boldsymbol{v}-\boldsymbol{v}^{(b)}) + \boldsymbol{J}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} & \text{arbitrary } \mathcal{R}, \end{cases} \tag{21.56}$$

with the scalar fields assumed to satisfy the flux-form conservation equation

$$\rho\,\frac{\mathrm{D}\Pi}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J} \Longleftrightarrow \frac{\partial(\rho\,\Pi)}{\partial t} + \nabla\cdot(\rho\,\boldsymbol{v}\,\Pi + \boldsymbol{J}) = 0. \tag{21.57}$$

As discussed in Section 18.2, the partial differential equation (21.57) is referred to as the *strong formulation* of the scalar budget, whereas the integral expressions in equation (21.56) provide a variety of *weak formulations*. We thus see how the Leibniz-Reynolds transport theorem provides the mathematical framework to move between the strong form and weak form of the scalar bugets.

21.3 Brute force illustration of Leibniz-Reynolds

The Leibniz-Reynolds transport theorem

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V\right] = -\int_{\partial\mathcal{R}} \left[\rho\,\Pi\,(\boldsymbol{v}-\boldsymbol{v}^{(b)}) + \boldsymbol{J}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{21.58}$$

is an incredibly useful and elegant expression of the scalar budget over an arbitrary domain. Correspondingly, we make great use of it throughout this book. To further our understanding, we here consider the scalar budget for an ocean domain such as in Figure 21.4. Rather than make direct use of Leibniz-Reynolds, we use a brute force approach by expanding the volume integral according to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V\right] = \frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{A(t)} \mathrm{d}A \int_{\eta_{\mathrm{b}}}^{\eta} \rho\,\Pi\,\mathrm{d}z\right]. \tag{21.59}$$

In this equation, $\int_{A(t)} \mathrm{d}A$ is an integral over the horizontal area of the domain, with the lateral boundaries of the domain generally a function of time. This exercise requires the use of various kinematic boundary conditions and provides further practice with the Leibniz rule.

FIGURE 21.4: A depiction of fluid layers in which we formulate the budget for the total mass of scalar (e.g., tracer or potential enthalpy). The scalar mass within the layer, such as that one denoted by $\mathcal{R}$, is modified by dia-surface transport across interior layer interfaces, as well as transport across the surface and bottom boundaries. Note that an arbitrary layer might never intersect the bottom or surface boundaries. However, the layers depicted here each intersect boundaries, with such layers requiring extra care in formulating their budgets.

21.3.1 Leibniz's rule plus kinematic boundary conditions

Performing the time derivative in equation (21.59) and using Leibniz's rule yields

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V\right] = \int_{A(t)} [\partial_t \eta\,(\rho\,\Pi)_{z=\eta}]\,\mathrm{d}A + \frac{\mathrm{d}A}{\mathrm{d}t}\left[\int_{\eta_\mathrm{b}}^{\eta} \rho\,\Pi\,\mathrm{d}z\right]_{\text{bounds}} + \int_{A(t)} \mathrm{d}A \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial(\rho\,\Pi)}{\partial t}\,\mathrm{d}z. \quad (21.60)$$

The first term on the right hand side arises from time dependence to the free surface. This term is present even if the horizontal boundaries are rigid. The second term on the right hand side is evaluated along the lateral boundaries of the domain. If the boundaries are fixed in time, as in a rectangular box of seawater or a periodic channel, then $\mathrm{d}A/\mathrm{d}t = 0$. The more general case has a lateral boundary that is time dependent such as along a beach where fluid moves up and down the sloping shoreline. However, in that case the thickness of fluid vanishes at the lateral boundary, $\eta - \eta_\mathrm{b} = 0$, thus again revealing that the second term on the right hand side drops from the budget to render

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Pi\,\mathrm{d}V\right] = \int_{A(t)} [\partial_t \eta\,(\rho\,\Pi)_{z=\eta}]\,\mathrm{d}A + \int_{A(t)} \mathrm{d}A \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial(\rho\,\Pi)}{\partial t}\,\mathrm{d}z. \quad (21.61)$$

For the second term on the right hand side of equation (21.61) we make use of the scalar equation (21.57) and Leibniz's rule to write

$$\int_{\eta_\mathrm{b}}^{\eta} \frac{\partial(\rho\,\Pi)}{\partial t}\,\mathrm{d}z = -\int_{\eta_\mathrm{b}}^{\eta} \nabla_z \cdot (\rho\,\Pi\,\boldsymbol{u} + \boldsymbol{J}_h)\,\mathrm{d}z - \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial(\rho\,\Pi\,w + J^z)}{\partial z}\,\mathrm{d}z \quad (21.62a)$$

$$= -\nabla_z \cdot \int_{\eta_\mathrm{b}}^{\eta} (\rho\,\Pi\,\boldsymbol{u} + \boldsymbol{J}_h)\,\mathrm{d}z + \nabla(\eta - z) \cdot (\rho\,\Pi\,\boldsymbol{v} + \boldsymbol{J})_{z=\eta}$$
$$+ \nabla(z - \eta_\mathrm{b}) \cdot (\rho\,\Pi\,\boldsymbol{v} + \boldsymbol{J})_{z=\eta_\mathrm{b}} \quad (21.62b)$$

where we wrote $\boldsymbol{J} = \boldsymbol{J}_h + \hat{\boldsymbol{z}}\,J^z$. The surface terms ($z = \eta$) combine with the $\partial_t \eta$ term appearing

in equation (21.61) to yield

$$\rho\,\Pi\left[\frac{\partial\eta}{\partial t}+\boldsymbol{u}\cdot\nabla\eta-w\right]=\Pi\,Q_{\mathrm{m}}, \tag{21.63}$$

where we used the surface kinematic boundary condition (20.79) to introduce the surface boundary mass flux Q_{m}. The bottom kinematic boundary condition eliminates the advective contribution at the bottom, $z=\eta_{\mathrm{b}}$, via the no normal flow condition (20.41)

$$\nabla(z-\eta_{\mathrm{b}})\cdot\boldsymbol{v}=w-\boldsymbol{u}\cdot\nabla\eta_{\mathrm{b}}=0 \qquad \text{at } z=\eta_{\mathrm{b}}(x,y). \tag{21.64}$$

Finally, when integrated over the horizontal extent of the domain, the horizontal convergence term from equation (21.62b) vanishes. The reason it vanishes is because either the thickness of fluid vanishes at the horizontal boundaries (as along a beach); there is a no flux boundary condition if the boundary is a vertical wall; or the domain is periodic.

21.3.2 Summarizing the result

Bringing the results together yields the budget equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}}\rho\,\Pi\,\mathrm{d}V\right]=\int_{z=\eta}(\Pi\,Q_{\mathrm{m}}+\nabla(\eta-z)\cdot\boldsymbol{J})\,\mathrm{d}A+\int_{z=\eta_{\mathrm{b}}}\nabla(z-\eta_{\mathrm{b}})\cdot\boldsymbol{J}\,\mathrm{d}A. \tag{21.65}$$

We now use the identity (20.68e) between horizontal area element, $\mathrm{d}A=\mathrm{d}x\,\mathrm{d}y$, and area element on the surface

$$\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}=-\nabla(\eta-z)\,\mathrm{d}A \qquad \text{at } z=\eta \tag{21.66a}$$

$$\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}=-\nabla(z-\eta_{\mathrm{b}})\,\mathrm{d}A \qquad \text{at } z=\eta_{\mathrm{b}}, \tag{21.66b}$$

to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}}\rho\,\Pi\,\mathrm{d}V\right]=-\int_{z=\eta}(-\Pi\,\mathcal{Q}_{\mathrm{m}}+\hat{\boldsymbol{n}}\cdot\boldsymbol{J})\mathrm{d}\mathcal{S}-\int_{z=\eta_{\mathrm{b}}}\hat{\boldsymbol{n}}\cdot\boldsymbol{J}\,\mathrm{d}\mathcal{S}, \tag{21.67}$$

where

$$Q_{\mathrm{m}}\,\mathrm{d}A=\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S}=-\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\eta)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{21.68}$$

according to equation (20.73c). The budget for fluid mass is realized by setting Π to a constant and thus dropping the non-advective flux

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}}\rho\,\mathrm{d}V\right]=\int_{z=\eta}\mathcal{Q}_{\mathrm{m}}\,\mathrm{d}\mathcal{S}=-\int_{z=\eta}\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(\eta)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{21.69}$$

The manipulations in this section have succeeded in bringing the scalar and mass budgets into the form of the Leibniz-Reynolds transport theorem (21.58). The process of doing so required far more tedium as compared to the elegance of merely starting from equation (21.58). Even so, our efforts provide a useful means to ground the formalism by unpacking the many steps summarized by Leibniz-Reynolds. Furthermore, many of these steps are encountered in practical calculations of finite volume budgets.

21.4 Evolution of region mean scalar

We here consider a brief application of the formalism developed in this chapter by developing the evolution equations for the averaged scalar defined by

$$\langle \Pi \rangle = \frac{1}{M} \int_{\mathcal{R}} \rho \, \Pi \, \mathrm{d}V \qquad \text{with} \qquad M = \int_{\mathcal{R}} \rho \, \mathrm{d}V, \tag{21.70}$$

where the region domain, $\mathcal{R}$, is arbitrary.

21.4.1 Formulation

Use of the product rule leads to

$$\frac{\mathrm{d}[\langle \Pi \rangle \, M]}{\mathrm{d}t} = M \, \frac{\mathrm{d}\langle \Pi \rangle}{\mathrm{d}t} + \langle \Pi \rangle \, \frac{\mathrm{d}M}{\mathrm{d}t} = M \, \frac{\mathrm{d}\langle \Pi \rangle}{\mathrm{d}t} - \langle \Pi \rangle \oint_{\partial \mathcal{R}} \rho \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{21.71}$$

where the second equality made use of the mass budget (21.50). Inserting the transport theorem (21.49) for the left hand side yields

$$M \, \frac{\mathrm{d}\langle \Pi \rangle}{\mathrm{d}t} = - \oint_{\partial \mathcal{R}} \Big[\rho \, [\Pi - \langle C \rangle] \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) + \boldsymbol{J} \Big] \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{21.72}$$

The first term on the right hand side vanishes if the averaged concentration equals to the boundary concentration. That is, the region averaged tracer concentration is unchanged if the boundary fluxes of mass have a tracer concentration that matches the region average.

21.4.2 Application to a numerical ocean model grid cell

If the region is an ocean model grid cell that is adjacent to the ocean surface (see Figure 21.3 or 21.6), then use of the surface boundary condition (21.88) leads to

$$M \, \frac{\mathrm{d}\langle \Pi \rangle}{\mathrm{d}t} = \int_{z=\eta} [\Pi - \langle \Pi \rangle] \, Q_{\mathrm{m}} \, \mathrm{d}A - \int_{\partial \mathcal{R}_{\mathrm{int}}} \Big[\rho \, [\Pi - \langle \Pi \rangle] \, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) + \boldsymbol{J} \Big] \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} - \oint_{\partial \mathcal{R}} \boldsymbol{J} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{21.73}$$

where $\partial \mathcal{R}_{\mathrm{int}}$ is the interior boundary to the grid cell. As noted above, the first term on the right hand side vanishes if $\Pi(z = \eta) = \langle \Pi \rangle$. This situation is commonly assumed for temperature in the surface grid cell of an ocean model. That is, the temperature of evaporation, precipitation, and river runoff is commonly taken as the temperature in the surface model grid cell. In contrast, $\Pi(z = \eta) = 0$ is commonly the case for material tracers such as salt, whose concentration is commonly close to zero within boundary water fluxes.

21.5 Boundary conditions

We here study the boundary conditions relevant at the variety of boundaries encountered by a fluid. To be specific, consider Π to be a tracer concentration,

$$\Pi = C, \tag{21.74}$$

though note that the formalism holds for an arbitrary scalar satisfying the budget equation

$$\frac{\partial(\rho \, C)}{\partial t} + \nabla \cdot (\rho \, C \, \boldsymbol{v} + \boldsymbol{J}) = 0. \tag{21.75}$$

We continue to focus on a fluid layer such as shown in Figure 21.4, paying particular interest to fluid layers that intersect surface (as for the ocean) and/or bottom boundaries (as for the ocean or atmosphere). We commonly think of this layer as defined by isosurfaces of generalized vertical coordinates whose layers are monotonically stacked in the vertical according to the discussion from Sections 59.9.1 and 60.2. However, the treatment given here allows for the layers to be non-monotonic in the vertical (e.g., overturns are allowed), so that these results can be used for the water mass transformation analysis discussed in Chapter 68. For example, the layers can be defined by surfaces of constant Conservative Temperature or salinity within the ocean, with these fields generally exhibiting regions of non-monotonic vertical stratification.

The Leibniz-Reynolds transport theorem (21.49) provides the starting point

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, C\, \mathrm{d}V\right] = -\int_{\partial\mathcal{R}} \left[\rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) + \boldsymbol{J}\right] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{21.76}$$

The left hand side of equation (21.76) is the time tendency for the mass of tracer within the region, such as the region $\mathcal{R}$ shown in Figure 21.4. This tendency is affected by transport across the layer boundaries, with three boundaries considered here. We ignore interior sources, though note that the formalism can be readily extended in their presence.

21.5.1 Interior layer boundary conditions

The boundary transport across interior layer interfaces,

$$\text{interior boundary transport} = [\rho\, C\, (\boldsymbol{v} - \boldsymbol{v}^{(b)}) + \boldsymbol{J}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{21.77}$$

measures the tracer mass transport due to advective fluxes across the moving layer boundaries (first term) and sugbrid scale fluxes (second term). The advective flux is sometimes known as the *dia-surface transport*, with the kinematics of this transport discussed in Section 60.3.

21.5.2 Solid-earth boundary conditions

At the static material bottom boundary, the no-normal flow condition means that

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0. \tag{21.78}$$

Consider the velocity of a point attached to the layer interface, $\boldsymbol{v}^{(b)}$, and focus on where the interface intersects the bottom boundary. At this point, $\boldsymbol{v}^{(b)}$ tracks the position of the interface as it intersects the bottom boundary. By construction, the movement of this intersection point is tangential to the bottom boundary so that it too is orthogonal to the boundary outward normal direction

$$\boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}} = 0. \tag{21.79}$$

Hence, the only contribution to the tracer budget at the bottom boundary comes through the non-advective flux $\boldsymbol{J}$

$$\text{bottom boundary transport} = -\boldsymbol{J} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{21.80}$$

This equation says that if there is any transport through the bottom boundary (left hand side), then it induces a non-advective transport within the ocean whose normal component at the boundary equals to the bottom transport (right hand side).

Geothermal heating is the canonical solid-earth transport in the ocean. Assuming a known

geothermal heat flux, $\mathcal{Q}_{\text{geo-heat}}$, it leads to a non-advective ocean boundary flux

$$\mathcal{Q}_{\text{geo-heat}} = -c_{\text{p}}\, \boldsymbol{J}(\Theta) \cdot \hat{\boldsymbol{n}}, \tag{21.81}$$

where c_{p} is the ocean heat capacity and Θ is the Conservative Temperature (discussed in Section 27.11 and Chapter 67). Furthermore, if we assume the non-advective flux is parameterized as the downgradient diffusive flux (as in equation (67.54) in Chapter 67), then the geothermal boundary condition (21.81) takes the form

$$\mathcal{Q}_{\text{geo-heat}} = c_p\, \rho\, (\mathbb{K} \cdot \nabla \Theta) \cdot \hat{\boldsymbol{n}}, \tag{21.82}$$

where $\mathbb{K}$ is the diffusion tensor (Chapter 66).

For those cases where the geothermal heating vanishes, or more generally for tracers that have zero bottom boundary flux, then the tracer must satisfy the following no-normal flux (Neumann) boundary condition

$$\text{no flux bottom boundary} = (\mathbb{K} \cdot \nabla \Theta) \cdot \hat{\boldsymbol{n}} = 0. \tag{21.83}$$

In the case where diffusion next to the boundary is isotropic, as per molecular diffusion, then we reach the simpler result

$$\text{no flux bottom boundary} = \nabla C \cdot \hat{\boldsymbol{n}} = 0. \tag{21.84}$$

Namely, in this case, tracer isosurfaces are oriented normal to the boundary as depicted in Figure 21.5. Notably, this kinematic boundary condition holds at each point in time. For the dynamical tracers like temperature and salinity, this boundary condition affects flow near the boundary by modifying the density field and thus the pressure.

FIGURE 21.5: In the absence of a boundary tracer flux, and in the presence of isotropic downgradient diffusion, the isosurfaces of tracer, C, intersect solid boundaries normal to the boundary as per equation (21.84): $\nabla C \cdot \hat{\boldsymbol{n}} = 0$, where $\hat{\boldsymbol{n}}$ is the outward normal direction. This constraint holds at each time instance.

21.5.3 Upper ocean surface boundary conditions

Let us write the upper ocean surface boundary tracer transport as

$$\mathcal{Q}_C\, \mathrm{d}\mathcal{S} = \text{net tracer mass per time crossing ocean surface.} \tag{21.85}$$

The surface boundary transport is generally comprised of two terms: a non-advective term just like at the solid-earth in Section 21.5.2, plus an advective term afforded since the ocean surface is permeable. If we assume that the tracer transported via the advected matter is either a dissolved tracer, such as salinity, or a thermodynamic tracer, such as Conservative Temperature, then we can write the net tracer flux as

$$\mathcal{Q}_C = C_{\text{m}}\, \mathcal{Q}_{\text{m}} + \mathcal{Q}_C^{\text{non-adv}}, \tag{21.86}$$

FIGURE 21.6: A schematic of an infinitesimal region of the ocean surface boundary at $z = \eta(x, y, t)$, with $z < \eta$ the ocean region. $\mathcal{Q}_{\rm m}\,{\rm d}\mathcal{S}$ is the mass transport (mass per time) that crosses the interface and carries a tracer concentration $C_{\rm m}$. $\mathcal{Q}_C\,{\rm d}\mathcal{S}$ is the tracer mass transport that crosses the ocean surface. Continuity across the $z = \eta$ boundary means that the tracer mass transport at $z = \eta - \epsilon$ (ocean side) equals to that at $z = \eta + \epsilon$ (atmospheric side), with $\epsilon > 0$ a tiny number. The tracer concentration at the interface, $C(z = \eta)$, is not determined by kinematics. Many analyses and numerical model applications approximate $C(z = \eta)$ as the bulk tracer concentration within the upper few meters of the ocean, depending on details of the upper ocean turbulence. However, as model vertical grid spacing is refined to be finer than a meter, this assumption must be reconsidered.

where $\mathcal{Q}_C^{\rm non\text{-}adv}$ is the non-advective tracer flux, $C_{\rm m}$ is the tracer concentration within the mass transported across the surface, and $\mathcal{Q}_{\rm m}$ the mass per time per surface area of matter that crosses the boundary, as defined according to the kinematic boundary condition (20.63)

$$\mathcal{Q}_{\rm m} = -\rho\,\hat{\boldsymbol{n}}\cdot(\boldsymbol{v} - \boldsymbol{v}^{(\eta)}) \qquad \text{surface ocean boundary.} \tag{21.87}$$

As for the solid-earth boundary condition, specification of $\mathcal{Q}_C$ requires information concerning the flux of tracer mass into or out of the ocean, and this flux equals to the net flux on the ocean side of the surface

$$\mathcal{Q}_C = C_{\rm m}\,\mathcal{Q}_{\rm m} + \mathcal{Q}_C^{\rm non\text{-}adv} \equiv -[\rho\,C\,(\boldsymbol{v} - \boldsymbol{v}^{(b)}) + \boldsymbol{J}]\cdot\hat{\boldsymbol{n}} = C\,\mathcal{Q}_{\rm m} - \boldsymbol{J}\cdot\hat{\boldsymbol{n}}, \tag{21.88}$$

We thus see that the surface transport of tracer mass induces the following non-advective flux within the ocean at $z = \eta$

$$-\boldsymbol{J}\cdot\hat{\boldsymbol{n}} = \mathcal{Q}_C - C\,\mathcal{Q}_{\rm m} = \mathcal{Q}_C^{\rm non\text{-}adv} + (C_{\rm m} - C)\,\mathcal{Q}_{\rm m}. \tag{21.89}$$

Figure 21.6 offers a schematic to summarize these results. We make use of these results when discussing the surface ocean boundary conditions in Sections 67.5 and 68.8.3.

21.6 Exercises

EXERCISE 21.1: EQUATION FOR TRACER MASS PER FLUID VOLUME

In some treatments it can be suitable to define a volumetric tracer concentration as the mass of tracer per volume of fluid

$$\phi = \frac{\text{mass of constituent } n \text{ in fluid element}}{\text{volume of fluid element}} = C\,\rho, \tag{21.90}$$

where C is the mass concentration defined by equation (21.17) and satisfying the tracer equation (21.21). Derive the corresponding equation satisfied by ϕ.

Chapter 22

Non-divergent flows

In this chapter, we study the kinematics of a non-divergent fluid velocity field.[1] In many areas of fluid mechanics, flows with a non-divergent velocity, $\nabla \cdot \boldsymbol{v} = 0$, are referred to as *incompressible* since the density is assumed to be constant everywhere; i.e., "incompressible".[2] However, as seen when studying the Boussinesq ocean in Chapter 30, a non-divergent fluid flow can still admit compressibility effects and the associated density variations. We are thus led to distinguish between a *fluid property* versus a *flow property*. Namely, the Boussinesq ocean allows for an expression of compressibility (a property of the fluid), whereas the flow admitted by a Boussinesq ocean is non-divergent (a property of the flow). In this chapter we study the non-divergent nature of the flow and the attendant kinematics.

READER'S GUIDE TO THIS CHAPTER

We presume an understanding of the kinematics of mass conservation from Chapter 20 as well as many of the results from Cartesian tensor analysis in Chapter 2. This chapter introduces many concepts and tools of use in the remainder of the book.

[1] A somewhat trivial example of a non-divergent fluid flow is given by $\boldsymbol{v}(x,y,z) = u(y,z)\,\hat{\boldsymbol{x}} + v(x,z)\,\hat{\boldsymbol{y}} + w(x,y)\,\hat{\boldsymbol{z}}$. However, there are far less trivial flows that are non-divergent, such as realized by the Boussinesq ocean studied in Chapter 30.

[2] In some presentations, $\nabla \cdot \boldsymbol{v} = 0$ is referred to as a *solenoidal velocity*, in analog to the non-divergent or solenoidal magnetic field occurring in classical electrodynamics.

22.1 Loose threads

- Need more work for the general Ψ in Section 22.7.4 to prove that it is a streamfunction.

22.2 Introduction to non-divergent flow

For many purposes in fluid mechanics, we can make the simplifying assumption regarding the fluid kinematics whereby the volume of a fluid element is approximated as a constant. In particular, this situation holds for the Boussinesq ocean discussed in Chapter 30. Recalling the expression

$$\frac{1}{\delta V}\frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \nabla \cdot \boldsymbol{v} \tag{22.1}$$

from Section 19.6.1, we see that a constant volume for a fluid element constrains the velocity field to be non-divergent

$$\frac{1}{\delta V}\frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = 0 \Longrightarrow \nabla \cdot \boldsymbol{v} = 0. \tag{22.2}$$

Flow satisfying $\nabla \cdot \boldsymbol{v} = 0$ is said to be *incompressible* since the volume of a fluid element is materially invariant. We illustrate this situation in Figure 22.1.

FIGURE 22.1: Illustrating volume continuity for a non-divergent velocity flow in a pipe. On the left the pipe has a relatively large diameter whereas on the right the pipe is narrower. A plug of water on the left moves through the pipe and becomes longer when it moves into the narrower region so that the volume of the plug remains the same. Correspondingly, the speed of the flow increases when moving into the narrower portion of the pipe.

A slightly less onerous constraint arises from the *anelastic approximation*, whereby

$$\nabla \cdot (\rho \boldsymbol{v}) = 0. \tag{22.3}$$

The anelastic approximation is sometimes motivated for the atmosphere. However, it is less commonly used for atmospheric dynamics than the Boussinesq ocean is used for the ocean. We thus focus on the Boussinesq case here, whereby $\nabla \cdot \boldsymbol{v} = 0$.

The non-divergence constraint (22.2) reduces by one the number of functional degrees of freedom possessed by the velocity field. What that means in practice is that we need one fewer velocity component to determine the flow since one component can be diagnosed from the other two components. This property manifests by our ability to introduce a streamfunction to specify the velocity, as further developed in this chapter.

22.3 Kinematic boundary conditions

For non-divergent flow, there are slight modifications to the boundary conditions detailed in Section 20.4. Whereas the material conditions remain identical, the non-material conditions are applied with a constant reference density, ρ_0, rather than the local *in situ* density, ρ. The reason is that we switch from specifying a mass transport condition as per equation (20.63) to a volume transport condition

$$\rho_0 \left(\boldsymbol{v} - \boldsymbol{v}^{(s)}\right) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = -\mathcal{Q}_{\mathrm{m}} \, \mathrm{d}\mathcal{S} = -Q_{\mathrm{m}} \, \mathrm{d}A \qquad \text{moving non-material boundary condition,} \tag{22.4}$$

where the second equality introduced the mass flux per unit horizontal area, Q_{m}, according to equation (20.73c). Correspondingly, the kinematic boundary condition (20.79) applied at the ocean free surface takes on the form

$$\rho_0 \frac{\mathrm{D}(z-\eta)}{\mathrm{D}t} = -Q_{\mathrm{m}} \Longrightarrow w + \frac{Q_{\mathrm{m}}}{\rho_0} = \frac{\partial \eta}{\partial t} + \boldsymbol{u} \cdot \nabla \eta. \tag{22.5}$$

Making use of the non-divergence condition on the velocity allows us to write this equation in the equivalent forms[3]

$$\partial_t \eta - Q_{\mathrm{m}}/\rho_0 = (\hat{\boldsymbol{z}} - \nabla \eta) \cdot \boldsymbol{v} = \nabla (z-\eta) \cdot \boldsymbol{v} = \nabla \cdot [(z-\eta)\, \boldsymbol{v}]. \tag{22.6}$$

In Section 22.8 we derive the kinematic free surface equation (22.81), which also shows that $\partial_t \eta - Q_{\mathrm{m}}/\rho_0$ is a total divergence.

22.4 Streamfunction for two-dimensional flow

Vertical stratification of buoyancy plus the effects from planetary rotation inhibit vertical motion in geophysical flows. Therefore, as an idealization it is sometimes useful to assume the geophysical fluid flow is horizontal (two-dimensional) as well as non-divergent. The non-divergent constraint for two-dimensional flow can be satisfied by writing the horizontal velocity in the form

$$\boldsymbol{u} = \nabla \times (z \, \nabla \psi) = \hat{\boldsymbol{z}} \times \nabla \psi = \hat{\boldsymbol{z}} \times \nabla_z \psi = -\hat{\boldsymbol{x}} \frac{\partial \psi}{\partial y} + \hat{\boldsymbol{y}} \frac{\partial \psi}{\partial x}, \tag{22.7}$$

where

$$\nabla_z = \hat{\boldsymbol{x}} \, \partial_x + \hat{\boldsymbol{y}} \, \partial_y \tag{22.8}$$

is the horizontal gradient operator. The constraint $\nabla_z \cdot \boldsymbol{u} = 0$ is satisfied since the partial derivative operators commute

$$\frac{\partial^2 \psi}{\partial x \partial y} = \frac{\partial^2 \psi}{\partial y \partial x}. \tag{22.9}$$

[3] In equation (22.6), we set $z = \eta$ after applying the gradient operator in the penultimate expression and the divergence in the final expression.

We refer to ψ as the *streamfunction*, with this name motivated by the following considerations.[4]

22.4.1 Streamfunction isolines are streamlines

At any fixed time instance, the exact differential of the streamfunction is

$$\mathrm{d}\psi = \frac{\partial \psi}{\partial x}\,\mathrm{d}x + \frac{\partial \psi}{\partial y}\,\mathrm{d}y = v\,\mathrm{d}x - u\,\mathrm{d}y, \tag{22.10}$$

where the second equality follows from equation (22.7). Instantaneous lines along which ψ is a constant satisfy

$$\mathrm{d}\psi = 0 \Longrightarrow \frac{\mathrm{d}x}{u} = \frac{\mathrm{d}y}{v}. \tag{22.11}$$

Furthermore, the normal direction to constant ψ lines

$$\hat{\boldsymbol{n}} = \frac{\nabla_z \psi}{|\nabla_z \psi|} = \frac{v\,\hat{\boldsymbol{x}} - u\,\hat{\boldsymbol{y}}}{|\boldsymbol{u}|} \tag{22.12}$$

is normal to the velocity

$$\boldsymbol{u} \cdot \nabla_z \psi = u\,v - v\,u = 0. \tag{22.13}$$

Consequently, at each time instance, lines of constant ψ are streamlines, which means (following Section 18.11.2) that curves of constant ψ define integral curves for the instantaneous velocity field. This property motivates the name *streamfunction*. Furthermore, through each point of a two-dimensional non-divergent flow and at any particular time instance, there is one and only one streamline passing through that point.

22.4.2 Streamfunction is constant on material boundaries

As a corollary to the results from Section 22.4.1, we know that the streamfunction is a spatial constant when evaluated along static material boundaries where $\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = 0$. This property follows from equation (22.13). We can also see it from

$$0 = \boldsymbol{u} \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{z}} \times \nabla_z \psi) \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}) \cdot \nabla_z \psi = \hat{\boldsymbol{t}} \cdot \nabla_z \psi, \tag{22.14}$$

where $\hat{\boldsymbol{t}}$ a unit vector pointing tangent to the boundary. The operator $\hat{\boldsymbol{t}} \cdot \nabla_z \psi$ is the derivative of ψ computed along the boundary tangent at any given boundary point. Hence, $\hat{\boldsymbol{t}} \cdot \nabla_z \psi = 0$ means that ψ is a spatial constant along the boundary. Even though spatially constant, ψ along the boundary is generally a function of time.

We emphasize that a constant streamfunction along a boundary, $\hat{\boldsymbol{t}} \cdot \nabla_z \psi = 0$, is distinct from a vanishing normal derivative at the boundary. Indeed, the streamfunction for a two-dimensional non-divergent flow generally has a nonzero normal derivative at boundaries, $\hat{\boldsymbol{n}} \cdot \nabla_z \psi \neq 0$.

22.4.3 The streamfunction and fluid transport

Consider an arbitrary curve in the fluid with endpoints $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ as depicted in Figure 22.2. At any particular time instance, the difference in streamfunction between these two points is given

[4] In this section we could choose to relax notation by dispensing with the z subscript on the horizontal gradient operator, ∇_z, since we are here concerned only with two-dimensional horizontal flow. Even so, we find it useful to be pedantic as doing so clearly distinguishes the two-dimensional formulations in this section from the analogous three-dimensional case considered in Section 22.5.

by

$$\psi(\boldsymbol{x}_2) - \psi(\boldsymbol{x}_1) = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \mathrm{d}\psi = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \left[\mathrm{d}x\,\frac{\partial\psi}{\partial x} + \mathrm{d}y\,\frac{\partial\psi}{\partial y}\right] = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \nabla_z\psi\cdot\mathrm{d}\boldsymbol{x} = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \nabla_z\psi\cdot\hat{\boldsymbol{t}}\,\mathrm{d}s. \quad (22.15)$$

For the final equality we wrote

$$\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{t}}\,\mathrm{d}s, \quad (22.16)$$

where

$$\mathrm{d}s = |\mathrm{d}\boldsymbol{x}| \quad (22.17)$$

is the element of arc length along the curve, and $\hat{\boldsymbol{t}}$ is the unit tangent vector that points in the direction along the curve from $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$. Now introduce the unit normal vector along the curve according to

$$\hat{\boldsymbol{t}} = \hat{\boldsymbol{n}}\times\hat{\boldsymbol{z}}, \quad (22.18)$$

where $\hat{\boldsymbol{n}}$ points to the left when facing in the $\hat{\boldsymbol{t}}$ direction. We thus have

$$\psi(\boldsymbol{x}_2) - \psi(\boldsymbol{x}_1) = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \nabla_z\psi\cdot(\hat{\boldsymbol{n}}\times\hat{\boldsymbol{z}})\,\mathrm{d}s = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} (\hat{\boldsymbol{z}}\times\nabla_z\psi)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s = \int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s, \quad (22.19)$$

with the final equality an expression for the net area transport of fluid normal to the curve (dimensions of area per time). As the chosen curve connecting the points is arbitrary, we conclude that the difference in streamfunction values between two points measures the transport across any curve connecting the points. Correspondingly, the stronger the gradient in the streamfunction, the larger the transport since

$$|\boldsymbol{u}| = |\nabla_z\psi|. \quad (22.20)$$

Given the connection between the transport between two points and the value of the streamfunction at those two points, we are motivated to name ψ the *transport streamfunction*.

FIGURE 22.2: Depicting the transport between two points in a two-dimensional fluid. The transport is the line integral, $\int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s$, from point $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$, with the unit normal, $\hat{\boldsymbol{n}}$, pointing to the left when facing in the direction of the local unit tangent vector, $\hat{\boldsymbol{t}}$. By construction, $\hat{\boldsymbol{t}}\times\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, where $\hat{\boldsymbol{z}}$ points vertically out of the page. For a two-dimensionally non-divergent flow, $\nabla_z\cdot\boldsymbol{u} = 0$, the transport between any two points is the streamfunction difference at these two points, $\int_{\boldsymbol{x}_1}^{\boldsymbol{x}_2} \boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s = \psi(\boldsymbol{x}_1) - \psi(\boldsymbol{x}_2)$. This result holds regardless the path taken between these two points, so long as the path remains simple; i.e., it does not intersect itself.

22.4.4 Gauge symmetry

For a two-dimensional non-divergent flow, the constraint $\nabla_z\cdot\boldsymbol{u} = 0$ reduces the functional degrees of freedom from two (the two velocity components (u, v)) to one (the streamfunction). However, the streamfunction is arbitrary up to a constant, k, since

$$\psi' = \psi + k \Rightarrow \boldsymbol{u}' = \boldsymbol{u}. \quad (22.21)$$

So the value of the streamfunction at a particular point has no unambiguous physical meaning. Rather, only the difference in streamfunction between two points is physically relevant. The ability to add a constant to the streamfunction is termed a *gauge symmetry*.

22.4.5 Exact differential formulation

We here connect our discussion of velocity streamfunction to the discussion of exact differentials in Section 2.8. For that purpose introduce the differential

$$\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} \equiv (\boldsymbol{u} \times \hat{\boldsymbol{z}}) \cdot \mathrm{d}\boldsymbol{x} = v\,\mathrm{d}x - u\,\mathrm{d}y. \tag{22.22}$$

By construction

$$\hat{\boldsymbol{z}} \cdot (\nabla_z \times \boldsymbol{A}) = 0 \qquad \text{since} \qquad \nabla_z \cdot \boldsymbol{u} = 0, \tag{22.23}$$

which means that $\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x}$ is an exact differential (Section 2.8.1). Consequently, we can write

$$\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} = (\boldsymbol{u} \times \hat{\boldsymbol{z}}) \cdot \mathrm{d}\boldsymbol{x} = \nabla_z \psi \cdot \mathrm{d}\boldsymbol{x} = \mathrm{d}\psi, \tag{22.24}$$

which then leads to the results derived earlier in this section where ψ is the transport streamfunction.

22.4.6 Concerning the Helmholtz decomposition

We close the discussion in this section by tidying up some mathematical niceties concerning the Helmholtz decomposition studied in Section 3.7. For two-dimensional flows the decomposition takes the form

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla_z \Gamma + \nabla_z \Phi, \tag{22.25}$$

for some functions Γ and Φ. For non-divergent flows, Φ is constrained to be harmonic[5]

$$\nabla \cdot \boldsymbol{u} = 0 \Longrightarrow \nabla_z^2 \Phi = \nabla_z \cdot \nabla_z \Phi = 0. \tag{22.26}$$

As summarized in Table 22.1, it is sufficient to make use of just a streamfunction, ψ, for vortical flow and just a *velocity potential*, ϕ, for irrotational flow.[6] In the following we verify why it is sufficient to make use of this truncated version of the Helmholtz decomposition for non-divergent two-dimensional flows.

NON-DIVERGENT VORTICAL FLOW	NON-DIVERGENT IRROTATIONAL FLOW
$\nabla_z \cdot \boldsymbol{u} = 0$	$\nabla_z \cdot \boldsymbol{u} = 0$
$\nabla_z \times \boldsymbol{u} \neq 0$	$\nabla_z \times \boldsymbol{u} = 0$
$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla_z \psi$	$\boldsymbol{u} = \nabla_z \phi$
$\hat{\boldsymbol{z}} \cdot (\nabla_z \times \boldsymbol{u}) = \nabla_z^2 \psi$	$\nabla_z^2 \phi = 0.$

TABLE 22.1: Summarizing some mathematical properties of non-divergent two-dimensional velocity fields, $\nabla \cdot \boldsymbol{u} = 0$. The streamfunction is ψ whereas the harmonic velocity potential is ϕ.

Non-divergent vortical flow

Return to the exact differential formulation from Section 22.4.5. In that formulation we noted that $\nabla_z \cdot \boldsymbol{u} = 0$ means that the differential $\boldsymbol{A} \cdot \mathrm{d}\boldsymbol{x} = (\boldsymbol{u} \times \hat{\boldsymbol{z}}) \cdot \mathrm{d}\boldsymbol{x}$ is exact. Making use of the

[5] Recall our discussion of harmonic functions in Sections 2.2.2 and 3.4.1.

[6] The vorticity, $\nabla_z \times \boldsymbol{u}$, is a measure of the spin in the fluid and is the focus of Part VII of this book.

Helmholtz decomposition (22.25) renders

$$\boldsymbol{A}\cdot \mathrm{d}\boldsymbol{x} = (\boldsymbol{u}\times\hat{\boldsymbol{z}})\cdot \mathrm{d}\boldsymbol{x} \tag{22.27a}$$
$$= [(\hat{\boldsymbol{z}}\times\nabla_z\Gamma)\times\hat{\boldsymbol{z}} + \nabla_z\Phi\times\hat{\boldsymbol{z}}]\cdot \mathrm{d}\boldsymbol{x} \tag{22.27b}$$
$$= [\nabla_z\Gamma + \nabla_z\Phi\times\hat{\boldsymbol{z}}]\cdot \mathrm{d}\boldsymbol{x}. \tag{22.27c}$$

To reveal the exactness of the right hand side requires the harmonic property of Φ so that we can write

$$\hat{\boldsymbol{z}}\cdot[\nabla_z\times(\nabla_z\Phi\times\hat{\boldsymbol{z}})] = -\nabla_z^2\Phi = 0 \Longrightarrow \nabla_z\Phi\times\hat{\boldsymbol{z}} \equiv \nabla_z\Upsilon, \tag{22.28}$$

in which case

$$\boldsymbol{A}\cdot \mathrm{d}\boldsymbol{x} \equiv v\,\mathrm{d}x - u\,\mathrm{d}y = \mathrm{d}(\Gamma+\Upsilon) \equiv \mathrm{d}\psi. \tag{22.29}$$

We conclude that for non-divergent vortical flow, we lose no generality by working just with the streamfunction, ψ, of Section 22.4.3. There is no need to also include a harmonic function.

Non-divergent irrotational flow

Consider now non-divergent and irrotational flow. The irrotational condition holds so long as Γ is harmonic

$$\hat{\boldsymbol{z}}\cdot[\nabla_z\times(\hat{\boldsymbol{z}}\times\nabla_z\Gamma)] = \nabla_z^2\Gamma = 0. \tag{22.30}$$

Consequently, we can write

$$\hat{\boldsymbol{z}}\times\nabla_z\Gamma = \nabla_z\gamma, \tag{22.31}$$

in which case

$$\boldsymbol{u} = \hat{\boldsymbol{z}}\times\nabla_z\Gamma + \nabla_z\Phi = \nabla_z(\gamma+\Phi) \equiv \nabla_z\phi. \tag{22.32}$$

Hence, for non-divergent irrotational flow, it is sufficient to work just with the harmonic velocity potential, ϕ.

22.4.7 A caveat: transport with curl-free + divergent flow

Consider a horizontal velocity that has a non-zero divergence, $\nabla\cdot\boldsymbol{u}\neq 0$, and yet it has a zero curl, $\nabla\times\boldsymbol{u}=0$. The zero curl allows us to write $\boldsymbol{u}=\nabla_z\phi$, with ϕ the velocity potential. Hence, $\mathrm{d}\Phi = \nabla_z\phi\cdot\mathrm{d}\boldsymbol{x}$ is an exact differential and so its closed loop integral vanishes: $\oint \mathrm{d}\Phi = 0$. However, there is no connection between velocity potential and transport. That is, we cannot conclude anything about the net transport across a closed curve based on properties of ϕ.

22.5 Vector streamfunction for three-dimensional flow

A three-dimensional non-divergent velocity, $\nabla\cdot\boldsymbol{v}=0$, can be specified by a vector streamfunction

$$\boldsymbol{v} = \nabla\times\boldsymbol{\Psi}. \tag{22.33}$$

The constraint $\nabla\cdot\boldsymbol{v}=0$ is trivially satisfied since the divergence of the curl vanishes

$$\nabla\cdot(\nabla\times\boldsymbol{\Psi}) = 0. \tag{22.34}$$

22.5.1 Gauge symmetry

For three-dimensional non-divergent flow, the constraint $\nabla\cdot\boldsymbol{v}=0$ reduces the three functional degrees of freedom down to two, meaning that one of the velocity components can be diagnosed

from the other two. Gauge symmetry manifests through the ability to add the gradient of an arbitrary function to the streamfunction, $\boldsymbol{\Psi}$, without altering $\boldsymbol{v}$:

$$\boldsymbol{\Psi}' = \boldsymbol{\Psi} + \nabla\lambda \Rightarrow \boldsymbol{v}' = \boldsymbol{v}, \tag{22.35}$$

which follows since $\nabla \times \nabla\lambda = 0$. Hence, the vector streamfunction has no absolute physical meaning since it can be modified by adding an arbitrary gauge function.

22.5.2 The streamfunction and transport through a surface

The volume transport (volume per time) of fluid crossing a surface is defined by the area integral

$$\mathcal{T}(\mathcal{S}) = \int_{\mathcal{S}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{22.36}$$

where $\hat{\boldsymbol{n}}$ is the outward unit normal vector on the surface. Introducing the vector streamfunction and making use of Stokes' Theorem (Section 2.6) then leads to

$$\mathcal{T}(\mathcal{S}) = \int_{\mathcal{S}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}} (\nabla \times \boldsymbol{\Psi}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \boldsymbol{\Psi} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s, \tag{22.37}$$

where $\hat{\boldsymbol{t}} \, \mathrm{d}s$ is the oriented arc distance increment along the boundary of $\mathcal{S}$, and $\oint_{\partial\mathcal{S}}$ is the oriented line integral around the boundary $\partial\mathcal{S}$. Hence, the volume transport of fluid through the surface depends only on the vector streamfunction on the perimeter of the surface. Furthermore, if the transport through the surface vanishes (e.g., no-flux material surface such as a solid earth boundary), then on the surface the vector streamfunction can be written as the gradient of an arbitrary scalar field, $\boldsymbol{\Psi} = \nabla\chi$, since

$$\oint_{\partial\mathcal{S}} \boldsymbol{\Psi} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = \oint_{\partial\mathcal{S}} \nabla\chi \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = \oint_{\partial\mathcal{S}} \nabla\chi \cdot \mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}} \mathrm{d}\chi = 0. \tag{22.38}$$

Because $\boldsymbol{\Psi}$ has a connection to fluid transport, we sometimes refer to it as the *transport streamfunction*, just as for the streamfunction ψ in two-dimensional non-divergent flows (Section 22.4.3).

22.5.3 Scalar streamfunctions and transport

We can expose the two degrees of freedom of the vector streamfunction by writing it as the product of a scalar field and the gradient of another scalar field

$$\boldsymbol{\Psi} = \gamma \, \nabla\psi \tag{22.39}$$

so that the velocity is given by[7]

$$\boldsymbol{v} = \nabla \times \boldsymbol{\Psi} = \nabla\gamma \times \nabla\psi. \tag{22.40}$$

By construction the velocity satisfies

$$\boldsymbol{v} \cdot \nabla\gamma = \boldsymbol{v} \cdot \nabla\psi = 0, \tag{22.41}$$

so that the velocity is parallel to surfaces of constant γ and ψ. Correspondingly, the velocity streamlines are intersections of the γ and ψ isosurfaces, as depicted in Figure 22.3. We thus

[7] Equation (22.40) is sometimes referred to as *Euler's form*, for, as noted on page 21 of *Truesdell* (1954), it was Euler who originally proved its validity.

refer to γ and ψ as the two *scalar streamfunctions* for the three dimensional non-divergent flow. However, note that γ and ψ have different dimensions. By convention, we choose γ to have dimensions of length, so that it is not a traditional streamfunction, whereas ψ has the traditional streamfunction dimensions of length squared per time.

As a check that the formalism is sensible, consider the special case of two-dimensional flow so that all streamlines are in the horizontal x-y plane. Taking $\gamma = z$ then renders

$$\boldsymbol{\Psi} = z\,\nabla\psi \quad \text{and} \quad \boldsymbol{v} = \nabla \times \boldsymbol{\Psi} = \hat{\boldsymbol{z}} \times \nabla\psi, \tag{22.42}$$

which agrees with the scalar streamfunction in equation (22.7) for two dimensional non-divergent flow.

FIGURE 22.3: Isosurfaces of constant scalar streamfunctions, γ and ψ, for a three dimensional non-divergent flow. Streamlines are defined by the intersections of the γ and ψ isosurfaces, as shown by four streamlines along the corners of this particular volume. The volume transport of fluid through the surface, $\mathcal{S}$, is determined by the line integral, $\oint_{\partial\mathcal{S}} \gamma\,\mathrm{d}\psi = -\oint_{\partial\mathcal{S}} \psi\,\mathrm{d}\gamma = (\gamma_1 - \gamma_2)\,(\psi_2 - \psi_1)$, around the boundary circuit.

The volume transport through a surface defined by the two streamfunction isosurfaces takes the form

$$\mathcal{T}(\mathcal{S}) = \int_{\mathcal{S}} \boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \boldsymbol{\Psi}\cdot\hat{\boldsymbol{t}}\,\mathrm{d}s = \oint_{\partial\mathcal{S}} \gamma\,\nabla\psi\cdot\hat{\boldsymbol{t}}\,\mathrm{d}s = \oint_{\partial\mathcal{S}} \gamma\,\mathrm{d}\psi = -\oint_{\partial\mathcal{S}} \psi\,\mathrm{d}\gamma. \tag{22.43}$$

To reach the penultimate step we set

$$\mathrm{d}\psi = \nabla\psi\cdot\mathrm{d}\boldsymbol{x} = \nabla\psi\cdot\hat{\boldsymbol{t}}\,\mathrm{d}s, \tag{22.44}$$

and for the final step we used the identity

$$\oint_{\partial\mathcal{S}} \gamma\,\mathrm{d}\psi = \oint_{\partial\mathcal{S}} \mathrm{d}(\gamma\,\psi) - \oint_{\partial\mathcal{S}} \psi\,\mathrm{d}\gamma = -\oint_{\partial\mathcal{S}} \psi\,\mathrm{d}\gamma. \tag{22.45}$$

This identity follows from

$$\oint_{\partial\mathcal{S}} \mathrm{d}(\gamma\,\psi) = 0, \tag{22.46}$$

which holds since $\mathrm{d}(\gamma\,\psi)$ is an exact differential and its line integral vanishes when computed around a closed path.[8] The volume transport for the particular surface shown in Figure 22.3 is

[8]The identity (22.46) follows from the fundamental theorem of calculus, whereby the closed loop integral of an exact differential vanishes.

given by

$$\mathcal{T}(\mathcal{S}) = \oint_{\partial\mathcal{S}} \gamma \, \mathrm{d}\psi = \gamma_1 (\psi_2 - \psi_1) + \gamma_2 (\psi_1 - \psi_2) = (\gamma_1 - \gamma_2)(\psi_2 - \psi_1). \tag{22.47}$$

Hence, the volume transport through a streamtube defined by isosurfaces of γ and ψ is given by the product of the difference between the isosurfaces.

22.5.4 Concerning a harmonic velocity potential

As for the two-dimensional case discussed in Section 22.4.6, we consider the relevance of an arbitrary harmonic velocity potential, χ, so that the velocity takes the form

$$\boldsymbol{v} = \nabla \times \boldsymbol{\Gamma} + \nabla\chi \qquad \text{with} \qquad \nabla^2\chi = 0. \tag{22.48}$$

Since $\nabla \cdot \nabla\chi = 0$ we can write $\nabla\chi$ as the curl of another vector

$$\nabla \cdot \nabla\chi = 0 \Longrightarrow \nabla\chi = \nabla \times \boldsymbol{\Lambda}, \tag{22.49}$$

in which case the velocity takes the form

$$\boldsymbol{v} = \nabla \times \boldsymbol{\Gamma} + \nabla\chi = \nabla \times (\boldsymbol{\Gamma} + \boldsymbol{\Lambda}) \equiv \nabla \times \boldsymbol{\Psi}. \tag{22.50}$$

Consequently, just as for the two-dimensional case, we are at liberty to work with the transport streamfunction $\boldsymbol{\Psi}$ if that suits our needs. Otherwise, we can work with the harmonic potential, χ, which is commonly used when the velocity is both non-divergent and irrotational, such as for our studies of surface gravity waves in Chapter 50.

22.5.5 The vertical gauge streamfunction

To explicitly reveal the two functional degrees of freedom possessed by the non-divergent velocity field, we establish that the velocity field can be constructed from the following *vertical gauge* streamfunction[9]

$$\boldsymbol{\Psi}^{\mathrm{vg}} = \hat{\boldsymbol{x}}\, \Psi_1^{\mathrm{vg}} + \hat{\boldsymbol{y}}\, \Psi_2^{\mathrm{vg}}, \tag{22.51}$$

which has a zero vertical component, $\Psi_3^{\mathrm{vg}} = 0$. In addition to proving that $\boldsymbol{v} = \nabla \times \boldsymbol{\Psi}^{\mathrm{vg}}$, we show that $\boldsymbol{\Psi}^{\mathrm{vg}}$ provides a measure of the horizontal volume transport of fluid beneath a chosen depth. It is this property of $\boldsymbol{\Psi}^{\mathrm{vg}}$ that makes it commonly used for studies of ocean mesoscale eddy parameterizations, such as in Section 64.7.1.

Proof that $\boldsymbol{v} = \nabla \times \boldsymbol{\Psi}^{vg}$

In terms of the vertical gauge streamfunction, the velocity components are given by

$$u = -\frac{\partial \Psi_2^{\mathrm{vg}}}{\partial z} \qquad \text{and} \qquad v = \frac{\partial \Psi_1^{\mathrm{vg}}}{\partial z} \qquad \text{and} \qquad w = \frac{\partial \Psi_2^{\mathrm{vg}}}{\partial x} - \frac{\partial \Psi_1^{\mathrm{vg}}}{\partial y}. \tag{22.52}$$

[9] There are occasions in which it is suitable to use either $\boldsymbol{\Psi} = \hat{\boldsymbol{x}}\, \Psi_1 + \hat{\boldsymbol{z}}\, \Psi_3$ or $\boldsymbol{\Psi} = \hat{\boldsymbol{y}}\, \Psi_2 + \hat{\boldsymbol{z}}\, \Psi_3$. In this section we focus on the vertical gauge (22.51) since that is more commonly used in applications.

Vertically integrating the u, v equations from the bottom at $z = \eta_{\rm b}(x, y)$ up to an arbitrary geopotential leads to[10]

$$\boldsymbol{\Psi}^{\rm vg}(x, y, z, t) = \int_{\eta_{\rm b}(x,y)}^{z} \boldsymbol{u}(x, y, z', t)\, {\rm d}z' \times \hat{\boldsymbol{z}} \equiv \boldsymbol{U}(x, y, z, t) \times \hat{\boldsymbol{z}}, \tag{22.53}$$

where

$$\boldsymbol{U}(x, y, z, t) = \int_{\eta_{\rm b}(x,y)}^{z} \boldsymbol{u}(x, y, z', t)\, {\rm d}z' \tag{22.54}$$

is the horizontal transport of fluid from the bottom up to a chosen vertical position above the bottom. We trivially see that $u = -\partial \Psi_2^{\rm vg}/\partial z$ and $v = \partial \Psi_1^{\rm vg}/\partial z$. It takes a bit more work to verify that this streamfunction also renders w through noting that

$$\frac{\partial \Psi_2^{\rm vg}}{\partial x} = u(\eta_{\rm b})\, \partial_x \eta_{\rm b} - \int_{\eta_{\rm b}}^{z} \partial_x u\, {\rm d}z' \qquad \text{and} \qquad \frac{\partial \Psi_1^{\rm vg}}{\partial y} = \int_{\eta_{\rm b}}^{z} \partial_y v\, {\rm d}z' - v(\eta_{\rm b})\, \partial_y \eta_{\rm b}, \tag{22.55}$$

so that

$$\frac{\partial \Psi_2^{\rm vg}}{\partial x} - \frac{\partial \Psi_1^{\rm vg}}{\partial y} = \boldsymbol{u}(\eta_{\rm b}) \cdot \nabla \eta_{\rm b} - \int_{\eta_{\rm b}}^{z} \left[\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right] {\rm d}z' = w(\eta_{\rm b}) + \int_{\eta_{\rm b}}^{z} \frac{\partial w}{\partial z'}\, {\rm d}z' = w(z), \tag{22.56}$$

where we used the bottom kinematic boundary condition (20.41) to write $\boldsymbol{u}(\eta_{\rm b}) \cdot \nabla \eta_{\rm b} = w(\eta_{\rm b})$. We conclude that knowledge of the vector streamfunction (22.53), which just has two functional degrees of freedom, contains all the information of the three velocity components.

We close by noting that the transport through the solid-earth bottom, $z = \eta_{\rm b}(x, y)$, vanishes according to equation (22.37) discussed below. We can trivially verify this result for the vertical gauge since

$$\boldsymbol{\Psi}^{\rm vg}(z = \eta_{\rm b}) = 0, \tag{22.57}$$

so that $\oint_{\partial \mathcal{S}} \boldsymbol{\Psi}^{\rm vg} \cdot \hat{\boldsymbol{t}}\, {\rm d}s = 0$ on the bottom.

Comments on the vertical gauge streamfunction

Consider a streamfunction with nonzero components in all three directions

$$\overline{\boldsymbol{\Psi}} = \hat{\boldsymbol{x}}\, \overline{\Psi}_1 + \hat{\boldsymbol{y}}\, \overline{\Psi}_2 + \hat{\boldsymbol{z}}\, \overline{\Psi}_3. \tag{22.58}$$

Following Section 22.5.1, introduce a gauge transformation so that

$$\boldsymbol{\Psi} = \overline{\boldsymbol{\Psi}} + \nabla \lambda. \tag{22.59}$$

Is it possible to remove one of the components of $\overline{\boldsymbol{\Psi}}$? For example, can we find a λ so that $\boldsymbol{\Psi}$ is a horizontal vector and is thus a vertical gauge streamfunction? For that to occur we need, at each time instance, to satisfy

$$\nabla \lambda(x, y, z) = -\hat{\boldsymbol{z}}\, \overline{\Psi}_3(x, y, z). \tag{22.60}$$

This equation is not generally solvable since the gradient of a function, $\lambda(x, y, z)$, has vector components in all three directions rather than just in the vertical. We conclude that the vertical gauge streamfunction is not the result of a gauge transformation from a streamfunction of the form (22.58). Even so, it is a legitimate streamfunction, as noted by the above proof that $\boldsymbol{v} = \nabla \times \boldsymbol{\Psi}^{\rm vg}$.

[10] We expose the functional dependencies in equations (22.53) and (22.54), as it can be useful when first encountering these equations. Otherwise, we typically use a more terse notation.

22.6 Evolution of volume and area

In this section we develop kinematic equations for the evolution of volume and area within a non-divergent flow, starting with a material region and then considering an arbitrary region.

22.6.1 Material volumes and areas

As shown by equation (22.2), the volume of a fluid element remains constant in a non-divergent flow. Correspondingly, a fluid region moving with the velocity field maintains a constant volume

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}(\boldsymbol{v})} \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = \int_{\mathcal{R}(\boldsymbol{v})} (\nabla\cdot\boldsymbol{v})\,\mathrm{d}V = \oint_{\partial\mathcal{R}(\boldsymbol{v})} \boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0. \tag{22.61}$$

The appearance of a material time derivative on the inside of the integral arises since the integral is computed following fluid particles whose trajectories define integral curves of the flow (see Section 21.2.7). Likewise, following from the area element equation (19.80), the area of a region moving with a two-dimensional non-divergent flow remains materially constant

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}(\boldsymbol{v})} \mathrm{d}\mathcal{S} = \int_{\mathcal{S}(\boldsymbol{v})} \frac{\mathrm{D}(\delta \mathcal{S})}{\mathrm{D}t} = \int_{\mathcal{S}(\boldsymbol{v})} (\nabla\cdot\boldsymbol{u})\,\mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s = 0. \tag{22.62}$$

This area preservation property is illustrated in Figure 22.4, in which a two-dimensional non-divergent flow is seen to deform an initially square patch of fluid while retaining a constant area for the patch.

FIGURE 22.4: Illustrating the rotation and straining of fluid patches in a two-dimensional circular and non-divergent flow with non-dimensional velocity, $\boldsymbol{v} = f(|\boldsymbol{x}|)\,\hat{\boldsymbol{z}}\times\boldsymbol{x} = f(|\boldsymbol{x}|)\,(x\,\hat{\boldsymbol{y}} - y\,\hat{\boldsymbol{x}}) = f(|\boldsymbol{x}|)\,\hat{\boldsymbol{\vartheta}}$, where $\boldsymbol{x} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}$ is the position vector for a fluid particle relative to the origin (at center of the panels), and $\hat{\boldsymbol{\vartheta}}$ is the angular unit vector pointed counter-clockwise relative to the positive x-axis (see Section 10.3). As discussed in Section 22.6, the area of each fluid patch remains fixed as it moves with the non-divergent flow. The top row shows a rigid rotational flow (pure rotation with zero strain) with $f(|\boldsymbol{x}|) = 1$, with time increasing to the right and with the right-most column showing the rigid rotating fluid flow. The bottom row shows the result from a rotating and straining flow with $f(|\boldsymbol{x}|) = \sqrt{x^2+y^2}$. Thanks to Kentaro Hanson for providing the Python notebook to generate the grid advection panels.

22.6.2 Arbitrary volume and area

We make use of the Leibniz-Reynolds transport theorem from Section 21.2.4 to develop the evolution equation for the volume of an arbitrary region. In particular, equation (21.48) gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \mathrm{d}V\right] = \oint_{\partial\mathcal{R}} \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{22.63}$$

This result holds for both divergent and non-divergent flows. But for non-divergent flows we can go one step further by noting that

$$0 = \int_{\mathcal{R}} \nabla \cdot \boldsymbol{v}\, \mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{22.64}$$

Importantly, this result holds only when integrating around the boundary of the closed volume, $\partial\mathcal{R}$. It does not necessarily mean that $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$ holds at every point along the boundary. Indeed, when the boundary is time dependent, then $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} \neq 0$ generally holds along the boundary.

Making use of equation (22.64) allows us to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \mathrm{d}V\right] = \oint_{\partial\mathcal{R}} \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}} (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{22.65}$$

This result is identical to the mass budget equation (21.50) for the special case of a constant reference density appropriate for a Boussinesq ocean. The dia-surface transport, $(\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}$, measures the volume per time crossing the boundary of the region, whether that region has a static or moving boundary. For example, if the boundary is the ocean free surface, then we can make use of the surface kinematic boundary condition (22.4).

22.7 Meridional-depth circulation

Geophysical fluid flow is generally three-dimensional. However, it is sometimes useful to summarize aspects of that flow by integrating the mass transport over one of the directions. A common approach is to integrate over the zonal direction either between two solid-wall boundaries (as in an ocean basin) or over a periodic domain (as in the atmosphere or within the Southern Ocean). Doing so leaves a two-dimensional transport in the meridional-depth plane

$$V^{\rho} = \int_{x_1}^{x_2} \rho\, v\, \mathrm{d}x \qquad \text{and} \qquad W^{\rho} = \int_{x_1}^{x_2} \rho\, w\, \mathrm{d}x, \tag{22.66}$$

where

$$x_1 = x_1(y, z) \quad \text{and} \quad x_2 = x_2(y, z) \tag{22.67}$$

are expressions for the zonal boundaries as a function of (y, z), with Figure 22.5 offering a schematic. In some cases the zonal direction is periodic, as in the case of the global zonally integrated circulation in the atmosphere or for the Drake Passage latitudes in the Southern Ocean. In such cases we can dispense with x_1 and x_2 as the integration extends around the periodic domain. In other cases the basin has zonal boundaries, as in the Atlantic and Indian-Pacific oceans, and as depicted in Figure 22.5.

In this section we derive a streamfunction for the zonally integrated flow, with a streamfunction available when the zonally integrated flow is non-divergent. We focus on the meridional-depth streamfunction, with extention in Section 60.11 to the case of a circulation partitioned according to generalized vertical coordinates.

FIGURE 22.5: Geometry needed to compute the meridional-depth streamfunction. The zonal boundaries are written $x = x_1(y, z)$ and $x = x_2(y, z)$, which are generally functions of latitude and vertical position. The bottom is written as $z = \eta_{\rm b}(x, y)$ and the vertical position of an arbitrary constant depth surface is written $z =$ constant. We also display the constant zonal positions, $x_{1,2}^{\rm rock}$, which are fully within the rock, as well as the bottom position, $\eta_{\rm b}^{\rm rock}$, which is also within the rock. These rock coordinates allow us to dispense with much of the kinematic formalities needed to compute the streamfunction, with fluid flow taken as zero inside the rock.

22.7.1 The zonally integrated transport is non-divergent

In Section 7.1.3 we introduced the geometry of surfaces specified by the zonal position as in equation (22.67). There, we noted that by writing the functions $x_1(y, z)$ and $x_2(y, z)$, we must assume that the normal direction along the boundary everywhere has a nonzero and single-signed projection in the $\hat{\boldsymbol{x}}$ direction. If that is indeed the case (we dispense with this assumption below), then we can write the normal direction as

$$\hat{\boldsymbol{n}}_i = \frac{\nabla(x - x_i)}{|\nabla(x - x_i)|} = \frac{\hat{\boldsymbol{x}} - \hat{\boldsymbol{y}}\,\partial_y x_i - \hat{\boldsymbol{z}}\,\partial_z x_i}{|\sqrt{1 + (\partial_y x_i)^2 + (\partial_z x_i)^2}|}, \tag{22.68}$$

for boundaries $i = 1, 2$. Furthermore, the no-normal flow boundary condition at the bottom (Section 20.4.1) takes on the form

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}}_i = 0 \Longrightarrow u = v\,\partial_y x_i + w\,\partial_z x_i \quad \text{at } x = x_i(y, z). \tag{22.69}$$

We make use of this boundary condition in this section to prove that the zonally integrated flow is non-divergent.

To see how to create a streamfunction, consider the zonal integrated area transport for a non-divergent flow[11]

$$V(y, z, t) = \int_{x_1(y,z)}^{x_2(y,z)} v(x', y, z, t)\,\mathrm{d}x' \qquad \text{and} \qquad W(y, z, t) = \int_{x_1(y,z)}^{x_2(y,z)} w(x', y, z, t)\,\mathrm{d}x'. \tag{22.70}$$

Taking the meridional derivative of the meridional transport, and making use of Leibniz's rule

[11] The case for a steady compressible flow follows analogously since in that case $\nabla \cdot (\rho\,\boldsymbol{v}) = 0$, in which case we would consider $(\rho\,v, \rho\,w)$ rather than (v, w).

and the non-divergence condition, leads to

$$\frac{\partial V}{\partial y} = \frac{\partial}{\partial y}\left[\int_{x_1}^{x_2} v(x', y, z)\,\mathrm{d}x\right] \tag{22.71a}$$

$$= v(x_2)\,\partial_y x_2 - v(x_1)\,\partial_y x_1 + \int_{x_1}^{x_2} \frac{\partial v}{\partial y}\,\mathrm{d}x \tag{22.71b}$$

$$= v(x_2)\,\partial_y x_2 - v(x_1)\,\partial_y x_1 - \int_{x_1}^{x_2} \left[\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z}\right]\mathrm{d}x \tag{22.71c}$$

$$= -[u - v\,\partial_y x - w\,\partial_z x]_{x=x_2} + [u - v\,\partial_y x - w\,\partial_z x]_{x=x_1} - \frac{\partial}{\partial z}\int_{x_1}^{x_2} w(x', y, z)\,\mathrm{d}x \tag{22.71d}$$

$$= -\frac{\partial W}{\partial z}. \tag{22.71e}$$

To reach the final equality we made use of the no-normal flow boundary condition in the form of equation (22.69), so that the boundary terms vanish identically. We thus conclude that the zonally integrated transport is non-divergent

$$\frac{\partial V}{\partial y} + \frac{\partial W}{\partial z} = 0. \tag{22.72}$$

22.7.2 Meridional-depth streamfunction

As a consequence of the non-divergence condition (22.72), we can introduce a meridional-depth streamfunction

$$\Psi(y, z, t) = -\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{z} V(y, z', t)\,\mathrm{d}z' = -\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{z} \left[\int_{x_1(y,z')}^{x_2(y,z')} v(x', y, z', t)\,\mathrm{d}x'\right]\mathrm{d}z', \tag{22.73}$$

whose derivatives specify the zonally integrated flow. An idealized version of the meridional-depth circulation is shown in Figure 22.6, with this circulation in the form of an overturning cell. Note that the z dependence for the streamfunction (22.73) arises just from the upper limit of the vertical integral. Furthermore, the lower limit of $z = \eta_{\mathrm{b}}^{\mathrm{rock}}$ is a spatial constant that is chosen so that the lower limit on the integral is beneath the fluid anywhere in the full domain, with the convention that there is zero transport for any region below the fluid bottom (i.e., no fluid transport in rock). This specification for the lower integration limit ensures that the streamfunction has its spatial dependence just on (y, z). We further discuss this extension into the rock in Section 22.7.4.

FIGURE 22.6: An idealized depiction of a steady meridional-depth overturning circulation for the zonally integrated flow. Shown here are streamlines (isolines of constant Ψ) for the zonally integrated flow between two solid boundaries or over a zonally periodic domain. The flow is assumed to be non-divergent, as per equation (22.72). In the upper reaches of the fluid, flow moves northward (positive y), with downward motion as it reaches the northern boundary, then southward motion at depth and eventual return towards the surface near the southern boundary.

22.7.3 Verifying that Ψ is a streamfunction

It is a useful exercise to verify that Ψ as defined by equation (22.73) is indeed a streamfunction for the zonally integrated flow. Suppressing the time dependence for notational brevity, we first show that

$$\frac{\partial \Psi}{\partial z} = -\frac{\partial}{\partial z}\left[\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{z} V(y,z')\,\mathrm{d}z'\right] = -V(y,z), \tag{22.74}$$

where we used Leibniz's rule and noted that only the upper integration limit is a function of z. For the meridional derivative we have

$$\frac{\partial \Psi}{\partial y} = -\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{z} \frac{\partial V(y,z')}{\partial y}\,\mathrm{d}z' = \int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{z} \frac{\partial W(y,z')}{\partial z'}\,\mathrm{d}z' = W(y,z), \tag{22.75}$$

where we used the non-divergent condition (22.72), and we also set

$$W(z=\eta_{\mathrm{b}}^{\mathrm{rock}}) = 0, \tag{22.76}$$

which follows from our convention that $\eta_{\mathrm{b}}^{\mathrm{rock}}$ is below the deepest fluid region. Also, we are able to move the $\partial/\partial y$ derivative across the lower limit of the integral since $\eta_{\mathrm{b}}^{\mathrm{rock}}$ is a constant. We have thus shown that Ψ is a streamfunction since its derivatives equal to the zonally integrated flow.

To evaluate the streamfuction (22.73) at the ocean surface, $z=\eta(x,y,t)$, we follow a method similar to how we deal with the bottom. Namely, introduce a constant η^{air} that is larger than any value of $\eta(x,y,t)$ and with the convention that the transport is zero in regions above the ocean surface. In this case the streamfunction computed across the full depth of the domain is given by minus the net meridional transport across the chosen latitude

$$\Psi(y,z=\eta^{\mathrm{air}}) = -\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{\eta^{\mathrm{air}}} V\,\mathrm{d}z' = -\int_{\eta_{\mathrm{b}}^{\mathrm{rock}}}^{\eta^{\mathrm{air}}}\left[\int_{x_1}^{x_2} v\,\mathrm{d}x\right]\mathrm{d}z'. \tag{22.77}$$

Volume conservation means that this transport vanishes in the steady state but it is generally nonzero in the presence of transients or boundary volume fluxes.

22.7.4 Generalizing to arbitrary domains

The method of extending the integration into the rock, and thus transforming a spatially dependent integration limit to a constant, serves to capture the flow while simplifying the practical calculation of the streamfunction. Indeed, it is a necessary method for computing the streamfunction in realistic domains such as those where the zonal boundaries are not monotonic functions of latitude or depth. A further generalization is found by introducing zonal rock coordinate values, $x_{1,2}^{\mathrm{rock}}$, which are fully outside of the ocean fluid domain as depicted in Figure 22.5. Making use of these values allows us to write the streamfunction (22.73) in the equivalent form

$$\Psi(y,z,t) = -\int_{x_1^{\mathrm{rock}}}^{x_2^{\mathrm{rock}}}\left[\int_{\eta_{\mathrm{b}}(x',y)}^{z} v(x',y,z',t)\,\mathrm{d}z'\right]\mathrm{d}x'. \tag{22.78}$$

Relative to equation (22.73), we moved the zonal integral to the outside and vertical integral to the inside. Reference to Figure 22.5 offers a pictural explanation for why this integral is identical to equation (22.73). The streamfunction expression (22.78) offers a more suitable framework for studying circulation partitioned according to surfaces of constant generalized vertical coordinate

rather than constant depth. That formulation requires kinematics arising from generalized vertical coordinates, and so its discussion is postponed until Section 60.11.

22.7.5 $\Psi(y, z)$ does not generally delineate particle pathlines

In Section 18.11 we showed that a fluid particle pathline equals to a streamline when the flow is steady, and then in Section 22.4.1 we showed that streamfunction isolines are streamlines. One might then be led to infer that for a steady flow, the meridional-depth streamfunction delineates fluid particle pathlines in the y-z plane. That inference, however, is generally wrong. The reason is that that zonal integration removes spatial degrees of freedom that can hide crucial flow properties.

Two examples are the Ferrel Cell in the atmosphere (*Andrews et al.*, 1987) and overturning circulation in the Southern Ocean (*Döös and Webb*, 1994) (see *Karoly et al.* (1997) for a unified discussion of their streamfunctions). For both of these circulations, fluid particles in the fluid interior are mostly confined to constant potential density or specific entropy surfaces. Since these surfaces are not flat, and generally have slopes in the zonal direction, then closed north-south motion on such surfaces can appear as closed isolines when projected into the meridional-depth plane. The accumulation of such motions on vertically stacked potential density surfaces creates a single closed meridional-depth streamfunction contour. This closed streamfunction contour suggests that fluid particle motion extends from near the top of the fluid column to near the bottom of the fluid column. In fact, no such motion occurs for a single fluid particle since the potential density surfaces generally do not extend from the top to bottom of the column.

This example motivates the study of overturning circulation as projected onto potential density coordinates (for the ocean) or isentropic coordinates (for the atmosphere). The associated circulation streamfunctions expose flow properties that are complementary to the meridional-depth streamfunction. We postpone the development of such streamfunctions until Section 60.11, after developing the kinematics of generalized vertical coordinates.

22.8 Kinematic free surface equation

We here derive the volume budget over a column of fluid. This budget provides a kinematic expression for the free surface evolution in a non-divergent flow.

22.8.1 Derivation

Vertically integrate the constraint, $\nabla \cdot \boldsymbol{v} = 0$, over the depth of an ocean column, from $z = \eta_{\mathrm{b}}(x, y)$ at the bottom to $z = \eta(x, y, t)$ at the free surface and use the bottom and surface kinematic boundary conditions. This calculation yields

$$0 = \int_{\eta_{\mathrm{b}}}^{\eta} \nabla \cdot \boldsymbol{v} \, \mathrm{d}z \tag{22.79a}$$

$$= w(\eta) - w(\eta_{\mathrm{b}}) + \int_{\eta_{\mathrm{b}}}^{\eta} \nabla \cdot \boldsymbol{u} \, \mathrm{d}z \tag{22.79b}$$

$$= w(\eta) - w(\eta_{\mathrm{b}}) + \nabla \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \right] - \boldsymbol{u}(\eta) \cdot \nabla \eta + \boldsymbol{u}(\eta_{\mathrm{b}}) \cdot \nabla \eta_{\mathrm{b}} \tag{22.79c}$$

$$= [w(\eta) - \boldsymbol{u}(\eta) \cdot \nabla \eta] - [w(\eta_{\mathrm{b}}) - \boldsymbol{u}(\eta_{\mathrm{b}}) \cdot \nabla \eta_{\mathrm{b}}] + \nabla \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \right], \tag{22.79d}$$

where we made use of Leibniz's Rule to move the horizontal divergence outside of the integral. We now make use of the surface kinematic boundary condition (22.5) and the bottom no-flow

condition

$$w(\eta) - \boldsymbol{u} \cdot \nabla \eta = -Q_{\mathrm{m}}/\rho_0 + \partial_t \eta \qquad z = \eta \tag{22.80a}$$

$$w = \boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} \qquad z = \eta_{\mathrm{b}} \tag{22.80b}$$

to render the free surface equation for a fluid with a non-divergent flow

$$\partial_t \eta = Q_{\mathrm{m}}/\rho_0 - \nabla \cdot \boldsymbol{U}, \tag{22.81}$$

where

$$\boldsymbol{U} = \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \tag{22.82}$$

is the depth integrated horizontal transport. For the special case of a steady state with zero boundary mass flux, the depth integrated flow is non-divergent

$$\nabla \cdot \boldsymbol{U} = 0 \qquad \text{if } Q_{\mathrm{m}} = 0 \text{ and } \partial \eta / \partial t = 0. \tag{22.83}$$

22.8.2 Comments

Comparing to the surface kinematic boundary condition

Recall that we can write the surface kinematic boundary condition for a non-divergent flow in the special form of equation (22.6). Comparing to the free surface equation (22.81) renders the identity

$$\partial_t \eta - Q_{\mathrm{m}}/\rho_0 = -\nabla \cdot \boldsymbol{U} = \nabla \cdot [(z - \eta) \, \boldsymbol{v}], \tag{22.84}$$

where the final expression is evaluated at $z = \eta$ after evaluating the divergence.

Concerning the evolution of sea level

Comparing the free surface equation (22.81) holding for a non-divergent flow to the free surface equation (20.84) holding for a divergent flow indicates that the non-divergent case is missing a contribution from the material changes in density

$$\frac{\partial \eta}{\partial t} = \frac{Q_{\mathrm{m}}}{\rho_0} - \nabla \cdot \boldsymbol{U} \qquad \text{Boussinesq ocean } (\nabla \cdot \boldsymbol{v} = 0) \tag{22.85a}$$

$$\frac{\partial \eta}{\partial t} = \frac{Q_{\mathrm{m}}}{\rho(\eta)} - \nabla \cdot \boldsymbol{U} - \int_{\eta_{\mathrm{b}}}^{\eta} \frac{1}{\rho} \frac{\mathrm{D}\rho}{\mathrm{D}t} \, \mathrm{d}z \qquad \text{non-Boussinesq ocean } (\nabla \cdot \boldsymbol{v} \neq 0). \tag{22.85b}$$

The material time changes to density arise from mixing and boundary fluxes of buoyancy. The particular absence of an impact from surface buoyancy fluxes means that the free surface in a Boussinesq ocean is not impacted by global thermal expansion, such as that arising from ocean warming. *Greatbatch* (1994) and *Griffies and Greatbatch* (2012) provide a recipe for diagnostically addressing this formulational limitation, thus enabling a study of global mean sea level with Boussinesq ocean models.

22.9 Exercises

EXERCISE 22.1: NON-DIVERGENT AND IRROTATIONAL FLOW IN POLAR COORDINATES
Consider the following two-dimensional velocity field written using polar coordinates (Section 10.3)

$$\boldsymbol{u}(r,\vartheta) = \hat{\boldsymbol{r}}\, U\,(1 - a^2/r^2)\cos\vartheta - \hat{\boldsymbol{\vartheta}}\, U\,(1 + a^2/r^2)\sin\vartheta. \tag{22.86}$$

(a) Show that the flow is non-divergent, $\nabla \cdot \boldsymbol{u} = 0$.

(b) Show that the flow is irrotational, $\nabla \times \boldsymbol{u} = 0$.

EXERCISE 22.2: STREAMLINES FOR CELLULAR FLOW
Sketch the velocity field for this streamfunction

$$\psi(x,y) = A\,\sin(k\,x)\,\sin(l\,y), \tag{22.87}$$

where (k,l) are the zonal and meridional components to the wavevector, respectively. Hint: assume any convenient value for k,l and the amplitude, A, but indicate what values were chosen. Furthermore, show vectors so that the sense of the flow is clear.

EXERCISE 22.3: ZERO NET AREA TRANSPORT THROUGH STATIC CLOSED CURVE
For a two-dimensional non-divergent flow, show that there is zero net area transport of fluid crossing an arbitrary static and simply connected closed curve. Consequently, the area remains unchanged for any closed region moving with the fluid flow. Note that in two space dimensions, the area transport of fluid across a line has dimensions $\mathrm{L}^2\ \mathrm{T}^{-1}$, thus representing an area transport.

EXERCISE 22.4: ZERO NET VOLUME TRANSPORT THROUGH STATIC CLOSED SURFACE
For a three-dimensional non-divergent flow, show that there is zero net volume transport of fluid crossing an arbitrary static and simply connected closed surface within the fluid interior. Note that in three space dimensions, the transport of fluid across a surface has dimensions $\mathrm{L}^3\ \mathrm{T}^{-1}$, thus representing a volume transport.

EXERCISE 22.5: NET FLUID TRANSPORT ACROSS AN ARBITRARY SURFACE
Consider flow in a container with static sides/bottom. Draw an arbitrary static surface, $\mathcal{S}$, within the fluid from one side of the container to the other as in Figure 22.7. Integrate the fluid volume transport over the surface, $\int_{\mathcal{S}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}$.

(a) For a non-divergent flow, show that the volume transport, $\int_{\mathcal{S}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}$, vanishes. That is, the net volume transport across the surface is zero.

(b) Specialize the above result to a horizontal surface so that we see there is zero integrated vertical volume transport across the surface, $\int_{\mathcal{S}} w\, \mathrm{d}x\, \mathrm{d}y = 0$. Discuss these results. Note: see Section 60.3.8 for the more general case of a non-static surface.

(c) Rework part (a) for the case of a compressible fluid so that fluid elements conserve their mass rather than their volume, in which case mass continuity is given by equation (20.10)

$$\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{v}. \tag{22.88}$$

Again, we are to compute the volume transport across a surface, but now for the case of a compressible flow rather than non-divergent flow.

FIGURE 22.7: Schematic for exercise 22.5, whereby we show that the net flow vanishes across a static surface, $\mathcal{S}$, that extends from one boundary to the other within a non-divergent flow.

EXERCISE 22.6: RIGID-BODY ROTATION

Consider a velocity field corresponding to a time-independent rigid-body rotation on a plane

$$\boldsymbol{u} = \Omega\, \hat{\boldsymbol{z}} \times \boldsymbol{x} = \Omega\, (-y\, \hat{\boldsymbol{x}} + x\, \hat{\boldsymbol{y}}), \tag{22.89}$$

where $\Omega > 0$ is a constant rotation rate.

(a) Compute the relative vorticity, $\boldsymbol{\omega} = \nabla \times \boldsymbol{u}$.

(b) Compute the streamfunction $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$. Draw streamfunction contours; i.e., lines of constant streamfunction. Put arrows to orient the flow along the streamlines.

(c) Describe the geometry of material lines. Hint: since the velocity field is time-independent, material parcel trajectories are coincident with streamlines.

EXERCISE 22.7: ALTERNATIVE FORM OF MERIDIONAL-DEPTH STREAMFUNCTION

In equation (22.73), we introduced the meridional-depth overturning streamfunction

$$\Psi(y, z, t) = -\int_{\eta_{\mathrm{b}}^{\min}}^{z} V(y, z', t)\, \mathrm{d}z'. \tag{22.90}$$

Show that an alternative streamfunction is given by

$$\Gamma(y, z, t) = \int_{y_s}^{y} W(y', z, t)\, \mathrm{d}y', \tag{22.91}$$

where y_s is a constant latitude southward of the southern-most latitude where fluid exists. That is, show that

$$\frac{\partial \Gamma}{\partial y} = W \quad \text{and} \quad \frac{\partial \Gamma}{\partial z} = -V. \tag{22.92}$$

EXERCISE 22.8: VOLUME TRANSPORT THROUGH STREAMTUBE ENDS

Recall our discussion of streamtubes in Section 18.11.2 (see in particular Figure 18.6). Show that for a non-divergent flow field, the volume transport (volume per time) through the two streamtube ends balances

$$\int_{\mathcal{S}_1} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}_1\, \mathrm{d}\mathcal{S} + \int_{\mathcal{S}_2} \boldsymbol{v} \cdot \hat{\boldsymbol{n}}_2\, \mathrm{d}\mathcal{S} = 0, \tag{22.93}$$

where $\hat{\boldsymbol{n}}_1$ and $\hat{\boldsymbol{n}}_2$ are the outward normals at the two end caps $\mathcal{S}_1$ and $\mathcal{S}_2$. Since the end caps have oppositely directed outward normals, equation (22.93) says that the volume transport entering one streamtube end equals to that leaving the other end. Furthermore, the area of the streamtube is inversely proportional to the local normal velocity, so that flow speeds up when moving through a narrower region of the tube.

The identity (22.93) holds whether the flow is steady or not. Yet for an unsteady flow, streamlines and pathlines are not generally equivalent. So although the volume transport through the two ends is the same, the material contained in that transport is not necessarily the same. That is, the pathlines of fluid particles are not necessarily parallel to streamlines, so that fluid particles can generally cross the streamtube boundaries.

FIGURE 22.8: Schematic for exercise 22.9 with $z = \eta(x, y, t)$ the free surface at the top of the fluid. This exercise shows that the area integrated time tendency for the free surface vanishes in the absence of mass transport across the free surface.

EXERCISE 22.9: AREA AVERAGE OF FREE SURFACE TIME TENDENCY

Consider a non-divergent ocean flow bounded by a free upper surface and a solid bottom. Let $z = \eta_{\mathrm{b}}(x, y)$ be the vertical position of the static bottom, and $z = \eta(x, y, t)$ be the position of the transient free surface, so that the thickness of the layer is $h = -\eta_{\mathrm{b}} + \eta$ (see Figure 22.8). The horizontal extent of the layer is a function of time, and is defined by a vanishing thickness $h = -\eta_{\mathrm{b}} + \eta = 0$ (e.g., ocean water reaching the shoreline). Assume no material crosses either the surface or bottom boundaries, so that both boundaries are material surfaces. Show that the free surface has a time derivative, $\partial\eta/\partial t$, whose area average vanishes. Discuss this result.

EXERCISE 22.10: VOLUME INTEGRAL OF THE NON-DIVERGENT CARTESIAN VELOCITY FIELD

Consider a non-divergent ocean flow in Cartesian coordinates bounded by a free upper surface and a solid bottom over a domain $\mathcal{R}$. Let $z = \eta_{\mathrm{b}}(x, y)$ be the vertical position of the static bottom, and $z = \eta(x, y, t)$ be the position of the transient free surface as in Figure 22.8. Prove that the domain integral of the velocity is given by

$$\int_{\mathcal{R}} \boldsymbol{v}\, \mathrm{d}V = \int_{z=\eta} \boldsymbol{x}\, (\boldsymbol{v} \cdot \hat{\boldsymbol{n}})\, \mathrm{d}\mathcal{S} = \int_{z=\eta} \boldsymbol{x}\, (\partial_t \eta - Q_{\mathrm{m}}/\rho_0)\, \mathrm{d}x\, \mathrm{d}y. \tag{22.94}$$

Hint: make use of the results from Section 2.7.7 and then use the kinematic boundary conditions from Section 22.3. Note that to enable this exercise we assume Cartesian coordinates, which is required when integrating a vector.

EXERCISE 22.11: VERIFYING THAT Ψ IS A STREAMFUNCTION

In Section 22.7.3 we verified that the meridional-depth streamfunction, Ψ, is indeed a streamfunction when it is written in the form of equation (22.73). Provide an analogous derivation to show that the alternative expression in equation (22.78) is indeed also a streamfunction. Hint: the derivation closely follows that in Section 22.7.3.

Part IV

Equilibrium thermodynamics

Thermodynamics is a phenomenological discipline focused on relations between macroscopic properties of physical systems, in particular how those properties change as the system transitions from one state to another. Thermodynamics is a necessary ingredient for understanding the stability, evolution, and transformation of macroscopic systems, with such topics at the heart of geophysical fluid mechanics. In this part of the book we develop elements of equilibrium thermodynamics relevant to a multi-component fluid. We limit concern to a single phase of matter (liquid or gas), noting that a more complete treatment relevant to geophysical fluids must consider multiple phases and their transitions.

We focus on classical thermodynamics, which means we are generally concerned with macroscopic states of a fluid system; i.e., a *macrostate* that is specified by a few macroscopic properties such as temperature, pressure, and matter concentration. For our purposes, a macrostate is synonymous with *thermodynamic state*. This nomenclature must be modified when discussing statistical mechanics and quantum mechanics, whereby the complementary notion of a microstate takes on a far more central role than considered in this book.

The name "thermodynamics" suggests that the discipline concerns how heat moves through a system. Indeed, that topic formed the focus of the subject in the 19th century, as exemplified by *Maxwell* (1872). However, treatments following the formulation from Gibbs generally focus on energy and entropy, from which temperature is derived. Energy and entropy are logically distinct concepts that together form the basis for thermodynamics. Energy is a concept borrowed from mechanics. *Internal energy* refers to the energy of microscopic degress of freedom, with this energy the concern of Chapter 23, where we focus on transitions between thermodynamic equilibrium states in the absence of gravity. In Chapter 24 we extend the equilibrium theory to include a geopotential, with this study directly relevant to geophysical fluid mechanics.

Our study of thermodynamics is incompletely addressed in this part of the book. Further treatment concerns the melding of thermodynamics with the mechanics describing macroscropic fluid motion. After introducing the basics of momentum and mechanical energy for macroscopic motion in Chapter 25, we return to thermodynamics in Chapter 27 as applied to a moving fluid. That study necessarily moves beyond the restrictions of equilibrium thermodynamics considered in Chapters 23 and 24, but only slightly. The key assumption we make in Chapter 27 is that each fluid element is locally within thermodynamic equilibrium. The assumption of local thermodynamic equilibrium allows us to bring forward the key facets of equilibrium thermodynamics to the nonequilibrium thermodynamics required for moving fluids.

Thermodynamics is a deep subject whose subtleties rarely cease to puzzle and amaze both the novice and expert. For some perspective, consider the following reflections from two giants of physics on the enduring and profound nature of thermodynamics.

> Thermodynamics is a funny subject. The first time you go through it, you do not understand it at all. The second time you go through it, you think you understand it, except for one or two points. The third time you go through it, you know you do not understand it, but by that time you are so used to the subject it does not bother you anymore. *Attributed to Arnold Sommerfeld, unknown source*

> A theory is the more impressive the greater the simplicity of its premises, the more different kinds of things it relates, and the more extended is its area of applicability. Therefore the deep impression which classical thermodynamics made upon me. It is the only physical theory of universal content concerning which I am convinced that, within the framework of the applicability of its basic concepts, it will never be overthrown. *Einstein* (1949)

Chapter 23

Equilibrium thermodynamics

We here study equilibrium thermodynamics following classical treatments, with emphasis on the needs for atmosphere and ocean fluid mechanics. Thermodynamics is conceptually subtle but technically straightforward, thus making this chapter relatively long on words yet short on equations.

CHAPTER GUIDE

Our treatment follows *Callen* (1985), *Reif* (1965), chapter 2 of *Landau and Lifshitz* (1980), and chapter 2 of *Ebeling and Feistel* (2011). Mathematical tools required for thermodynamics include the basics of partial differential calculus from Chapter 2.

23.1 Conceptual foundations

In our study of equilibrium thermodynamics, we are concerned with macroscopic fluid systems whose evolution tends toward states in which its properties are determined by intrinsic factors rather than depending on memory of previous external influences. These particular *macrostates* are known as *thermodynamic equilibria.* One aim for thermodynamics is the determination of a new thermodynamic equilibrium after the removal of a constraint. When a constraint is removed, the system moves through a sequence of macrostates as it evolves towards its new equilibrium, with the time evolution through such macrostates referred to as a *process*. Any macrostate is comprised of a huge number of microscopic degrees of freedom; i.e., *microstates*. The allure of thermodynamics is that we can describe macroscopic systems, and the process of moving from one thermodynamic equilibria to another, using just a handful of macroscopically measurable properties.

23.1.1 Thermodynamic equilibrium

Equilibrium thermodynamics is the study of physical systems in *thermodynamic equilibrium* and how these systems transit from one thermodynamic equilibrium state to another through quasi-static processes. We explore the defining characteristics of thermodynamic equilibrium within this chapter. At a basic level, a system in thermodynamic equilibrium could remain in that state for all time, with details of the equilibrium dependent on the constraints imposed on the system. When such constraints are removed, then a system generally transitions to another equilibrium state. Note that "for all time" is a loaded term. More precisely, we mean "for a time extremely long compared to any time scale relevant to the physical system under consideration".

A system in thermodynamic equilibrium experiences no time changes to the system's macroscopic properties. However, all mechanical steady states are not necessarily in thermodynamic equilibrium. For example, consider a region of fluid with nonzero heat fluxes yet with no heat flux convergence so the temperature of the region does not change. As we see in this chapter, a temporally constant temperature is a signature of a macroscopic steady state, whereas the flow of heat is the sign of thermodynamic disequilibrium. The distinction is sometimes subtle and always important.

To provide motivation for the study of thermodynamic equilibrium, consider an isolated system, defined as a physical system that does not exchange heat, matter, or mechanical forces with its surroundings, though possibly experiencing body forces such as from gravity.[1] Given sufficient time, all isolated systems will reach their thermodynamic equilibrium consistent with the constraints on that system. Geophysical fluids are routinely exposed to mechanical and thermal interactions with their surrounding environment, and as such as they are not isolated. Even so, it is useful to understand the basic properties of isolated systems and their corresponding thermodynamic equilibrium, as doing so provides the starting point for understanding how systems deviate from thermodynamic equilibrium. Furthermore, a fundamental assumption of thermodynamics applied to moving fluids (Chapter 27) is that each fluid element is in a local thermodynamic equilibrium, even while the macroscopic fluid does not reach a global thermodynamic equilibrium. Hence, we are motivated to study equilibrium thermodynamics since it forms the foundations for a study of moving fluids, even when those moving fluids are globally far from thermodynamic equilibrium.

23.1.2 Exchanges between thermodynamic systems

In the study of thermodynamics it is important to characterize how a physical system interacts with its surrounding environment through mechanical, thermal, and material interactions and exchanges. Infinitesimal fluid elements, and their accumulation into finite fluid regions, constitute the physical systems we are concerned with in this book.[2] We are concerned with systems that routinely interact mechanically with their surroundings so that the systems are mechanically open; i.e., they feel pressure from the surrounding environment. Hence, we here focus on characterizing how a physical system interacts thermally and materially with its surroundings.

- THERMALLY OPEN (DIABATIC) AND MATERIALLY OPEN: An open physical system exchanges matter, thermodynamic properties, and mechanical forces with its surrounding environment. All naturally occuring fluid systems are open in this manner.

- THERMALLY OPEN (DIABATIC) AND MATERIALLY CLOSED: We have occasion to consider a thermodynamic system that is mechanically and thermally open yet materially closed. Such systems maintain a fixed matter content yet exchange thermal and mechanical energy with their surrounding environment.

- THERMALLY CLOSED (ADIABATIC) AND MATERIALLY CLOSED: We sometimes consider a thermodynamic system that is both materially and thermally closed and yet mechanically open. In fluid mechanics, such systems constitute *material fluid parcels* (Section 18.3), defined as infinitesimal regions that maintain fixed matter and thermal properties yet move according to the mechanical forces acting on the parcel. A *perfect fluid* is a continuum of infinitesimal material fluid parcels.

Again, each of the above interactions is mechanically open, so that the system is exposed to mechanical forces, either contact forces such as pressure and friction or body forces such as gravity and Coriolis. For pedagogical purposes we first study thermodynamics of fluid elements that are thermally open yet materially closed and then extend to fluid elements that are both thermally and materially open. As a somewhat overloaded terminology, "adiabatic" in fluid mechanics is often used for a fluid element that is *both* thermally closed *and* materially closed. However, we maintain the distinction in our treatment to maintain consistency with the physics literature.

[1] We define body and contact forces in Section 25.2 when studying Newton's second law.
[2] See Section 18.3.4 for a reminder of how we define fluid elements.

23.1.3 Extensive and intensive properties

We characterize thermodynamic properties according to whether they are *extensive* or *intensive*. Extensive properties scale with the size of the system, with examples including mass, internal energy and entropy. Mathematically, we say that extensive properties scale with a power 1 with the size of the system (we return to this point in Section 3.8).

A *homogeneous fluid* is one in which all *intensive properties* are identical, with temperature, pressure, and chemical potential the canonical examples. This characteristic of intensive properties contrasts to extensive properties. Hence, intensive properties do not scale with the size of a system. That is, intensive properties are scale invariant and thus scale with power 0 as the size of the system changes. Intensive properties describe possible gradients within a thermodynamic system. In the absence of an externally imposed force field such as gravity, intensive properties are uniform for systems in thermodynamic equilibrium (we show this property in Sections 23.2.8 and 24.1.2). However, as discussed in Section 24.1, hydrostatic balance is realized in thermodynamic equilibrium for a fluid in an externally imposed gravity field, in which case pressure is not uniform.

Extensive and intensive properties come as conjugate pairs in thermodynamics, whereby intensive properties always multiply their conjugate extensive property (e.g., pressure-volume and temperature-entropy) when appearing in the various forms of the first law of thermodynamics. In this chapter, extensive properties are labeled with a superscript e (except for the mass and volume), with this label *not* a tensor index. In Section 23.5 we introduce the internal energy per mass and entropy per mass, as doing so is most convenient when studying thermodynamic systems of fixed mass. In this manner we can convert the extensive properties to their specific (per mass) form in which case we drop the e superscript. It is the specific form of extensive properties that provides a straightforward transfer to the study of constant mass fluid elements.

23.1.4 Thermodynamic configuration space

The configuration space of a thermodynamic system is not specified by coordinates in geographical space. Rather, it is specified by a suite of continuous thermodynamic properties and then studying how those properties change for processes arising from the removal of constraints. In this manner, we conceive of thermodynamic properties as defining coordinates for a point within *thermodynamic configuration space*.[3] Each point in thermodynamic configuration space is a thermodynamic equilibrium state, whereas non-equilibrium thermodynamic states.

We observe that one commonly encounters thermodynamic configuration space diagrams with orthogonal axes specifying values of thermodynamic properties. However, there is no notion of distance or angle between points in thermodynamic configuration space since there is no metric structure.[4] Mathematically, we say that thermodynamic configuration space comprises a *differentiable manifold*.[5]

23.1.5 Reversible processes and quasi-static processes

In our study of classical point particle mechanics in Section 14.3, we noted that the particle motion time reversal symmetric in the absence of dissipation.[6] That is, for mechanically reversible

[3] We follow Section 4.2 of *Callen* (1985) in this presentation of thermodynamic configuration space.

[4] See Section 9.1 for a discussion of the metric tensor used in geographic space.

[5] A summary of the mathematical structure of equilibrium thermodynamics can be found in this online tutorial from Salamon et al. Note that there are some formulations of thermodynamics that do introduce a metric through properties of the entropy. In so doing, these formulations transform the differentiable manifold to a Riemannian manifold. There are tradeoffs when doing so, with *Andresen et al.* (1988) offering a survey of the tradeoffs. Here, we follow the approach of Gibbs as articulated in the books by *Reif* (1965) and *Callen* (1985).

[6] We extend the point particle discussion to a perfect fluid in Section 26.8.11.

processes, there is no physical means to distinguish the time direction. Consequently, an animation of the motion looks sensible when viewed either forward or backward in time.

We here extend the notion of mechanical reversibility to thermodynamic processes. Namely, a thermodynamically *reversible process* can traverse a path through thermodynamic configuraton space in either direction. It follows that a reversible process continuously moves between thermodynamic equilibria, which in turn means that a reversible process traces out a continuous path through thermodynamic configuration space. As seen in Section 23.2.7, the net entropy of a physical system plus its surrounding environment remains unchanged by reversible processes, whereas irreversible processes are characterized by an increase in the net entropy.

Like a reversible process, a *quasi-static process* moves continuosly between thermodynamic equilibrium states, so it traces out a path in thermodynamic configuration space. However, a quasi-static process can be either reversible or irreversible. If a quasi-static process is irreversible, then its path in thermodynamic configuration space is in a direction that increases the net entropy of the system plus environment, whereas if it is reversible then the path leaves the net entropy unchanged. In this manner, all reversible processes are quasi-static, and yet some quasi-static processes are irreversible.[7]

A quasi-static process is fully defined by its continuous path through thermodynamic configuration space. Hence, it does not involve time or rates of change. Evidently, a quasi-static process is not a real physical process. However, we can use a real physical process to approximate a quasi-static process, so long as the quasi-static process has a monotonically nondecreasing entropy. For example, consider a quasi-static path that moves from point A to point B in thermodynamic configuration space. Approximating this path with a real physical process involves intermediate states that are not in necessarily thermodynamic equilibrium, so that the intermediate states are not representable by points in a thermodynamic configuration space. The accuracy of the approximation is a function of the rate to which thermodynamic equilibrium is approached, which itself is a function of the degree to which constraints are modified as the real physical system moves from A to B.

We are afforded the means to unambiguously measure thermodynamic properties (e.g., temperature, pressure, chemical potential) only when a physical system is in thermodynamic equilibrium. Hence, when a system traverses a quasi-static path through thermodynamic configuration space, its properties are well defined, whereas when a system is out of equilibrium the properties are fuzzy. This importance placed on thermodynamic equilibrium is of clear concern when applying thermodynamics to a moving geophysical fluid, in which case the fluid is generally far from equiliibrium. We return to this important point in Chapter 27 where we introduce the hypothesis of *local thermodynamic equilibrium*, which is the foundation upon which equilibrium thermodynamics is extended to continuous media such as a fluid.

23.1.6 Internal energy and total energy

As discussed in Chapter 17, there are a huge number of microscopic (molecular) degrees of freedom that are averaged over when describing a fluid as a continuous media. *Internal energy* embodies the energy of microscopic degrees of freedom not explicitly considered in a macroscopic continuum treatment. Internal energy is not readily accessed or harnessed, which contrasts to the mechanical energy of the macroscopic motion.

For a simple ideal gas (Section 24.4), internal energy arises from the translational kinetic energy of molecular motion, as well as degrees of freedom associated with rotation and vibration.

[7] Some authors do not make a distinction between a quasi-static process and a reversible process. Our treatment follows *Callen* (1985) (see his sections 4.2 and 4.3) and *Reif* (1965) (see his sections 2.9 and 2.10), whereby reversible processes are subsets of quasi-static processes.

Kinetic theory studies of a simple ideal gas suggests that we conceive of internal energy as *thermal energy*. That is, we idealize molecules as point masses whose kinetic energy is directly related to temperature, and with the internal energy of an ideal gas directly proportional to temperature. However, for a general fluid, particularly for liquids, the internal energy is far more than a measure of the kinetic energy of molecules, as real molecules exhibit intermolecular potential energy arising from molecular interactions. In general, the concept of internal energy is rather slippery. We are thus motivated to sidestep internal when getting serious about quantitative notions, such as when studying energetics of fluid flow in Chapter 27. We do so by appealing to the conservation of *total energy* as postulated in Section 23.1.7. Even so, to lay the foundations we largely focus on internal energy in this chapter.

23.1.7 Postulates of thermodynamics

Thermodynamics is not a first principles theory, though it does have its roots in statistical mechanics. We follow *Callen* (1985) by building thermodynamics from a set of postulates from which deductive results are derived. The following postulates render a logical basis for the subject, with the bulk of this chapter exemplifying these postulates and developing implications.

- ⋆ THERMODYNAMIC EQUILIBRIUM: There exists states of thermodynamic equilibrium that are completely characterized macroscopically by a few extensive properties, including internal energy, volume, and mass (or mole number). For each thermodynamic equilibrium there exists a scalar intensive property, called the *thermodynamic temperature*, or more brielfly the temperature, that is uniquely defined. Furthermore, the termpature has the same value for two systems in thermodynamic equilibrium with one another.

- ⋆ ZEROTH LAW OF THERMODYNAMICS: When two systems, A and B, are each separately in thermodynamic equilibrium with a third system, C, then the systems A and B are also in thermodynamic equilibrium with one another.

- ⋆ MAXIMUM ENTROPY: *Entropy* is an extensive property of a macrostate. The values assumed by the other extensive properties are those that maximize the entropy over the manifold of constrained thermodynamic equilibrium states. This postulate is fundamental to how we determine properties of thermodynamic equilibria.

- ⋆ ENTROPY INCREASES: The entropy of a composite macroscopic system is additive over the constituent subsystems. Furthermore, entropy is a continuous and differential function that is a monotonically increasing function of the internal energy. This postulate is fundamental to how we use thermodynamics for composite systems such as a fluid.

- ⋆ TOTAL ENERGY IS CONSERVED: The total energy of a thermodynamic system is locally (in space and time) conserved while undergoing a thermodynamic process. This property constitutes the *first law of thermodynamics*. For a macroscopic fluid, total energy is the sum of the internal energy arising from microscopic degrees of freedom plus the mechanical energy of macroscopic degrees of freedom. In this chapter, as well as Chapter 24, we are mostly concerned with internal energy, whereas Chapters 25 and 27 extend the discussion to include mechanical energy. Space and time locality of total energy conservation means that physical processes are not allowed in which total energy disappears from one point in space or time only to reappear at a distant point. As a corollary, we are afforded a local budget equation for total energy, whereby energy is transferred from one form to another and with particular forms of this budget equation a topic of Chapter 27. Note that energy is well defined for both microstates and macrostates, whereas entropy is only defined for macrostates.

- ⋆ THIRD LAW OF THERMODYNAMICS: Internal energy and entropy are extensive scalar quantities that are finite for finite systems and bounded from below. In the limit of zero thermodynamic temperature for single-phase systems (single state of matter), the derivatives of entropy with respect to extensive variables disappear asymptotically. Many take the zero temperature limit to have zero entropy, though statistical fluctuations break this assumption (see page 51 of *Ebeling and Feistel* (2011) for discussion). We have little direct use for the third law, though it takes on an important role when considering quantum statistical mechanics.

The two postulates concerning entropy (entropy maximum and entropy increasing) constitute the *second law of thermodynamics*. Statistical mechanics reveals the statistical nature of entropy and the second law. In Sections 23.2.8 and 24.1.2, we see how it provides the basis for determining properties at thermodynamic equilibrium, and for how systems approach equilibrium. We make further use of the second law in Chapter 27 to constrain certain processes acting in a multicomponent fluid.

23.2 Materially closed systems

We here apply the foundational concepts from Section 23.1 to develop the thermodynamics of a physical system that is materially closed.

23.2.1 First law of thermodynamics

The first law of thermodynamics for a materially closed system establishes a relationship between infinitesimal changes of internal energy of a physical system, the work done to or by the system, and the thermal energy transferred between the system and its surrounding environment. The first law takes on the mathematical form

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = \text{đ}\mathcal{W} + \text{đ}\mathcal{Q} \qquad \Longleftarrow \text{materially closed.} \tag{23.1}$$

In this equation, $\mathrm{d}\mathcal{I}^{\mathrm{e}}$ is the exact differential of the internal energy; $\text{đ}\mathcal{W}$ is the change in internal energy due to work applied to the system (*working*); and $\text{đ}\mathcal{Q}$ is the internal energy change due to thermal energy transferred to the system (*heating*). We only have occasion to study mechanical work in this book, though note that there are other forms such as those arising from electromagnetic forces.

The first law of thermodynamics is a statement of energy conservation for a physical system, where energy changes arise from working and heating applied to the system or by the system. We are only interested in changes to the energy, with the absolute value of the energy of no concern. We focus on the internal energy by ignoring the mechanical energy associated with moving fluids. This assumption is relaxed in Chapter 27, where we include mechanical energy of macroscopic motion (Section 27.4) along with internal energy, thus forming the total energy of a moving fluid.

23.2.2 The nature of working and heating

Working and heating are both path-dependent thermodynamic processes that transform a system from one thermodynamic state to another. That is, working and heating represent *path functions* whose value depends on their history. They are mathematically represented by inexact differentials as denoted by the đ symbol. It is remarkable that the first law in equation (23.4) shows that the sum of two inexact differentials equals to an exact differential which, in the absence of macroscopic motion, is the exact differential of the internal energy.

The internal energy is a *state function* that is a property of the thermodynamic state of a system and not a function of the path history taken to reach that state. The term *thermodynamic potential* is synonymous with state function. It follows that if the internal energy change occurs in the absence of heating then the working process must occur as a path independent process. The converse holds if internal energy changes without any working. Furthermore, the first law (23.4) allows us to decompose changes to internal energy according to mechanical and thermal contributions. However, it is not possible to perform that decomposition for the internal energy itself.

Working and heating denote actions applied to a system (verbs) rather than properties of a system (nouns). They are energy *in transition* that arise at the boundary of a thermodynamic system. We raise this somewhat pedantic yet subtle point since the terms "work" and "heat" are often used instead of "working" and "heating". Indeed, we will often make use of that language in this book. However, such usage should be used with care as it can spuriously lead one to seek information concerning the "work content" or "heat content" of a physical system; i.e., to incorrectly consider work and heat as state properties (i.e., nouns). Rather, in thermodynamics we only consider the work imparted to change a system's energy (working), or likewise the thermal energy used to change a system (heating).

These conceptual points are particularly relevant when asking questions about the heat transported by a fluid (with dimensions energy per time and SI units of Watt = Joule per second). One is then led to analyze a heat budget, in which it is tempting to define the "heat content" of a fluid element or fluid region according to its temperature, mass, and heat capacity. But the notion of heat content spuriously conflates a thermodynamic process whereby a system moves from one state to another (heating) with a thermodynamic state property (e.g., enthalpy, which is a property of the state; see Section 23.6.4). Furthermore, any definition of heat content is ambiguous due to the arbitrariness of the temperature scale; i.e., heat content based on the Celsius scale is distinct from that based on the Kelvin scale. Therefore, when working with heat transport, care should be exercised if also including the notion of heat content. One way to detect an error is to ask whether a particular conclusion is modified by changing the temperature scale. If so, then one should revisit assumptions of the analysis since the results might be unphysical.

23.2.3 Mechanical work from pressure

As forces do work on a physical system they change its internal energy and mechanical energy. We are here concerned only with the effects on internal energy, though note that mechanical changes that alter internal energy are generally balanced by compensating changes to mechanical energy (see Section 27.7). One way to perform mechanical work is via changes to the volume of a fluid element through the action of pressure (a contact force per area) on the boundary of the fluid element. For example, if a fluid element increases its volume, it must do work against the surrounding environment to overcome the compressive force from pressure.

When volume changes occur quasi-statically, then we can write the *pressure work* in the mathematical form

$$đ\mathcal{W} = -p\,\mathrm{d}V, \tag{23.2}$$

where p is the pressure that acts on the boundaries of the fluid element. The assumption that the mechanical process is quasi-static allows us to unambiguously define pressure acting on the system, and thus to write equation (23.2) for the work. The negative sign arises since the compression of a fluid element into a smaller volume, $\mathrm{d}V < 0$, requires positive mechanical work be applied to the fluid element, $đ\mathcal{W} > 0$. The mathematical form of pressure work derives from the general

form of mechanical work given by

$$\text{work} = \text{force} \times \text{distance} = \text{force/area} \times \text{distance} \times \text{area} = \text{force/area} \times \text{volume}. \tag{23.3}$$

Stated alternatively, we note that pressure is a force per unit area acting on a surface, and the product of the surface area and its normal displacement is the volume swept out during a time increment.

We offer the following points in regards to this form of mechanical work.

- Pressure is an intensive property that measures the *intensity* of a force (per area) that is conjugate to the extensive property, V. In general, work applied to a thermodynamic system, thus leading to a change in the internal energy, takes on the form of an intensive property multiplying the change of an extensive property.
- From a mathematical perspective, pressure is the *integrating factor* that connects the inexact (path dependent) differential $đ\mathcal{W}$ to the exact differential $\mathrm{d}V$. We studied the mathematics of inexact differentials in Section 2.8.
- For a quasi-static process, pressure changes the internal energy of a fluid through the pressure work according to equation (23.2). As seen in Section 27.3, pressure also changes the kinetic energy of a moving fluid by changing the fluid speed. When combining the internal energy and mechanical energy budgets in Section 27.7, we see how pressure affects the total energy of a fluid element.
- Surface tension acting on fluid interfaces can give rise to mechanical work. However, we generally ignore surface tension in this book since it is negligible for scales larger than a few centimeters (see Section 26.11).

23.2.4 Entropy and the quasi-static transfer of internal degrees of freedom

The internal energy of a thermodynamic system can change when the molecular degrees of freedom are energized. For a materially closed system whose internal energy changes in a quasi-static manner, we consider the thermal energy change as relates to entropy changes via

$$đ\mathcal{Q} = T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} \qquad \text{materially closed system.} \tag{23.4}$$

T is the thermodynamic temperature (measured relative to absolute zero) and it is an intensive variable whereas $\mathcal{S}^{\mathrm{e}}$ is the extensive form of entropy. Entropy is an extensive state function so that T provides the integrating factor connecting the inexact differential $đ\mathcal{Q}$ to the exact differential $\mathrm{d}\mathcal{S}^{\mathrm{e}}$. A nonzero $đ\mathcal{Q}$ in a geophysical fluid can arise from radiative fluxes external to the fluid element; internal sources from viscous friction; and the exchange of thermal energy through the mixing of fluid properties. Since heating has dimensions of energy, the entropy has dimensions of energy per temperature.

23.2.5 Gibbs' fundamental thermodyanamic relation

We summarize the discussion of this section by writing the first law for quasi-static materially closed processes

$$\mathrm{d}\mathcal{J}^{\mathrm{e}} = -p\,\mathrm{d}V + T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} \quad \Longleftarrow \quad \text{quasi-static materially closed processes.} \tag{23.5}$$

This equation is known as the *Gibbs relation* or more commonly the *fundamental thermodyanamic relation* for quasi-static materially closed processes moving from one thermodynamic equilibrium

state to another. This relation suggests that we interpret minus the pressure as the amount of internal energy required to add one unit of volume to the system while holding entropy fixed. Likewise, temperature is the internal energy required to add one unit of entropy to the system while holding volume fixed.

The fundamental thermodynamic relation (23.5) is an integrable differential equation, with a solution found by performing a path integral within thermodynamic configuration space. The solution provides one of the extensive properties, such as internal energy or entropy, as a function of the other extensive properties. However, we generally do not require this solution since it is the differentials, as determined by the Gibbs relation, that are sufficient for determining practical thermodyanamic properties such as temperature, pressure, and chemical potential.

All differentials within the fundamental thermodynamic relation (23.5) are exact differentials of state functions. This property is a result of assuming the thermodynamic processes are quasi-static, in which case we can determine the integrating factors pressure and temperature to thus replace the inexact differentials $đ\mathcal{W}$ and $đ\mathcal{Q}$ with exact differentials. Even with the quasti-static restriction, equation (23.5) offers great utility (with its extension to materially open systems given in Section 23.5). Since we are only concerned with quasi-static changes to fluid elements in this book, the fundamental thermodynamic relation (23.5) provides the central expression of the first law of thermodynamics for our purposes.

It follows from the first law expression in equation (23.5) that the internal energy is a natural function of volume and entropy

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = -p\,\mathrm{d}V + T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} \Longrightarrow \mathcal{I}^{\mathrm{e}} = \mathcal{I}^{\mathrm{e}}(V, \mathcal{S}^{\mathrm{e}}). \tag{23.6}$$

Conversely, the entropy for a materially closed system is naturally a function of volume and internal energy

$$T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} = \mathrm{d}\mathcal{I}^{\mathrm{e}} + p\,\mathrm{d}V \Longrightarrow \mathcal{S}^{\mathrm{e}} = \mathcal{S}^{\mathrm{e}}(V, \mathcal{I}^{\mathrm{e}}). \tag{23.7}$$

We see that both of the extensive state functions, $\mathcal{I}^{\mathrm{e}}$ and $\mathcal{S}^{\mathrm{e}}$, are functions of extensive properties, with such dependence having implications for the scaling discussed in Section 23.3.1. Furthermore, we note that both $\mathcal{I}^{\mathrm{e}}$ and $\mathcal{S}^{\mathrm{e}}$ are functions of the volume of a system, but not of the shape. This behavior is strictly only appropriate for fluids, and it ignores effects from interfaces. Both of these assumptions are suitable for our study of geophysical fluids.

23.2.6 Partial derivatives

The fundamental thermodynamic relation (23.6) appears in terms of internal energy, which is written as a natural function of the extensive properties volume and entropy. We arrive at two partial derivative identities by expanding the exact derivative of internal energy

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial V}\right]_{\mathcal{S}^{\mathrm{e}},M} \mathrm{d}V + \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial \mathcal{S}^{\mathrm{e}}}\right]_{V,M} \mathrm{d}\mathcal{S}^{\mathrm{e}} \tag{23.8}$$

and then identifying this expression with the fundamental thermodynamic relation (23.6) to reveal

$$\left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial \mathcal{S}^{\mathrm{e}}}\right]_{V,M} = T \tag{23.9}$$

$$\left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial V}\right]_{\mathcal{S}^{\mathrm{e}},M} = -p. \tag{23.10}$$

Each equation relates an intensive property (right hand side) to the partial derivative of internal energy with respect to an extensive property. Furthermore, since each of the extensive properties

is a homogeneous function of degree one, then it follows that the intensive properties are homogeneous functions of degree zero. That is, the intensive properties, T and p, do not scale with the size of the system. Rather, intensive properties are scale invariant. We arrive at analogous partial derivative identities for entropy, $\mathcal{S}^{\mathrm{e}}(V, \mathcal{J}^{\mathrm{e}})$, by expanding its exact differential and then comparing to equation (23.7)

$$\left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial \mathcal{J}^{\mathrm{e}}}\right]_{V,M} = \frac{1}{T} \tag{23.11}$$

$$\left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial V}\right]_{\mathcal{J}^{\mathrm{e}},M} = \frac{p}{T}. \tag{23.12}$$

Recall that partial derivatives are defined with the complement variables held fixed during the differentiation. Hence, so long as we are clear about functional dependence, extra subscripts such as those exposed in equations (23.9)-(23.10) are not needed for the partial derivatives. Nonetheless, traditional thermodynamic notation exposes all of the subscripts in order to remain explicit about the dependent and independent variables. Such notation, though clumsy, can be essential when in the midst of manipulations with thermodynamic potentials and their derivatives.

23.2.7 Entropy and thermodynamic processes

A *reversible process* can, at each stage, go either forward or backward in time so that there is symmetry in time. In the absence of non-conservative forces (e.g., dissipation such as friction), Newton's dynamical laws are reversible. For example, one observes nothing unphysical about the motion of an ideal pendulum with time moving backward rather than forward.[8]

From a thermodynamic perspective, a reversible process does not alter the net entropy of a physical system plus its surrounding environment. Reversible thermodynamic processes are quasi-static and yet not all quasi-static processes are reversible. For example, a process that involves friction can evolve quasi-statically and yet frictional processes, as with any dissipative process, increases entropy. When the net entropy changes, we say the process occurs *irreversibly*, with the second law of thermodynamics stating that the net entropy change is positive. Quasi-static is a property of how a system changes, whereas reversibility is a statement about how both the system and its surrounding environment change. Any natural process is irreversible, with irreversibility providing an arrow for the evolution of physical systems; i.e., it breaks the symmetry between past and future.

The entropy differential for a quasi-static process in a materially closed system is given by $\mathrm{d}\mathcal{S}^{\mathrm{e}} = \text{đ}\mathcal{Q}/T$, with $T > 0$ (recall T is the Kelvin thermodynamic temperature) so that the entropy differential has the same sign as the heating differential, and entropy for a materially closed system remains unchanged in the absence of heating. The idealization of a heat bath allows us to perform reversible heating; i.e., heating without change in net entropy for a thermodynamic system plus the heat bath. Heat baths are held at a fixed temperature, which is the idealization of the case when the surrounding environment is arbitrarily larger than the thermodynamic system under consideration. Now imagine exchanging heat between a thermodynamic system and a series of heat baths to progressively alter the system's temperature by differential, $\mathrm{d}T$. In each exchange of heat, the entropy of the system plus heat bath is constructed to remain unchanged since we are exchanging an equal magnitude of entropy between them

$$\mathrm{d}\mathcal{S}^{\mathrm{e}}_{\mathrm{net}} = \mathrm{d}\mathcal{S}^{\mathrm{e}}_{\mathrm{system}} + \mathrm{d}\mathcal{S}^{\mathrm{e}}_{\mathrm{bath}} = \text{đ}\mathcal{Q}/T - \text{đ}\mathcal{Q}/T = 0. \tag{23.13}$$

[8] We briefly discussed time-reversal symmetry in Section 14.3. We also consider time symmetry for the perfect fluid equations (Euler equations) in Section 26.8.11.

To reverse the process, we merely reverse the heat exchanges between the thermodynamic system and the heat baths.

As noted above, when any thermodynamic process occurs irreversibly there is a net increase in entropy of the universe, which is a statement of the second law of thermodynamics. In statistical mechanics, entropy is computed by counting the number of microstates accessible to any given macrostate. Reversible processes do not modify the number of accessible microstates so there is zero change in the entropy. In contrast, irreversible processes increase entropy by increasing the number of accessible microstates.

23.2.8 Properties of thermodynamic equilibrium

Consider two systems labelled[9] by α and β that are separately in thermodynamic equilibrium with internal energies, $\mathcal{I}^{\mathrm{e}}_\alpha$, $\mathcal{I}^{\mathrm{e}}_\beta$, and volumes, V_α, V_β. Allow these two systems to interact mechanically and thermally, but do not allow for any exchange of matter. Furthermore, assume that the interactions conserve the total internal energy and volume of the combined system so that the system maintains the following constraints during the interaction process

$$\mathrm{d}(\mathcal{I}^{\mathrm{e}}_\alpha + \mathcal{I}^{\mathrm{e}}_\beta) = 0 \quad \text{and} \quad \mathrm{d}(V_\alpha + V_\beta) = 0. \tag{23.14}$$

When the composite system reaches thermodynamic equilibrium, the entropy maximum postulate forming the second law of thermodynamics (Section 23.1.7) means that

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = \mathrm{d}(\mathcal{S}^{\mathrm{e}}_\alpha + \mathcal{S}^{\mathrm{e}}_\beta) = 0 \tag{23.15}$$

for the combined composite system. Importantly, this condition holds only at equilibrium, whereas the constraints (23.14) hold throughout the process of reaching equilibrium. From equation (23.7) we know that entropy is naturally a function of volume and internal energy so that

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = \left[\frac{\partial \mathcal{S}^{\mathrm{e}}_\alpha}{\partial \mathcal{I}^{\mathrm{e}}_\alpha}\right]_{V_\alpha, M_\alpha} \mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \left[\frac{\partial \mathcal{S}^{\mathrm{e}}_\alpha}{\partial V_\alpha}\right]_{\mathcal{I}^{\mathrm{e}}_\alpha, M_\alpha} \mathrm{d}V_\alpha + \left[\frac{\partial \mathcal{S}^{\mathrm{e}}_\beta}{\partial \mathcal{I}^{\mathrm{e}}_\beta}\right]_{V_\beta, M_\beta} \mathrm{d}\mathcal{I}^{\mathrm{e}}_\beta + \left[\frac{\partial \mathcal{S}^{\mathrm{e}}_\beta}{\partial V_\beta}\right]_{\mathcal{I}^{\mathrm{e}}_\beta, M_\beta} \mathrm{d}V_\beta \tag{23.16a}$$

$$= \frac{1}{T_\alpha}\,\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \frac{p_\alpha}{T_\alpha}\,\mathrm{d}V_\alpha + \frac{1}{T_\beta}\,\mathrm{d}\mathcal{I}^{\mathrm{e}}_\beta + \frac{p_\beta}{T_\beta}\,\mathrm{d}V_\beta \tag{23.16b}$$

$$= \left[\frac{1}{T_\alpha} - \frac{1}{T_\beta}\right]\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \left[\frac{p_\alpha}{T_\alpha} - \frac{p_\beta}{T_\beta}\right]\mathrm{d}V_\alpha, \tag{23.16c}$$

where we used the partial derivative identities (23.11) and (23.12) for the second equality, and the constraints (23.14) for the final equality. Again, $\mathrm{d}\mathcal{S}^{\mathrm{e}} = 0$ at thermodynamic equilibrium, and this condition holds for arbitrary and independent $\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha$ and $\mathrm{d}V_\alpha$. We are thus led to the thermal and mechanical equilibrium conditions

$$T_\alpha = T_\beta \quad \text{and} \quad p_\alpha = p_\beta \quad \text{at thermodynamic equilibrium.} \tag{23.17}$$

That is, the temperature and pressure are uniform when the composite system reaches thermodynamic equilibrium.[10]

To understand how the two systems thermally approach thermodynamic equilibrium, assume the volumes of the two systems are fixed so that there is no mechanical work from pressure. Furthermore, assume the two systems are initially separated by an adiabatic wall with initial

[9] The labels α and β are not tensor labels. Instead, they merely label the system under consideration.

[10] As seen in Chapter 24, pressure at thermodynamic equilibrium is not a uniform constant for a system within a gravity field.

temperatures $T_\alpha^{\text{init}} > T_\beta^{\text{init}}$. Now allow for the flow of heat by switching from an adiabatic wall to a diathermal wall. Since the temperature differs for the two systems, they are mutually out of equilibrium. Heat flows in a manner to bring the two systems into equilibrium, during which time entropy of the composite system increases. At the new equilibrium, temperature is uniform and entropy has reached its maximum within the constraints imposed on the composite system. At a time instant after the wall changes from adiabatic to diathermal, the infinitesimal entropy change takes the form

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = \left[\frac{1}{T_\alpha^{\text{init}}} - \frac{1}{T_\beta^{\text{init}}}\right] \mathrm{d}\mathcal{J}_\alpha^{\mathrm{e}} > 0, \tag{23.18}$$

where the inequality follows from the second law of thermodynamics (Section 23.1.7). If $T_\alpha^{\text{init}} > T_\beta^{\text{init}}$, then an increase in entropy requires $\mathrm{d}\mathcal{J}_\alpha^{\mathrm{e}} < 0$, which means that heat leaves the system α and flows to the system β. Hence, as the composite system approaches thermodynamic equilibrium, heat flows from the region with higher temperature to the region with lower temperature. This result, deduced from the second law of thermodynamics, accords with common experience.

Further to the time scale for equilibration, we note that mechanical equilibrium (pressure equality) generally arises much sooner than thermal equilibrium (temperature equality). The reason is that mechanical equilibrium is facilitated by force imbalances that lead to macroscopic motion (e.g., acoustic waves), whereas thermal equilibrium arises from microscopic motion (e.g., molecular diffusion). This time scale separation means that real fluid systems are far closer to mechanical equilibrium than thermal equilibrium.

23.3 Characterizing materially open systems

A thermodynamic system is generally open to the transfer of matter across its boundaries. We here summarize methods used to characterize systems and processes that allow for the movement of matter, with extensive use of Euler's theorem for homogeneous functions as presented in Section 3.8.

23.3.1 Homogeneous functions

Following Section 3.8, consider a suite of Q independent variables, $X_1, X_2, ...X_Q$, and an arbitrary function of these variables, $F(X_1, X_2, ...X_Q)$. We say that this function is a *homogeneous function* of degree γ if the following property holds

$$F(\lambda\, X_1, \lambda\, X_2, ...\lambda\, X_Q) = \lambda^\gamma\, F(X_1, X_2, ...X_Q), \tag{23.19}$$

with λ an arbitrary scalar. The left hand side is the function evaluated with each of the independent variables scaled by the same number, λ. The right hand side is the function evaluated with the unscaled variables, but multiplied by the scale raised to the power γ. As proved in Section 3.8, *Euler's theorem* for homogeneous functions states that

$$\sum_{q=1}^{Q} X_q \left[\frac{\partial F(X_1, X_2, ...X_Q)}{\partial X_q}\right]_{X_{r\neq q}} = \gamma\, \lambda^{\gamma-1}\, F(X_1, X_2, ...X_Q). \tag{23.20}$$

The simplest homogeneous function are those of degree $\gamma = 0$, with examples including intensive thermodynamic propertie, meaning these properties are scale invariant. For example, a bucket of homogeneous water has the same temperature whether or not we remove an arbitrary sample of the water. In contrast, as discussed below, extensive thermodynamic properties are

homogeneous functions of degree $\gamma = 1$.

Both the internal energy, $\mathcal{I}^{\rm e}$, and entropy, $\mathcal{S}^{\rm e}$, are extensive properties of a fluid system. Consequently, the transfer of matter across the system boundaries leads to an additive change in $\mathcal{I}^{\rm e}$ and $\mathcal{S}^{\rm e}$. The internal energy and entropy thus have their natural functional dependencies (23.6) and (23.7) extended to include the matter content

$$\mathcal{I}^{\rm e} = \mathcal{I}^{\rm e}(V, \mathcal{S}^{\rm e}, M_n) \qquad \text{and} \qquad \mathcal{S}^{\rm e} = \mathcal{S}^{\rm e}(V, \mathcal{I}^{\rm e}, M_n), \tag{23.21}$$

where the M_n argument is shorthand for $M_1, M_2 ... M_N$ for the N matter constituents.[11]

What happens when we scale the system by an arbitrary parameter λ? Under this scale operation, the extensive variables, $\mathcal{I}^{\rm e}$, $\mathcal{S}^{\rm e}$, as well as the volume, V, and masses, M_n, scale by the same scale factor. The relation (23.21) thus leads to the scaling

$$\lambda\, \mathcal{I}^{\rm e}(V, \mathcal{S}^{\rm e}, M_n) = \mathcal{I}^{\rm e}(\lambda\, V, \lambda\, \mathcal{S}^{\rm e}, \lambda\, M_n) \qquad \text{and} \qquad \lambda\, \mathcal{S}^{\rm e}(V, \mathcal{I}^{\rm e}, M_n) = \mathcal{S}^{\rm e}(\lambda\, V, \lambda\, \mathcal{I}^{\rm e}, \lambda\, M_n), \tag{23.22}$$

thus revealing that $\mathcal{I}^{\rm e}(V, \mathcal{S}^{\rm e}, M_n)$ and $\mathcal{S}^{\rm e}(\lambda\, V, \lambda\, \mathcal{I}^{\rm e}, \lambda\, M_n)$ are homogeneous functions of degree one. Making use of Euler's theorem (23.20) with $\gamma = 1$ leads to

$$\mathcal{I}^{\rm e}(V, \mathcal{S}^{\rm e}, M_n) = V \left[\frac{\partial \mathcal{I}^{\rm e}}{\partial V}\right]_{\mathcal{S}^{\rm e}, M_n} + \mathcal{S}^{\rm e} \left[\frac{\partial \mathcal{I}^{\rm e}}{\partial \mathcal{S}^{\rm e}}\right]_{V, M_n} + \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{I}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{S}^{\rm e}, M_{m\neq n}} \tag{23.23a}$$

$$\mathcal{S}^{\rm e}(V, \mathcal{I}^{\rm e}, M_n) = V \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial V}\right]_{\mathcal{I}^{\rm e}, M_n} + \mathcal{I}^{\rm e} \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial \mathcal{I}^{\rm e}}\right]_{V, M_n} + \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{I}^{\rm e}, M_{m\neq n}}. \tag{23.23b}$$

These are very special expressions for the internal energy and entropy that are of great use throughout thermodynamics.

23.3.2 Chemical potential and the Euler form

We can further massage the results (23.23a) and (23.23b) by making use of the partial derivative identities from Section 23.2.6 to render

$$\mathcal{I}^{\rm e} = -p\, V + T\, \mathcal{S}^{\rm e} + \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{I}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{S}^{\rm e}, M_{m\neq n}} \tag{23.24}$$

$$T\, \mathcal{S}^{\rm e} = p\, V + \mathcal{I}^{\rm e} + \sum_{n=1}^{N} T\, M_n \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{I}^{\rm e}, M_{m\neq n}}. \tag{23.25}$$

Self-consistency requires

$$\left[\frac{\partial \mathcal{I}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{S}^{\rm e}} = -T \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{I}^{\rm e}, M_{m\neq n}}, \tag{23.26}$$

which motivates defining the *chemical potential*

$$\mu_n \equiv \left[\frac{\partial \mathcal{I}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{S}^{\rm e}, M_{m\neq n}} = -T \left[\frac{\partial \mathcal{S}^{\rm e}}{\partial M_n}\right]_{V, \mathcal{I}^{\rm e}, M_{m\neq n}} \tag{23.27}$$

[11] Note that in this subsection the subscript refers to the matter constituents, $n = 1, ...N$, whereas in Section 23.3.1 we used $q = 1., , , Q$ to label the number of independent variables.

thus leading to

$$\mathcal{I}^{\mathrm{e}} = T\,\mathcal{S}^{\mathrm{e}} - p\,V + \sum_{n=1}^{N} \mu_n\,M_n \Longleftrightarrow T\,\mathcal{S}^{\mathrm{e}} = \mathcal{I}^{\mathrm{e}} + p\,V - \sum_{n=1}^{N} \mu_n\,M_n. \tag{23.28}$$

These are the *Euler forms* for the internal energy and entropy.

By definition, the chemical potential, μ_n, is an intensive property that measures the change in the internal energy, $\mathcal{I}^{\mathrm{e}}$, when altering the mass, M_n, of the constituent n, while fixing the entropy, volume, and mass of the other components. Equivalently, it is minus the temperature weighted change in the entropy, $\mathcal{S}^{\mathrm{e}}$, when altering the mass, M_n while fixing the volume, internal energy, and mass of the other components. We can define a chemical potential for a single component system, in which it is the change arising from altering the mass of the system. Despite its name, the chemical potential does not necessarily refer to the existence of chemical reactions, though we note that it does appear prominently in the thermodynamics of chemical reactions (*Atkins and de Paula*, 2006).

23.3.3 Molar mass and molar chemical potential

It is sometimes convenient to write the mass of a constituent as the product of the number of moles, N_n, and the mass per mole, $\mathfrak{M}_n$ (the *molar mass*), so that

$$M_n = N_n\,\mathfrak{M}_n \quad \text{no implied sum.} \tag{23.29}$$

In this way, an infinitesimal mass change is given by

$$\mathrm{d}M = \sum_{n=1}^{N} \mathrm{d}M_n = \sum_{n=1}^{N} \mathrm{d}(N_n\,\mathfrak{M}_n) = \sum_{n=1}^{N} \mathfrak{M}_n\,\mathrm{d}N_n, \tag{23.30}$$

so that mass changes are signalled by changes in the number of moles. We furthermore note the identity (no implied sum)

$$M_n\,\mu_n = M_n \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial M_n}\right]_{V,\mathcal{S}^{\mathrm{e}},M_{m\neq n}} = N_n\,\mathfrak{M}_n \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial (N_n\,\mathfrak{M}_n)}\right]_{V,\mathcal{S}^{\mathrm{e}},N_{m\neq n}} = N_n\,\tilde{\mu}_n, \tag{23.31}$$

where we defined the molar chemical potential determined according to mole number

$$\tilde{\mu}_n = \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial N_n}\right]_{V,\mathcal{S}^{\mathrm{e}},N_{m\neq n}} = \mathfrak{M}_n\,\mu_n. \tag{23.32}$$

We are similarly led to the identities (no implied sum)

$$M_n\,\mathrm{d}\mu_n = N_n\,\mathrm{d}\tilde{\mu}_n \quad \text{and} \quad \mu_n\,\mathrm{d}M_n = \tilde{\mu}_n\,\mathrm{d}N_n. \tag{23.33}$$

23.3.4 Chemical work and the Gibbs-Duhem relation

Changes to the matter composition of a system changes the internal energy through *chemical work*, written as $đ\mathcal{C}$. If the changes to the matter composition occur quasi-statically then the chemical work is written

$$đ\mathcal{C} = \sum_{n=1}^{N} \mu_n\,\mathrm{d}M_n = \sum_{n=1}^{N} \tilde{\mu}_n\,\mathrm{d}N_n \tag{23.34}$$

so that the chemical potential is the integrating factor connecting the inexact differential measuring the chemical work to the exact differential change in matter content. The chemical potential is the energy absorbed or released due to an infinitesimal change in the matter content. As shown in Section 24.1.2, matter in a mixture tends to move from regions of high chemical potential to lower chemical potential, thus motivating the name "potential" in analog to the gravitational potential.

The inclusion of chemical work brings the first law of thermodynamics to the form

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = đ\mathcal{W} + đ\mathcal{Q} + đ\mathcal{C} \qquad \text{materially open} \tag{23.35a}$$

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = -p\,\mathrm{d}V + T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} + \sum_{n=1}^{N} \mu_n\,\mathrm{d}M_n \qquad \text{quasi-static and materially open.} \tag{23.35b}$$

Use of the quasi-static form of the first law (23.35b) along with the differential of the result (23.28) leads to the *Gibbs-Duhem* relation[12]

$$\mathcal{S}^{\mathrm{e}}\,\mathrm{d}T - V\,\mathrm{d}p + \sum_{n=1}^{N} M_n\,\mathrm{d}\mu_n = 0. \tag{23.36}$$

As a corollary we see that for processes occuring at constant temperature and pressure that

$$\sum_{n=1}^{N} M_n\,\mathrm{d}\mu_n = \sum_{n=1}^{N} N_n\,\mathrm{d}\tilde{\mu}_n = 0 \quad \text{constant } T, p. \tag{23.37}$$

23.3.5 Gibbs potential

We offer a formal study of thermodynamic potentials in Section 23.6. Among those, we find Gibbs potential of particular use for geophysical fluid mechanics and thus introduce it here

$$\mathcal{G}^{\mathrm{e}} = \mathcal{I}^{\mathrm{e}} - T\,\mathcal{S}^{\mathrm{e}} + p\,V = \sum_{n=1}^{N} \mu_n\,M_n. \tag{23.38}$$

The reason that the Gibbs potential is so useful is that it is a natural function of temperature, pressure, and matter content,

$$\mathcal{G}^{\mathrm{e}} = \mathcal{G}^{\mathrm{e}}(T, p, M_n), \tag{23.39}$$

with T, p, M_n readily measured fluid properties. This convenient functional dependence is confirmed by taking the differential, $\mathrm{d}\mathcal{G}^{\mathrm{e}}$, and using the fundamental thermodynamic relation (23.35b) to find

$$\mathrm{d}\mathcal{G}^{\mathrm{e}} = -\mathcal{S}^{\mathrm{e}}\,\mathrm{d}T + V\,\mathrm{d}p + \sum_{n=1}^{N} \mu_n\,\mathrm{d}M_n. \tag{23.40}$$

In turn, we can derive the following partial derivatives,

$$\left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial T}\right]_{p,M_n} = -\mathcal{S}^{\mathrm{e}} \quad \text{and} \quad \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial p}\right]_{T,M_n} = V \quad \text{and} \quad \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \mu_n \tag{23.41}$$

[12] In Exercise 23.1 we work through the derivation of Gibbs-Duhem (23.36) in a bit more detail.

along with the second derivative identities

$$\left[\frac{\partial \mu_n}{\partial p}\right]_{T,M_n} = \frac{\partial}{\partial p}\Big]_{T,M_n}\left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \frac{\partial}{\partial M_n}\Big]_{p,T,M_{m\neq n}}\left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial p}\right]_{T,M_n} = \left[\frac{\partial V}{\partial M_n}\right]_{p,T,M_{m\neq n}} \tag{23.42a}$$

$$\left[\frac{\partial \mu_n}{\partial T}\right]_{p,M_n} = \frac{\partial}{\partial T}\Big]_{p,M_n}\left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \frac{\partial}{\partial M_n}\Big]_{p,T,M_{m\neq n}}\left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial T}\right]_{p,M_n} = -\left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}}. \tag{23.42b}$$

The second derivative identities are particular examples of *Maxwell relations*, wtih Maxwell relations the result from commutativity of the partial derivative operation.

23.3.6 Extensive functions of (T, p, M_n)

Just as for the internal energy and entropy, the Gibbs function, $\mathcal{G}^{\mathrm{e}}(T, p, M_n)$, is an extensive function. Since the temperature and pressure are both intensive properties, we follow the scale analysis from Section 23.3.1 to arrive at the Euler form of the Gibbs function

$$\mathcal{G}^{\mathrm{e}}(T, p, M_n) = \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \sum_{n=1}^{N} \mu_n\, M_n, \tag{23.43}$$

which is consistent with the definition (23.38). Indeed, any extensive property written as a function of (T, p, M_n) can be written in the same fashion. For example, the internal energy, entropy, and volume take the form

$$\mathcal{I}^{\mathrm{e}}(T, p, M_n) = \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \sum_{n=1}^{N} N_n \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial N_n}\right]_{p,T,N_{m\neq n}} \tag{23.44a}$$

$$\mathcal{S}^{\mathrm{e}}(T, p, M_n) = \sum_{n=1}^{N} M_n \left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \sum_{n=1}^{N} N_n \left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial N_n}\right]_{p,T,N_{m\neq n}} \tag{23.44b}$$

$$V(T, p, M_n) = \sum_{n=1}^{N} M_n \left[\frac{\partial V}{\partial M_n}\right]_{p,T,M_{m\neq n}} = \sum_{n=1}^{N} N_n \left[\frac{\partial V}{\partial N_n}\right]_{p,T,N_{m\neq n}}. \tag{23.44c}$$

The partial derivatives, $[\partial(\mathcal{G}^{\mathrm{e}}, \mathcal{I}^{\mathrm{e}}, \mathcal{S}^{\mathrm{e}}, V)/\partial N_n]_{p,T,N_{m\neq n}}$, are intensive properties known as the *partial Gibbs potential*, *partial internal energy*, *partial entropy*, and *partial volume*. These relations mean that we can regard each of the extensive quantites as the sum of contributions from each of the material components as determined by their partial properties. For the particular case of a single matter component we have

$$\mathcal{G}^{\mathrm{e}}(T, p, M) = M \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M}\right]_{p,T} = \mu\, M \tag{23.45a}$$

$$\mathcal{I}^{\mathrm{e}}(T, p, M) = M \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial M}\right]_{p,T} = N \left[\frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial N}\right]_{p,T} \tag{23.45b}$$

$$\mathcal{S}^{\mathrm{e}}(T, p, M) = M \left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial M}\right]_{p,T} = N \left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial N}\right]_{p,T} \tag{23.45c}$$

$$V(T, p, M) = M \left[\frac{\partial V}{\partial M}\right]_{p,T} = N \left[\frac{\partial V}{\partial N}\right]_{p,T}. \tag{23.45d}$$

23.4 Thermodynamic equilibrium with matter flow

Consider a single-component fluid ($N = 1$) that consists of two regions or systems, labelled by α and β, with each of these two systems separately in thermodynamic equilibrium. Assume the composite system is enclosed in a container with fixed volume, $V_\alpha + V_\beta = V$. Allow the two systems to interact thermally, mechanically, and materially. What are the properties of thermodynamic equilibrium for the composite system, $\alpha \oplus \beta$?

To answer this question, we follow the procedure in Section 23.2.8, here here considering the case where matter flows between the systems in addition to thermal transfer and mechanical interactions. Such processes occur as the composite system approaches thermodynamic equilibrium. Initially, the α and β systems are separately in thermodynamic equilibrium with internal energies, $(\mathcal{I}^{\mathrm{e}}_\alpha, \mathcal{I}^{\mathrm{e}}_\beta)$, volumes, (V_α, V_β), and masses, (M_α, M_β). During the process of reaching thermodynamic equilibrium, the internal energy, volume, and mass of the composite system remains constant so that[13]

$$\mathrm{d}(\mathcal{I}^{\mathrm{e}}_\alpha + \mathcal{I}^{\mathrm{e}}_\beta) = 0 \quad \text{and} \quad \mathrm{d}(V_\alpha + V_\beta) = 0 \quad \text{and} \quad \mathrm{d}(M_\alpha + M_\beta) = 0. \tag{23.46}$$

From equation (23.21) we know that entropy is a natural function of volume, internal energy, and mass of each matter constituent. With only a single matter constituent we have

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = \frac{1}{T_\alpha}\,\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \frac{p_\alpha}{T_\alpha}\,\mathrm{d}V_\alpha - \frac{\mu_\alpha}{T_\alpha}\,\mathrm{d}M_\alpha + \frac{1}{T_\beta}\,\mathrm{d}\mathcal{I}^{\mathrm{e}}_\beta + \frac{p_\beta}{T_\beta}\,\mathrm{d}V_\beta - \frac{\mu_\beta}{T_\beta}\,\mathrm{d}M_\beta \tag{23.47a}$$

$$= \left[\frac{1}{T_\alpha} - \frac{1}{T_\beta}\right]\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \left[\frac{p_\alpha}{T_\alpha} - \frac{p_\beta}{T_\beta}\right]\mathrm{d}V_\alpha - \left[\frac{\mu_\alpha}{T_\alpha} - \frac{\mu_\beta}{T_\beta}\right]\mathrm{d}M_\alpha, \tag{23.47b}$$

where we used the partial derivative identities (23.11), (23.12), and (23.27). As before, $\mathrm{d}\mathcal{S}^{\mathrm{e}} = 0$ at thermodynamic equilibrium, and this condition holds for arbitrary and independent $\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha$, $\mathrm{d}V_\alpha$, and $\mathrm{d}M_\alpha$. We are thus led to the thermal, mechanical, and material conditions for thermodynamic equilibrium

$$T_\alpha = T_\beta \quad \text{and} \quad p_\alpha = p_\beta \quad \text{and} \quad \mu_\alpha = \mu_\beta. \tag{23.48}$$

That is, the temperature, pressure, and chemical potential are uniform when the composite system reaches thermodynamic equilibrium. Note that this thermodynamic equilibrium condition means that each term in the Gibbs-Duhem relation (23.36) separately vanishes. Furthermore, since the Gibbs potential equals to the mass times the chemical potential for a single component system (equation (23.43)), equality of the chemical potentials at equilibrium means that

$$\mu_\alpha = \mu_\beta \Longrightarrow \frac{\mathcal{G}^{\mathrm{e}}_\alpha}{M_\alpha} = \frac{\mathcal{G}^{\mathrm{e}}_\beta}{M_\beta}. \tag{23.49}$$

As for the direction of heat flow discussed in Section 23.2.8, we can determine the direction for matter flow as $\alpha \oplus \beta$ approaches thermodynamic equilibrium. For this purpose, assume the temperature and volumes are already uniform, but the matter content initially differs. At the instance the two systems start interacting, the entropy differential is given by

$$T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} = -(\mu_\alpha - \mu_\beta)\,\mathrm{d}M_\alpha > 0, \tag{23.50}$$

where T is the equilibrium temperature of the two systems, and where the inequality holds according to the second law of thermodynamics (Section 23.1.7). If $\mu_\alpha > \mu_\beta$, then this inequality requires $\mathrm{d}M_\alpha < 0$. Hence, in the process of approaching thermodynamic equilibrium, matter

[13] We here assume there is no macroscopic mechanical energy, so that the total energy is the internal energy. In Section 27.8 we relax this assumption by considering macroscopic motion.

flows from regions of high chemical potential to regions of low chemical potential. This behavior allows us to consider the chemical potential in a manner directly akin to temperature. That is, temperature differences measure the potential for heat to be fluxed, and likewise chemical potential differences measure the potential for matter to be fluxed. The chemical potential is central to the study of changes in matter states (e.g., solid to liquid, liquid to gas), as well as for chemical reactions (e.g., *Guggenheim*, 1967; *Atkins and de Paula*, 2006).

23.5 Materially open systems with fixed total mass

In our study of geophysical fluids, we make use of a continuum of fluid elements. Each fluid element is open mechanically, thermally, and materially while maintaining constant mass as it quasi-statically evolves through local thermodynamic equilibrium states. Hence, when formulating the equations of linear irreversible thermodynamics in Chapter 27, we make use of thermodynamic equations written in their "per unit mass" form. Here we present these equations, as well as extend our understanding of the formalism.

23.5.1 Matter concentrations

We generally make use of matter or tracer concentration as written

$$C_n = M_n/M \Longrightarrow \sum_{n=1}^{N} C_n = 1, \tag{23.51}$$

with the constant mass constraint $\sum_{n=1}^{N} C_n = 1$ meaning that only $N-1$ of the concentrations are linearly independent. Recall that we previously made use of tracer concentrations in Section 21.1 when developing the tracer equation.

23.5.2 Fundamental thermodynamic relation per unit mass

We scale away the mass of the system by setting the scale factor $\lambda = M^{-1}$ in our discussion in Section 23.3.1 of how extensive properties scale. The result is the *specific* (per mass) versions of the extensive properties

$$\mathcal{I}^{\mathrm{e}} = M\,\mathcal{I} \tag{23.52a}$$
$$\mathcal{S}^{\mathrm{e}} = M\,\mathcal{S} \tag{23.52b}$$
$$V = M/\rho = M\,\nu_{\mathrm{s}} \tag{23.52c}$$
$$M_n = M\,C_n, \tag{23.52d}$$

where

$$\nu_{\mathrm{s}} = 1/\rho \tag{23.53}$$

is the *specific volume* and the total mass, M, is held fixed. In the equality (23.52d), C_n is the mass fraction or concentration of species n in the fluid (Section 23.5.1). Substituting the specific quantities (23.52a)-(23.52d) into the fundamental thermodynamic relation (23.35b) leads to the fundamental thermodynamic relation in terms of specific thermodynamic quantities

$$\mathrm{d}\mathcal{I} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\rho^{-1} + \sum_{n} \mu_n\,\mathrm{d}C_n. \tag{23.54}$$

This is the form of the fundamental thermodynamic relation most commonly used in this book. Again, this relation holds for quasi-static processes where the total mass of the system is fixed, thus making it relevant for our study of constant mass fluid elements in Chapter 27.

23.5.3 Seawater as a binary fluid

The atmosphere is a multi-component and multi-phase fluid that is well approximated as a mixture of water vapor and dry air. However, we do not consider moist atmospheric processes in this book nor do we consider phases changes. In contrast, there are many occasions in this book that require us to consider seawater as a binary fluid system of salt dissolved in fresh water so that their concentrations satisfy the constraint[14]

$$C_{\text{salt}} + C_{\text{water}} = 1 \Longrightarrow \mathrm{d}C_{\text{water}} = -\mathrm{d}C_{\text{salt}}. \tag{23.55}$$

We are thus able to write the Gibbs fundamental thermodynamic relation (23.54) in the form

$$\mathrm{d}\mathcal{J} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\rho^{-1} + \mu_{\text{water}}\,\mathrm{d}C_{\text{water}} + \mu_{\text{salt}}\,\mathrm{d}C_{\text{salt}} \tag{23.56a}$$

$$= T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\rho^{-1} + \mu\,\mathrm{d}C, \tag{23.56b}$$

where

$$C = C_{\text{salt}} \tag{23.57}$$

is the concentration of salt (mass of salt per mass of seawater), and

$$\mu = \mu_{\text{salt}} - \mu_{\text{water}} \tag{23.58}$$

is the *relative chemical potential*, often referred to as the *seawater chemical potential*. We return in Section 23.58 to discuss how the chemical potentials are computed according to partial derivatives of the Gibbs potential, which is the preferred method for the ocean and atmosphere.

The *absolute salinity* S, with units parts per thousand (gram per kilogram), is related to C_{salt} via

$$S = 1000\,C_{\text{salt}}. \tag{23.59}$$

The range of absolute salinity in the ocean (roughly $0 \leq S \leq 40$) is more convenient than the range of C_{salt}, making salinity more commonly used in oceanography.

23.5.4 Further study

Chapters 1 and 2 of *Olbers et al.* (2012) provide a more complete suite of thermodynamic relations for seawater.

23.6 Thermodynamic potentials

Internal energy and entropy are referred to as state functions (functions only of the current state) as well as *thermodynamic potentials*, and they are related by equation (23.28), here written in its

[14] Salt in the ocean is largely comprised of chloride ions, sodium ions, sulphate ions, magnesium ions, calcium ions, potassium ions, and hydro-carbonate ions. The composition of the principal ions in seawater is roughly a constant, thus allowing us to be concerned only with the "salt" content and concentration rather than that for the individual components. In turn, we can accurately consider seawater as a two-component fluid comprised of fresh water and salt. See Section 1.4 of *Kamenkovich* (1977), Section 3.1 of *Gill* (1982), Section 1.2 of *Olbers et al.* (2012), or Section 1.4 of *Vallis* (2017) for more details.

specific form as appropriate for constant mass fluid elements

$$\mathcal{I} = T\,\mathcal{S} - p\,\nu_{\mathrm{s}} + \sum_{n=1}^{N} \mu_n\, C_n \Longleftrightarrow T\,\mathcal{S} = \mathcal{I} + p\,\nu_{\mathrm{s}} - \sum_{n=1}^{N} \mu_n\, C_n. \tag{23.60}$$

Each thermodynamic potential is a natural function of certain other thermodynamic properties, as determined by the fundamental thermodynamic relation.

It is useful to have access to a suite of thermodynamic potentials (internal energy, entropy, enthalpy, Gibbs potential, Helmbolz free energy) that have different natural functional dependencies, which in turn yield distinct expressions for the fundamental equation of state. Thermodynamic potentials are related mathematically through a *Legendre transformation*. Motivation for their introduction comes from the distinct laboratory and environmental conditions whereby the controlling parameters may differ. In this section we introduce the variety of thermodynamic potentials commonly used for fluid mechanics, and exhibit their natural functional dependencies.

In this section, we specialize to the case of a binary fluid, which is most commonly the case for the ocean and atmosphere. If there are more than two matter constituents, then the term $\mu\,\mathrm{d}C$ appearing in these formula become $\sum_{n=1}^{N} \mu_n\,\mathrm{d}C_n$. Partial derivatives are also modified accordingly. We choose the binary case since it is typically sufficient for the earth's atmosphere and ocean.

As a point of practice, it is important to commit to a single choice for the thermodynamic potential when manipulating thermodynamic equations. The reason is that functional dependencies change when switching to a different thermodynamic potential, thus exposing oneself to mistakes when swapping formulations midstream.

23.6.1 Equations of state

Equations (23.9), (23.10), and (23.27) provide expressions for intensive properties, T, p, and μ_n, in terms of the partial derivatives of the internal energy in terms of extensive functions $\mathcal{S}^{\mathrm{e}}$, V, and M_n. Hence, we can write T, p, and μ_n in the functional form

$$T = T(\mathcal{S}^{\mathrm{e}}, V, M_m) \qquad \text{and} \qquad p = p(\mathcal{S}^{\mathrm{e}}, V, M_m) \qquad \text{and} \qquad \mu_n = \mu_n(\mathcal{S}^{\mathrm{e}}, V, M_m). \tag{23.61}$$

These equations are known as *equations of state*. Knowledge of all the equations of state is equivalent to knowledge of the fundamental thermodynamic relation (23.35b). In the following, we develop similar equations of state based on other thermodynamic potentials.

23.6.2 Internal energy

Recall the fundamental thermodynamic relation (23.56b) written for a binary fluid

$$\mathrm{d}\mathcal{I} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\mathrm{s}} + \mu\,\mathrm{d}C. \tag{23.62}$$

Equation (23.62) identifies the specific internal energy, $\mathcal{I}$, as a natural function of specific entropy, $\mathcal{S}$, specific volume, ν_{s}, and matter concentration, C

$$\mathcal{I} = \mathcal{I}(\mathcal{S}, \nu_{\mathrm{s}}, C). \tag{23.63}$$

Knowledge of the fundamental thermodynamic relation (23.62) allows us to derive a variety of thermodynamic relations via partial differentiation. For example, we can identify

$$\left[\frac{\partial \mathcal{I}}{\partial \mathcal{S}}\right]_{\nu_s,C} = T \qquad \text{and} \qquad \left[\frac{\partial \mathcal{I}}{\partial \nu_s}\right]_{\mathcal{S},C} = -p \qquad \text{and} \qquad \left[\frac{\partial \mathcal{I}}{\partial C}\right]_{\mathcal{S},\nu_s} = \mu, \tag{23.64}$$

which are the specific (per mass) forms of equations (23.9), (23.10), and (23.27).

We see that equations (23.64) provide a relation between T, p, μ as derivatives of a function, the internal energy, which is itself a function $\mathcal{I}(\mathcal{S}, \nu_s, C)$. Hence, we may consider T, p, μ each as a function of $(\mathcal{S}, \nu_s, C)$, and thus write the equations of state

$$T = T(\mathcal{S}, \nu_s, C) \qquad \text{and} \qquad p = p(\mathcal{S}, \nu_s, C) \qquad \text{and} \qquad \mu = \mu(\mathcal{S}, \nu_s, C), \tag{23.65}$$

which are the equations of state (23.61) written in terms of specific (per mass) quantities. In turn, the exact differentials of the intensive properties are

$$T = T(\mathcal{S}, \nu_s, C) \Longrightarrow \mathrm{d}T = \left[\frac{\partial T}{\partial \mathcal{S}}\right]_{\nu_s,C} \mathrm{d}\mathcal{S} + \left[\frac{\partial T}{\partial \nu_s}\right]_{C,\mathcal{S}} \mathrm{d}\nu_s + \left[\frac{\partial T}{\partial C}\right]_{\mathcal{S},\nu_s} \mathrm{d}C \tag{23.66}$$

$$p = p(\mathcal{S}, \nu_s, C) \Longrightarrow \mathrm{d}p = \left[\frac{\partial p}{\partial \mathcal{S}}\right]_{\nu_s,C} \mathrm{d}\mathcal{S} + \left[\frac{\partial p}{\partial \nu_s}\right]_{C,\mathcal{S}} \mathrm{d}\nu_s + \left[\frac{\partial p}{\partial C}\right]_{\mathcal{S},\nu_s} \mathrm{d}C \tag{23.67}$$

$$\mu = \mu(\mathcal{S}, \nu_s, C) \Longrightarrow \mathrm{d}\mu = \left[\frac{\partial \mu}{\partial \mathcal{S}}\right]_{\nu_s,C} \mathrm{d}\mathcal{S} + \left[\frac{\partial \mu}{\partial \nu_s}\right]_{C,\mathcal{S}} \mathrm{d}\nu_s + \left[\frac{\partial \mu}{\partial C}\right]_{\mathcal{S},\nu_s} \mathrm{d}C. \tag{23.68}$$

23.6.3 Entropy

Rearrangement of the fundamental thermodynamic relation (23.62) leads to the exact differential for specific entropy

$$\mathrm{d}\mathcal{S} = \frac{1}{T}\,\mathrm{d}\mathcal{I} + \frac{p}{T}\,\mathrm{d}\nu_s - \frac{\mu}{T}\,\mathrm{d}C. \tag{23.69}$$

In this form, specific entropy has the functional dependence

$$\mathcal{S} = \mathcal{S}(\mathcal{I}, \nu_s, C), \tag{23.70}$$

whose knowledge provides yet another form of the fundamental equation of state. This functional dependence, along with equation (23.69), lead to the following identities

$$\left[\frac{\partial \mathcal{S}}{\partial \mathcal{I}}\right]_{\nu_s,C} = \frac{1}{T} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{S}}{\partial \nu_s}\right]_{\mathcal{I},C} = \frac{p}{T} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{S}}{\partial C}\right]_{\mathcal{I},\nu_s} = -\frac{\mu}{T}. \tag{23.71}$$

As for internal energy in Section 23.6.2, equation (23.71) provides a relation between T, p, μ as derivatives of a function, the entropy, which is itself a function $\mathcal{S}(\mathcal{I}, \nu_s, C)$. Hence, we may consider T, p, μ as each a function of $(\mathcal{I}, \nu_s, C)$ to thus write the equations of state

$$T = T(\mathcal{I}, \nu_s, C) \qquad \text{and} \qquad p = p(\mathcal{I}, \nu_s, C) \qquad \text{and} \qquad \mu = \mu(\mathcal{I}, \nu_s, C). \tag{23.72}$$

23.6.4 Enthalpy

Thus far we have worked only with the fundamental thermodynamic relation (23.62). We now introduce the specific enthalpy

$$\mathcal{H} = \mathcal{I} + p\,\nu_{\rm s} = T\,\mathcal{S} + \sum_{n=1}^{N} \mu_n\, C_n, \tag{23.73}$$

where the second equality made use of equation (23.60). Specializing to the case of a binary fluid, such as the ocean or atmosphere, and use of the fundamental thermodynamic relation (23.62), leads to the exact differential for enthalpy

$$\begin{aligned} \mathrm{d}\mathcal{H} &= \mathrm{d}\mathcal{I} + \mathrm{d}(p\,\nu_{\rm s}) && (23.74a)\\ &= T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\rm s} + \mu\,\mathrm{d}C + p\,\mathrm{d}\nu_{\rm s} + \nu_{\rm s}\,\mathrm{d}p && (23.74b)\\ &= T\,\mathrm{d}\mathcal{S} + \nu_{\rm s}\,\mathrm{d}p + \mu\,\mathrm{d}C. && (23.74c) \end{aligned}$$

Recalling that for quasi-static processes, $T\,\mathrm{d}\mathcal{S}$ equals to the thermal energy added to a fluid element. Hence, for processes occuring at constant pressure and constant matter content, changes in enthalpy are determined by the thermal energy added to the system. This connection motivates the name *heat function* sometimes applied to enthalpy (e.g., page 4 of *Landau and Lifshitz* (1987)).

Equation (23.74c) provides the fundamental thermodynamic relation with enthalpy rather than internal energy. Consequently, the *Legendre transformation* (23.73) renders a functional dependence for enthalpy

$$\mathcal{H} = \mathcal{H}(\mathcal{S}, p, C), \tag{23.75}$$

which in turn leads to the following partial derivative identities

$$\left[\frac{\partial \mathcal{H}}{\partial \mathcal{S}}\right]_{p,C} = T \qquad \text{and} \qquad \left[\frac{\partial \mathcal{H}}{\partial p}\right]_{\mathcal{S},C} = \nu_{\rm s} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{\mathcal{S},p} = \mu. \tag{23.76}$$

As for internal energy in Section 23.6.2, equations (23.76) provide a relation between $T, \nu_{\rm s}, \mu$ as derivatives of a function, the enthalpy, which is itself a function $\mathcal{H}(\mathcal{S}, p, C)$. Hence, we may consider $T, \nu_{\rm s}, \mu$ as each a function of $(\mathcal{S}, p, C)$ to thus render the following equations of state

$$T = T(\mathcal{S}, p, C) \qquad \text{and} \qquad \nu_{\rm s} = \nu_{\rm s}(\mathcal{S}, p, C) \qquad \text{and} \qquad \mu = \mu(\mathcal{S}, p, C). \tag{23.77}$$

Enthalpy's functional dependence (23.75) is more convenient for studies of geophysical fluids than that for internal energy, $\mathcal{I}(\mathcal{S}, \nu_{\rm s}, C)$, or for entropy $\mathcal{S}(\mathcal{I}, \nu_{\rm s}, C)$.

- In the laboratory or field, we generally have direct mechanical means for measuring pressure in a fluid, whereas specific volume requires indirect methods involving the equation of state for density discussed in Section 31.3.

- Correspondingly, the interaction between fluid elements typically occurs at near constant pressure. Hence, fluid elements exchange both their entropy and enthalpy when the exchange occurs as constant pressure.

- Specific entropy remains constant on a fluid element in the absence of mixing or other irreversible effects. Correspondingly, enthalpy remains constant for constant pressure motion without mixing. Conversely, in the presence of mixing at constant pressure, fluid elements mix their specific enthalpy, specific entropy, and tracer concentration.

23.6.5 Helmholtz free energy

The Helmholtz free energy is defined by the Legendre transformation

$$\mathcal{F} = \mathcal{I} - T\,\mathcal{S} = -p\,\nu_{\mathrm{s}} + \sum_{n=1}^{N} \mu_n\, C_n, \tag{23.78}$$

where the second equality made use of equation (23.60). The exact differential of the Helmholtz free energy is given by

$$\begin{aligned} \mathrm{d}\mathcal{F} &= \mathrm{d}\mathcal{I} - \mathrm{d}(T\,\mathcal{S}) && (23.79\mathrm{a}) \\ &= \mathrm{d}\mathcal{I} - T\,\mathrm{d}\mathcal{S} - \mathcal{S}\,\mathrm{d}T && (23.79\mathrm{b}) \\ &= -\mathcal{S}\,\mathrm{d}T - p\,\mathrm{d}\nu_{\mathrm{s}} + \mu\,\mathrm{d}C, && (23.79\mathrm{c}) \end{aligned}$$

where we used the fundamental thermodynamic relation (23.56b) for the final equality. Isothermal and constant concentration processes render the changes to the free energy equal to the pressure work applied to the system.

The Helmholtz free energy has the functional dependence

$$\mathcal{F} = \mathcal{F}(T, \nu_{\mathrm{s}}, C), \tag{23.80}$$

which then leads to the partial derivatives identities

$$\left[\frac{\partial \mathcal{F}}{\partial T}\right]_{\nu_{\mathrm{s}},C} = -\mathcal{S} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{F}}{\partial \nu_{\mathrm{s}}}\right]_{T,C} = -p \qquad \text{and} \qquad \left[\frac{\partial \mathcal{F}}{\partial C}\right]_{T,\nu_{\mathrm{s}}} = \mu. \tag{23.81}$$

As for internal energy in Section 23.6.2, equations (23.81) provide a relation between $\mathcal{S}, p, \mu$ as derivatives of a function, the Helmholtz free energy, which is itself a function $\mathcal{F}(T, \nu_{\mathrm{s}}, C)$. Hence, we may consider $\mathcal{S}, p, \mu$ each as a function of (T, ν_{s}, C) to render the equations of state

$$\mathcal{S} = \mathcal{S}(T, \nu_{\mathrm{s}}, C) \qquad \text{and} \qquad p = p(T, \nu_{\mathrm{s}}, C) \qquad \text{and} \qquad \mu = \mu(T, \nu_{\mathrm{s}}, C). \tag{23.82}$$

23.6.6 Gibbs potential

The Gibbs potential is defined by the Legendre transformation

$$\mathcal{G} = \mathcal{I} + p\,\nu_{\mathrm{s}} - T\,\mathcal{S} = \mathcal{H} - T\,\mathcal{S} = \sum_{n=1}^{N} \mu_n\, C_n, \tag{23.83}$$

where the final equality made use of equation (23.60). The exact differential of the Gibbs potential is given by

$$\begin{aligned} \mathrm{d}\mathcal{G} &= \mathrm{d}\mathcal{H} - \mathrm{d}(T\,\mathcal{S}) && (23.84\mathrm{a}) \\ &= T\,\mathrm{d}\mathcal{S} + \nu_{\mathrm{s}}\,\mathrm{d}p + \mu\,\mathrm{d}C - T\,\mathrm{d}\mathcal{S} - \mathcal{S}\,\mathrm{d}T && (23.84\mathrm{b}) \\ &= -\mathcal{S}\,\mathrm{d}T + \nu_{\mathrm{s}}\,\mathrm{d}p + \mu\,\mathrm{d}C, && (23.84\mathrm{c}) \end{aligned}$$

where we made use of the fundamental thermodynamic relation (23.74c) written in terms of enthalpy. The Gibbs potential has the functional dependence

$$\mathcal{G} = \mathcal{G}(T, p, C), \tag{23.85}$$

which leads to the partial derivatives identities

$$\left[\frac{\partial \mathcal{G}}{\partial T}\right]_{p,C} = -\mathcal{S} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C} = \nu_{\mathrm{s}} \qquad \text{and} \qquad \left[\frac{\partial \mathcal{G}}{\partial C}\right]_{T,p} = \mu. \tag{23.86}$$

As for internal energy in Section 23.6.2, equations (23.86) provide a relation between $\mathcal{S}, \nu_{\mathrm{s}}, \mu$ as derivatives of a function, the Gibbs potential, which is itself a function $\mathcal{G}(T, p, C)$. Hence, we may consider $\mathcal{S}, \nu_{\mathrm{s}}, \mu$ each as a function of (T, p, C) to render the following functional relations

$$\mathcal{S} = \mathcal{S}(T, p, C) \qquad \text{and} \qquad \nu_{\mathrm{s}} = \nu_{\mathrm{s}}(T, p, C) \qquad \text{and} \qquad \mu = \mu(T, p, C). \tag{23.87}$$

The form of the fundamental dependencies (23.85), and the associated equations of state (23.87), are often used in fluid mechanics and physical chemistry. The reason is that temperature, pressure, and concentration are readily measured in the laboratory and the environment. We can thus readily measure the partial derivatives of $\mathcal{G}$, and the functional dependence (23.87) provides a convenient means to express $\mathcal{S}$, ν_{s}, and μ (e.g., see the adiabatic lapse rate discussion in Section 24.2).

Given its convenient functional dependence, the Gibbs potential plays a central role in developing the thermodynamics of seawater as formulated by *Feistel* (1993) and codifed by *IOC et al.* (2010). We thus endeavor to exhibit how quantities (e.g., response functions as in Section 23.7) can be computed based on knowledge of the Gibbs potential and its partial derivatives. For example, use of equation (23.86) renders the expression for the enthalpy

$$\mathcal{H} = \mathcal{G} + T\,\mathcal{S} = \mathcal{G} - T\left[\frac{\partial \mathcal{G}}{\partial T}\right]_{p,C}. \tag{23.88}$$

23.6.7 Chemical potential and the Gibbs potential

Throughout this section we have displayed equations for the chemical potential of a binary fluid in terms of the partial derivatives of the thermodynamic potentials, such as equation (23.86) using the Gibbs potential. Here we consider some details that lead to further understanding of the partial derivatives. We start by writing the chemical potential of fresh water and salt as contained within seawater in terms of the partial derivatives of the extensive Gibbs potential

$$\mu_{\mathrm{water}} = \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_{\mathrm{water}}}\right]_{T,p,M_{\mathrm{salt}}} \qquad \text{and} \qquad \mu_{\mathrm{salt}} = \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_{\mathrm{salt}}}\right]_{T,p,M_{\mathrm{water}}}. \tag{23.89}$$

The total mass of a sample of seawater is given by $M = M_{\mathrm{water}} + M_{\mathrm{salt}}$. Consequently, to compute these partial derivatives requires us to alter the mass of the sample as we hold the mass of one component fixed while varying the mass of the other component. This sort of partial derivative is less convenient for our purposes since we prefer to work with constant mass samples, such as we encounter with constant mass fluid elements. For that purpose we introduce the specific Gibbs potential, in which case the chemical potential of fresh water is

$$\mu_{\mathrm{water}} = \left[\frac{\partial \mathcal{G}^{\mathrm{e}}}{\partial M_{\mathrm{water}}}\right]_{T,p,M_{\mathrm{salt}}} = \left[\frac{\partial (M\,\mathcal{G})}{\partial M_{\mathrm{water}}}\right]_{T,p,M_{\mathrm{salt}}} = \mathcal{G} + M\left[\frac{\partial \mathcal{G}}{\partial M_{\mathrm{water}}}\right]_{T,p,M_{\mathrm{salt}}}. \tag{23.90}$$

The specific Gibbs potential is a natural function of T, p, C_n, and since $C_{\mathrm{water}} + C_{\mathrm{salt}} = 1$ we can write the Gibbs potential in terms of just one of the concentrations, typically chosen as C_{salt}. We

are thus led to

$$\mu_{\text{water}} = \mathcal{G} + M \left[\frac{\partial \mathcal{G}}{\partial M_{\text{water}}}\right]_{T,p,M_{\text{salt}}} \tag{23.91a}$$

$$= \mathcal{G} + M \left[\frac{\partial \mathcal{G}}{\partial C_{\text{water}}}\right]_{T,p} \left[\frac{\partial C_{\text{water}}}{\partial M_{\text{water}}}\right]_{M_{\text{salt}}} \tag{23.91b}$$

where the concentration partial derivative is given by

$$\left[\frac{\partial C_{\text{water}}}{\partial M_{\text{water}}}\right]_{M_{\text{salt}}} = \left[\frac{\partial}{\partial M_{\text{water}}}\right]_{M_{\text{salt}}} \left[\frac{M_{\text{water}}}{M_{\text{water}} + M_{\text{salt}}}\right] = \frac{C_{\text{salt}}}{M}, \tag{23.92}$$

thus leading to the chemical potential of fresh water within seawater

$$\mu_{\text{water}} = \mathcal{G} + C_{\text{salt}} \left[\frac{\partial \mathcal{G}}{\partial C_{\text{water}}}\right]_{T,p} = \mathcal{G} - C_{\text{salt}} \left[\frac{\partial \mathcal{G}}{\partial C_{\text{salt}}}\right]_{T,p}. \tag{23.93}$$

We are thus able to work with the specific Gibbs function for a constant mass fluid element and compute its concentration partial derivative. Similar manipulations lead to the chemical potential for salt within seawater

$$\mu_{\text{salt}} = \mathcal{G} + C_{\text{water}} \left[\frac{\partial \mathcal{G}}{\partial C_{\text{salt}}}\right]_{T,p} = \mathcal{G} + (1 - C_{\text{salt}}) \left[\frac{\partial \mathcal{G}}{\partial C_{\text{salt}}}\right]_{T,p}. \tag{23.94}$$

We are thus led to the seawater chemical potential

$$\mu = \mu_{\text{salt}} - \mu_{\text{water}} = \left[\frac{\partial \mathcal{G}}{\partial C_{\text{salt}}}\right]_{T,p}, \tag{23.95}$$

which agrees with equation (23.86).

23.7 Response functions

Response functions measure the change in a thermodynamic property as the system is forced in some manner. We here introduce the heat capacity, thermal expansion coefficient, and haline contraction coefficient, which are three response functions commonly encountered in ocean and atmospheric fluid mechanics.

23.7.1 Specific heat capacities

The heat capacity measures the change in heat associated with a change in temperature at constant matter composition. There are two distinct heat capacities generally considered in fluid mechanics: one with specific volume held fixed and the other with pressure held fixed

$$c_{\text{v}} \equiv \frac{1}{M} \left[\frac{đ\mathcal{Q}}{\partial T}\right]_{\nu_{\text{s}},C} \qquad \text{SI units m}^2\ \text{s}^{-2}\ \text{K}^{-1}. \tag{23.96}$$

$$c_{\text{p}} \equiv \frac{1}{M} \left[\frac{đ\mathcal{Q}}{\partial T}\right]_{p,C} \qquad \text{SI units m}^2\ \text{s}^{-2}\ \text{K}^{-1}. \tag{23.97}$$

Each of these quantities are specific heat capacities since we have divided by the mass. If heating occurs quasi-statically, we can make use of the equation (23.4) that relates heating and entropy,

applied here in its specific (per mass) form $M^{-1}\,đ\mathcal{Q} = T\,d\mathcal{S}$. The result is a state function form of the specific heat capacities

$$c_{\mathrm{v}} = T\left[\frac{\partial \mathcal{S}}{\partial T}\right]_{\nu_{\mathrm{s}},C} = -T\,\frac{\partial}{\partial T}\Big]_{\nu_{\mathrm{s}},C}\left[\frac{\partial \mathcal{G}}{\partial T}\right]_{p,C} \tag{23.98}$$

$$c_{\mathrm{p}} = T\left[\frac{\partial \mathcal{S}}{\partial T}\right]_{p,C} = -T\,\frac{\partial}{\partial T}\Big]_{p,C}\left[\frac{\partial \mathcal{G}}{\partial T}\right]_{p,C} \tag{23.99}$$

where the second equalities in both of the above equations introduced the Gibbs potential according to equation (23.86). Furthermore, we can make use of the fundamental thermodynamic relation (23.54) with specific volume and matter concentration held fixed to yield

$$c_{\mathrm{v}} = T\left[\frac{\partial \mathcal{S}}{\partial T}\right]_{\nu_{\mathrm{s}},C} = \left[\frac{\partial \mathcal{I}}{\partial T}\right]_{\nu_{\mathrm{s}},C}. \tag{23.100}$$

The second form of c_{v} motivates the name *internal energy capacity* rather than heat capacity at fixed volume. Likewise, making use of the fundamental thermodynamic relation (23.74c) written in terms of enthalpy leads to the constant pressure heat capacity

$$c_{\mathrm{p}} = T\left[\frac{\partial \mathcal{S}}{\partial T}\right]_{p,C} = \left[\frac{\partial \mathcal{I}}{\partial T}\right]_{p,C} + p\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_{p,C} = \left[\frac{\partial \mathcal{H}}{\partial T}\right]_{p,C}. \tag{23.101}$$

That is, the constant pressure heat capacity is equivalently referred to as the *enthalpy capacity*.

23.7.2 Thermal expansion coefficient

The thermal expansion coefficient measures relative changes in density as temperature changes at constant pressure and concentration

$$\alpha_{\mathrm{T}} = -\frac{1}{\rho}\left[\frac{\partial \rho}{\partial T}\right]_{p,C} = \frac{1}{\nu_{\mathrm{s}}}\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_{p,C} = \frac{1}{(\partial \mathcal{G}/\partial p)_{T,C}}\,\frac{\partial}{\partial T}\Big]_{p,C}\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C} \tag{23.102}$$

where the final equality introduced the Gibbs function according to equation (23.86). The minus sign in the definition is introduced since density typically reduces when temperature increases, so that for most substances $\alpha_{\mathrm{T}} > 0$. Freshwater near its freezing point is an important counter-example, with $\alpha_{\mathrm{T}} < 0$ allowing for solid ice to float on liquid water.

23.7.3 Haline contraction coefficient

A similar response function measures changes to density arising from changes in the salt concentration (salinity) in seawater

$$\beta_{\mathrm{S}} = \frac{1}{\rho}\left[\frac{\partial \rho}{\partial S}\right]_{p,T} = -\frac{1}{\nu_{\mathrm{s}}}\left[\frac{\partial \nu_{\mathrm{s}}}{\partial S}\right]_{p,T} = -\frac{1}{(\partial \mathcal{G}/\partial p)_{T,S}}\,\frac{\partial}{\partial S}\Big]_{T,p}\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,S} \tag{23.103}$$

where $S = 1000\,C$ is the salinity (23.59). Seawater density typically increases (fluid element volume contracts) when salinity increases, so that $\beta_{\mathrm{S}} > 0$.

23.7.4 Speed of sound (acoustic) waves

Changes in density with respect to pressure at a fixed entropy define the inverse squared sound speed[15]

$$\frac{1}{c_{\mathrm{s}}^2} = \left[\frac{\partial \rho}{\partial p}\right]_{\mathcal{S}} = -\frac{1}{(\nu_{\mathrm{s}})^2}\left[\frac{\partial \nu_{\mathrm{s}}}{\partial p}\right]_{\mathcal{S}} = -\frac{1}{[(\partial \mathcal{G}/\partial p)_{T,S}]^2}\,\frac{\partial}{\partial p}\Big]_{\mathcal{S}}\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,S}. \tag{23.104}$$

The sound speed is a strong function of pressure, generally increasing with higher pressure, as well as temperature, generally decreasing with lower temperature. For the ocean, these two effects compete when moving into the ocean interior. In the upper 500 m to 1000 m, decreasing temperatures cause the sound speed to reduce whereas at deeper regions the higher pressures overcome the temperature effect thus increasing the sound speed. The result is a sound speed minimum between 500 m and 1000 m. The sound speed minimum and the associated acoustic waveguide play an important role in ocean acoustics, in particular for how certain whales are able to communicate across ocean basins. We consider the sound speed for an ideal gas in Section 24.4.8.

23.8 Maxwell relations for single component fluids

Thermodynamics makes use of basic properties of exact differentials for the purpose of developing identities between partial derivatives. Maxwell relations refer to a suite of partial derivative identities that follow from the equality of mixed second partial derivatives of thermodynamic potentials. We already made use of some Maxwell relations in Section 23.3.5 when discussing the Gibbs potential, and we use another in Section 24.2 for expressing the adiabatic lapse rate in terms of readily measurable thermo-mechanical properties. In this section we develop the Maxwell relations encountered with single component fluids, with similar relations readily derived for multi-component fluids.

23.8.1 Maxwell relation from internal energy

As seen from Section 23.6.2, the natural functional dependence for internal energy in a single-component fluid is given by its fundamental thermodynamic relation (23.62)

$$\mathrm{d}\mathcal{I} = \left[\frac{\partial \mathcal{I}}{\partial \mathcal{S}}\right]_{\nu_{\mathrm{s}}} \mathrm{d}\mathcal{S} + \left[\frac{\partial \mathcal{I}}{\partial \nu_{\mathrm{s}}}\right]_{\mathcal{S}} \mathrm{d}\nu_{\mathrm{s}} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\mathrm{s}} \Longrightarrow \mathcal{I} = \mathcal{I}(\mathcal{S}, \nu_{\mathrm{s}}). \tag{23.105}$$

The mixed second partial derivatives are equal

$$\frac{\partial}{\partial \nu_{\mathrm{s}}}\Big]_{\mathcal{S},C}\frac{\partial}{\partial \mathcal{S}}\Big]_{\nu_{\mathrm{s}},C}\mathcal{I} = \frac{\partial}{\partial \mathcal{S}}\Big]_{\nu_{\mathrm{s}},C}\frac{\partial}{\partial \nu_{\mathrm{s}}}\Big]_{\mathcal{S},C}\mathcal{I}, \tag{23.106}$$

so that, via the fundamental thermodynamic relation (23.105), we have the Maxwell relation

$$\left[\frac{\partial T}{\partial \nu_{\mathrm{s}}}\right]_{\mathcal{S}} = -\left[\frac{\partial p}{\partial \mathcal{S}}\right]_{\nu_{\mathrm{s}}}. \tag{23.107}$$

[15] We study sound waves in Chapter 49.

23.8.2 Summary of the Maxwell relations

The other thermodynamic potentials, and their associated fundamental thermodynamical relations, lead to further Maxwell relations as summarized here

$$\mathrm{d}\mathcal{I} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\mathrm{s}} \Longrightarrow \left[\frac{\partial T}{\partial \nu_{\mathrm{s}}}\right]_{\mathcal{S}} = -\left[\frac{\partial p}{\partial \mathcal{S}}\right]_{\nu_{\mathrm{s}}} \tag{23.108}$$

$$\mathrm{d}\mathcal{H} = T\,\mathrm{d}\mathcal{S} + \nu_{\mathrm{s}}\,\mathrm{d}p \Longrightarrow \left[\frac{\partial T}{\partial p}\right]_{\mathcal{S}} = \left[\frac{\partial \nu_{\mathrm{s}}}{\partial \mathcal{S}}\right]_{p} \tag{23.109}$$

$$\mathrm{d}\mathcal{G} = -\mathcal{S}\,\mathrm{d}T + \nu_{\mathrm{s}}\,\mathrm{d}p \Longrightarrow \left[\frac{\partial \mathcal{S}}{\partial p}\right]_{T} = -\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_{p}. \tag{23.110}$$

$$\mathrm{d}\mathcal{F} = -\mathcal{S}\,\mathrm{d}T - p\mathrm{d}\nu_{\mathrm{s}} \Longrightarrow \left[\frac{\partial \mathcal{S}}{\partial \nu_{\mathrm{s}}}\right]_{T} = \left[\frac{\partial p}{\partial T}\right]_{\nu_{\mathrm{s}}}. \tag{23.111}$$

These four Maxwell relations for single-component fluids involve permutations on cross derivatives of $(T, \mathcal{S})$ and (p, ν_{s}). In statistical mechanics, $(T, \mathcal{S})$ determine the density of accessible microscopic states forming the thermodynamic system, whereas (p, ν_{s}) involves an external control parameter and its corresponding generalized force.

23.9 Exercises

EXERCISE 23.1: DERIVATION OF THE GIBBS-DUHEM RELATION
Show all of the steps leading to the Gibbs-Duhem relation (23.36).

EXERCISE 23.2: CHEMICAL POTENTIAL IDENTITY
As seen in Section 27.6.6, we have need to consider the partial derivative

$$\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} \tag{23.112}$$

when determining the chemical work done by mixing within a fluid. Prove the identity

$$\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} = \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{\mathcal{S},p} - T\left[\frac{\partial \mu}{\partial T}\right]_{C,p} = \mu - T\left[\frac{\partial \mu}{\partial T}\right]_{C,p}. \tag{23.113}$$

Hint: as seen in Section 23.6.4, the natural functional dependence for enthalpy is $\mathcal{H}(\mathcal{S}, p, C)$, whereas in Section 23.6.6 we found the natural function dependence of the Gibbs potential to be $\mathcal{G}(T, p, C)$. Equate the exact differential expressions for enthalpy using the two functional dependencies $\mathcal{H}(\mathcal{S}, p, C)$ and $\mathcal{H}(T, p, C)$, and then derive a Maxwell relation based on the fundamental thermodynamic relation written in terms of the Gibbs potential.

EXERCISE 23.3: CONSTANT OF MOTION FOR ADIABATIC PROCESSES
Show that for a simple ideal gas, isentropic processes (i.e., both adiabatic and of constant matter concentration) maintain

$$p\,\nu_{\mathrm{s}}^{c_{\mathrm{p}}/c_{\mathrm{v}}} = \text{constant}, \tag{23.114}$$

where $\nu_{\mathrm{s}} = \rho^{-1}$ is the specific volume.

Chapter 24

Equilibrium thermodynamics with a geopotential

We here extend the equilibrium thermodynamics from Chapter 23 to allow for gravitational effects as embodied by the geopotential (which also includes the planetary centrifugal acceleration). Thermodynamic equilibrium of a fluid in a constant gravitational field is consistent with mechanical equilibrium; i.e., the fluid is in hydrostatic balance. We develop certain properties of hydrostatic fluids, such as the adiabatic lapse rate, potential temperature, and a variety of identities holding for an ideal gas (which offers a useful approximation to the atmosphere).

CHAPTER GUIDE

This chapter develops the rudiments of equilibrium thermodynamics in the presence of gravity, building on the foundations established in Chapter 23. There are relatively few presentations of gravity within standard thermodynamic texts. However, Chapter 9 of *Guggenheim* (1967) and §25 of *Landau and Lifshitz* (1980) are notable exceptions, along with Section 1.8 of the oceanography text from *Kamenkovich* (1977).

24.1 Thermodynamic equilibrium with a geopotential

What does thermodynamic equilibrium look like in the presence of a gravity field? To answer this question, we here consider a single-component system in the presence of a static gravity field. To further connect to geophysical fluids, we let the geopotential, Φ, represent the effects from central gravity plus the planetary centrifugal acceleration (Section 13.10.4). Throughout this analysis, we assume the acceleration from the geopotential is prescribed and is thus not affected by the mass of the thermodynamic system that feels the geopotential. Furthermore, we assume the force from the geopotential is terrestrial, so that it is weak enough to ignore general relativistic effects.[1]

24.1.1 The first law

As seen in Section 23.2.3, a thermodynamic system subjected to a pressure field undergoes pressure work as its volume changes. Analogously, when the mass of a thermodynamic system changes within a geopotential field, then it is subjected to geopotential work, which takes the form

$$đ\mathcal{W}^{\text{geopotential}} = \Phi \, \mathrm{d}M. \tag{24.1}$$

We thus see that the geopotential is an intensive property with mass its corresponding extensive property. Consequently, the first law for a quasi-static process is modified from equation (23.35b) to now read

$$\mathrm{d}\mathcal{J}^{\mathrm{e}} = -p \, \mathrm{d}V + T \, \mathrm{d}\mathcal{S}^{\mathrm{e}} + (\mu + \Phi) \, \mathrm{d}M \Longleftrightarrow \mathrm{d}\mathcal{S}^{\mathrm{e}} = T^{-1} \left[p \, \mathrm{d}V + \mathrm{d}\mathcal{J}^{\mathrm{e}} - (\mu + \Phi) \, \mathrm{d}M \right], \tag{24.2}$$

where μ is the chemical potential in the absence of a geopotential

$$\left[\frac{\partial \mathcal{J}^{\mathrm{e}}}{\partial M} \right]_{V, \mathcal{S}^{\mathrm{e}}} = \mu + \Phi \quad \text{and} \quad \left[\frac{\partial \mathcal{J}^{\mathrm{e}}}{\partial M} \right]_{V, \mathcal{S}^{\mathrm{e}}, \Phi = 0} = \mu. \tag{24.3}$$

The corresponding Gibbs-Duhem relation (23.36) now takes on the form

$$-V \, \mathrm{d}p + \mathcal{S}^{\mathrm{e}} \, \mathrm{d}T + M \, \mathrm{d}(\mu + \Phi) = 0. \tag{24.4}$$

24.1.2 Thermodynamic equilibrium with varying volume

Following our discussion in Section 23.4, we consider two adjoining fluid regions that are allowed to adjust toward thermodynamic equilibrium in the presence of a geopotential field. The entropy

[1] The relevant non-dimensional ratio is given by Φ/c^2, with c the speed of light. See *Santiago and Visser* (2018) for a concise review of how gravity leads to a spatially dependent temperature in thermal equilibrium through Tolman's temperature gradient. These considerations are important when Φ/c^2 is order unity. For terrestrial purposes, $\Phi/c^2 \lll 1$, so that relativistic gravitational effects are entirely negligible.

differential in equation (23.47b) now takes on the form

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = \left[\frac{1}{T_\alpha} - \frac{1}{T_\beta}\right]\mathrm{d}\mathcal{I}^{\mathrm{e}}_\alpha + \left[\frac{p_\alpha}{T_\alpha} - \frac{p_\beta}{T_\beta}\right]\mathrm{d}V_\alpha - \left[\frac{\mu_\alpha + \Phi_\alpha}{T_\alpha} - \frac{\mu_\beta + \Phi_\beta}{T_\beta}\right]\mathrm{d}M_\alpha, \tag{24.5}$$

which follows from the constraints (23.46) that assume fixed internal energy, mass, and volume for the composite system $\alpha \oplus \beta$. Equilibrium is characterized by $\mathrm{d}\mathcal{S}^{\mathrm{e}} = 0$, which leads to a uniform temperature, as for the case with uniform Φ. A further extension of Section 23.4 suggests that $\mathrm{d}p = 0$ and $\mathrm{d}(\mu + \Phi) = 0$ at equilibrium. However, our understanding of fluid statics leads us to expect pressure to vary according to the hydrostatic balance discussed in Section 25.6. That is, a uniform pressure does not arise for equilibrium with a nonuniform geopotential. For that purpose we consider different constraints as seen below.

24.1.3 Thermodynamic equilibrium with fixed volume

To recover hydrostatic balance at thermodynamic equilibrium, consider the case with each volume remaining fixed. In this manner we have

$$\mathrm{d}(\mathcal{I}^{\mathrm{e}}_\alpha + \mathcal{I}^{\mathrm{e}}_\beta) = 0 \quad \text{and} \quad \mathrm{d}V_\alpha = \mathrm{d}V_\beta = 0 \quad \text{and} \quad \mathrm{d}(M_\alpha + M_\beta) = 0. \tag{24.6}$$

An example consists of two vertically positioned fluid boxes, with $\nabla\Phi$ defining the local vertical direction and with adjustment towards equilibrium consisting of mass moving from one box to the other. By fixing each of the region volumes, pressure does no work so that internal energy changes only through entropy and mass changes

$$\mathrm{d}\mathcal{I}^{\mathrm{e}} = T\,\mathrm{d}\mathcal{S}^{\mathrm{e}} + (\mu + \Phi)\,\mathrm{d}M \Longleftrightarrow \mathrm{d}\mathcal{S}^{\mathrm{e}} = T^{-1}\left[\mathrm{d}\mathcal{I}^{\mathrm{e}} - (\mu + \Phi)\,\mathrm{d}M\right]. \tag{24.7}$$

Correspondingly, we find that thermodynamic equilibrium results when

$$\mathrm{d}T = 0 \quad \text{and} \quad \mathrm{d}(\mu + \Phi) = 0. \tag{24.8}$$

To interpret the equilibrium condition, $\mathrm{d}(\mu + \Phi) = 0$, take the derivative with respect to geopotential, holding temperature and mass fixed, to render

$$\left[\frac{\partial \mu}{\partial \Phi}\right]_{T,M} = -1. \tag{24.9}$$

Anticipating the hydrostatic balance, we assume that pressure at thermodynamic equilibrium is a monotonic function of Φ, so that

$$\left[\frac{\partial \mu}{\partial \Phi}\right]_{T,M} = \left[\frac{\partial \mu}{\partial p}\right]_{T,M}\left[\frac{\mathrm{d}p}{\mathrm{d}\Phi}\right]_{T,M} = -1. \tag{24.10}$$

Making use of the Maxwell relation (23.42a) and the identity (23.45d) leads to

$$\left[\frac{\mathrm{d}p}{\mathrm{d}\Phi}\right]_{T,M} = -M/V = -\rho, \tag{24.11}$$

where $\rho = M/V$ is the mass density. We thus recover the exact hydrostatic balance[2]

$$\mathrm{d}p = -\rho\,\mathrm{d}\Phi. \tag{24.12}$$

That is, thermodynamic equilibrium in a gravity field consists of a uniform temperature with pressure satisfying the exact hydrostatic balance.

24.1.4 Vertical salinity gradient at thermodynamic equilibrium

Consider the case of seawater as approximated as a two-component fluid, so that the entropy exact differential is given by

$$\mathrm{d}\mathcal{S}^{\mathrm{e}} = T^{-1}\left[p\,\mathrm{d}V + \mathrm{d}\mathcal{J}^{\mathrm{e}} - (\mu_{\mathrm{salt}} + \Phi)\,\mathrm{d}M_{\mathrm{salt}} - (\mu_{\mathrm{water}} + \Phi)\,\mathrm{d}M_{\mathrm{water}}\right]. \tag{24.13}$$

Separately holding the salt and freshwater masses fixed,[3] we apply the same formalism as pursued in Section 24.1.3 for a single component fluid, thus leading to

$$\mathrm{d}T = 0 \quad \text{and} \quad \mathrm{d}(\mu_{\mathrm{salt}} + \Phi) = 0 \quad \text{and} \quad \mathrm{d}(\mu_{\mathrm{sater}} + \Phi) = 0. \tag{24.14}$$

Subtracting the second and third equilibrium condition leads to the equilibrium condition for the seawater chemical potential,

$$\mathrm{d}(\mu_{\mathrm{salt}} - \mu_{\mathrm{water}}) = \mathrm{d}\mu = 0. \tag{24.15}$$

Now recall the seawater chemical potential is given by equation (23.95) in terms of the salinity derivative of the specific Gibbs potential

$$\mu = \mu_{\mathrm{salt}} - \mu_{\mathrm{water}} = \left[\frac{\partial \mathcal{G}}{\partial S}\right]_{T,p}, \tag{24.16}$$

where $S = C_{\mathrm{salt}}$ is the salt concentration. Hence, we may consider the seawater chemical potential to be a function of the temperature, presure, and salt concentration

$$\mu = \mu(T, p, S). \tag{24.17}$$

The equilibrium conditions $\mathrm{d}T = 0$ and $\mathrm{d}\mu = 0$ lead to

$$\frac{\partial \mu}{\partial S}\,\mathrm{d}S + \frac{\partial \mu}{\partial p}\,\mathrm{d}p = 0. \tag{24.18}$$

The hydrostatic relation $\mathrm{d}p = -\rho\,\mathrm{d}\Phi$ leads to

$$\frac{\partial \mu}{\partial S}\,\frac{\mathrm{d}S}{\mathrm{d}\Phi} = \rho\,\frac{\partial \mu}{\partial p}. \tag{24.19}$$

Of when the geopotential takes on the simple form, $\Phi = g\,z$, then

$$\frac{\partial \mu}{\partial S}\,\frac{\mathrm{d}S}{\mathrm{d}z} = g\,\rho\,\frac{\partial \mu}{\partial p}. \tag{24.20}$$

We thus conclude that at thermodynamic equilibrium, the salinity maintains a nonzero geopo-

[2] We discuss the exact hydrostatic balance in Section 25.6, and discuss the approximate hydrostatic balance in Chapter 28.

[3] This constraint is appropriate since we are looking for the entropy extrema for an isolated system with no boundary fluxes of either salt or freshwater.

tential gradient whereas the *in situ* temperature is uniform.

24.1.5 Comments and further study

A depth independent *in situ* temperature is not observed in the ocean or atmosphere. Likewise, as noted on page 28 of *Kamenkovich* (1977), the vertical salinity gradient implied by the equilibrium relation (24.19) is not observed in the ocean. Both results point to the absence of thermodynamic equilibrium for the macroscale atmosphere and ocean. The absence of global thermodynamic equilibrium is expected since both the atmosphere and ocean are not isolated systems. Furthermore, the fluids are both turbulently mixed rather than mixed solely by molecular processes, with turbulent mixing not leading to thermodynamic equilibrium.[4]

Although we do not generally observe temperature close to thermodynamic equilibrium, we do find a horizontally local hydrostatic balance to be well maintained by the large-scale atmosphere and ocean. In addition to being a thermodynamic equilibrium state, hydrostatic balance is a mechanical equilibrium state (Section 25.6). We thus conclude that for a moving and turbulent geophysical fluid, the mechanical equilibrium state of hydrostatic balance is far more robust than full thermodynamic equilibrium of *in situ* temperature and material tracers. The reason is that mechanical equilibrium is enabled by macroscopic motion (e.g., acoustic waves), whereas thermodynamic equilibrium required for uniform *in situ* temperature is enabled by the far slower molecular diffusion.

The presentation in this section largely follows §25 of *Landau and Lifshitz* (1980) and Section 1.8 of *Kamenkovich* (1977).

24.2 Adiabatic lapse rate

The temperature of a fluid can change without the transfer of heat. This *adiabatic* temperature change arises when the fluid pressure changes. We here introduce the *adiabatic lapse rate*, which measures the vertical variations in temperature for a static fluid placed in a gravity field. There are two lapse rates commonly considered: one related to height and one related to pressure. We introduce some manipulations commonly performed with thermodynamic state functions and their partial derivatives, with the goal of expressing the lapse rate in terms of commonly measured response functions.

The *in situ* temperature is globally uniform for a fluid in thermodynamic equilibrium. Hence, a fluid with a nonzero lapse rate is globally out of thermodynamic equilibrium. However, we again assume that each fluid element is locally in thermodynamic equilibrium so that we can make use of equilibrium thermodynamic relations to derive the lapse rate. Furthermore, we note that the atmosphere is observed to have an *in situ* temperature profile closer to the adiabatic lapse rate than to a uniform *in situ* temperature, thus further indicating that global thermodynamic equilibrium is not realized in geophysical fluids.

24.2.1 Isentropic rearrangement

Consider a finite region of a static fluid in a gravitational field. Assume the fluid is initially in a horizontal layer in thermodynamic equilibrium so that it has a uniform *in situ* temperature. Now rearrange the fluid into a vertical column, and do so without changing the entropy; i.e., without the transfer of heat across the fluid boundary (adiabatically) and without mixing any of its matter constituents. Performing this rearrangement raises the center of mass of the fluid and

[4] As emphasized in Section 23.1 and in Chapter 27, the macroscale atmosphere and ocean are not in thermodynamic equilibrium, and yet these fluids maintain local thermodynamic equilibrium at the scale of fluid elements.

thus increases the gravitational potential energy. This process requires mechanical work against the gravitational field.

Gravity makes pressure at the bottom of the vertical fluid column greater than at the top. This pressure difference modifies the temperature in the column, thus putting the fluid out of global thermodynamic equilibrium. We seek a general expression for how changes in pressure affects changes in temperature for a static fluid, with the pressure changes imparted reversibly and adiabatically so that entropy does not change. Mathematically, we seek an expression for the partial derivative

$$\hat{\Gamma} \equiv \left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}}, \tag{24.21}$$

which is known as the *adiabatic lapse rate*. The adiabatic lapse rate can be measured directly, with empirical expressions fit to laboratory measurements. Additionally, it is convenient to express it in terms of other thermodynamic response functions in order to garner further physical insight. The necessary manipulations form the bulk of this section.

24.2.2 Thermodynamic formulation

When the matter concentration is held fixed, the equation of state (23.87) allows us to consider entropy as a function of temperature and pressure so that

$$\mathrm{d}\mathcal{S} = \left[\frac{\partial \mathcal{S}}{\partial T}\right]_p \mathrm{d}T + \left[\frac{\partial \mathcal{S}}{\partial p}\right]_T \mathrm{d}p. \tag{24.22}$$

Substituting the definition of heat capacity from equation (23.99) leads to

$$T\,\mathrm{d}\mathcal{S} = c_{\mathrm{p}}\,\mathrm{d}T + T\left[\frac{\partial \mathcal{S}}{\partial p}\right]_T \mathrm{d}p. \tag{24.23}$$

It is useful to eliminate $(\partial\mathcal{S}/\partial p)_T$ in favor of a more easily measurable quantity. For that purpose we make use of the Maxwell relation (23.110) to write

$$\left[\frac{\partial \mathcal{S}}{\partial p}\right]_T = -\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_p. \tag{24.24}$$

Introducing the thermal expansion coefficient (23.102) yields an expression for changes in entropy in terms of changes in temperature and pressure

$$T\,\mathrm{d}\mathcal{S} = c_{\mathrm{p}}\,\mathrm{d}T - T\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_p \mathrm{d}p = c_{\mathrm{p}}\,\mathrm{d}T - \left[\frac{T\,\alpha_{\mathrm{T}}}{\rho}\right]\mathrm{d}p. \tag{24.25}$$

Since c_{p} and α_{T} are readily measurable response functions, the expression (24.25) is a useful means to compute infinitesimal entropy changes when matter concentration is held constant.

24.2.3 Adiabatic lapse rate for pressure changes

Equation (24.25) means that the change in temperature associated with changes in pressure, with $\mathrm{d}\mathcal{S} = 0$ and $\mathrm{d}C = 0$, can be written

$$\hat{\Gamma} = \left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}} = \frac{T\,\alpha_{\mathrm{T}}}{\rho\,c_{\mathrm{p}}}. \tag{24.26}$$

This relation holds for any form of pressure changes, such as those due to hydrostatic pressure changes or pressure fluctuations in an acoustic wave (see Section 49.4.4). Temperature indeed changes when pressure changes, even though there has been no heat exchanged with the environment. With $\hat{\Gamma}$ so defined, we can write the entropy change in equation (24.25) as

$$T\,\mathrm{d}\mathcal{S} = c_{\mathrm{p}}\,(\mathrm{d}T - \hat{\Gamma}\,\mathrm{d}p). \tag{24.27}$$

The term $\mathrm{d}T - \hat{\Gamma}\,\mathrm{d}p$ subtracts from the *in situ* temperature differential the pressure induced changes in temperature. In Section 24.3 we introduce the *potential temperature*, which is defined just for the purpose of removing changes due to pressure.

24.2.4 Adiabatic lapse rate for height changes

A static fluid in a gravity field is in exact hydrostatic balance, whereby the pressure at a point equals to the weight per area above that point (Section 25.6). Hydrostatic balance in a constant gravity field maintains the following relation between the pressure differential and the vertical differential

$$\mathrm{d}p = -g\,\rho\,\mathrm{d}z. \tag{24.28}$$

Use of the chain rule within the lapse rate expression (24.26) leads to

$$\Gamma = \left[\frac{\partial T}{\partial z}\right]_{C,\mathcal{S}} = \left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}}\left[\frac{\partial p}{\partial z}\right] = -\rho\,g\left[\frac{T\,\alpha_{\mathrm{T}}}{\rho\,c_{\mathrm{p}}}\right] = -\frac{g\,T\,\alpha_{\mathrm{T}}}{c_{\mathrm{p}}}. \tag{24.29}$$

This form for the lapse rates measures the change in temperature (the *lapse*) within a constant composition fluid element as it is isentropically moved vertically through a hydrostatic pressure field.

24.2.5 Further study

In Section 24.4.9 we consider the adiabatic lapse rate for the special case of a simple ideal gas. For this gas, the internal energy of a fluid element is represented entirely by its temperature, and pressure is caused solely by molecular thermal motion. For water, however, molecular interaction energies are important, and pressure arises not only from thermal motion but also from interaction forces of the densely packed molecules. It is these differences between the behavior of water and a perfect gas that were examined by *McDougall and Feistel* (2003) in terms of molecular dynamics. In particular, they note that the lapse rate, being proportional to the thermal expansion coefficient, can be negative when the thermal expansion is negative. A negative thermal expansion coefficient occurs in cool fresh water, such as the Baltic Sea, whereby its temperature decreases as work is done on the fluid element as pressure increases.

The addition of water to the atmosphere modifies the lapse rate, as the air is then no longer well approximated by an ideal gas. Chapter 18 of *Vallis* (2017) offers a pedagogical discussion of the thermodynamics of a moist tropical atmosphere.

24.3 Potential temperature

As discussed in Section 24.1, thermodynamic equilibrium of a fluid in a geopotential field sees the hydrostatic pressure balancing the weight of fluid. Thermodynamic equilibrium is also characterized by a uniform *in situ* temperature, T, which requires removal of the temperature gradient associated with the adiabatic lapse rate discussed in Section 24.2. The molecular diffusive processes (see Section 27.11) that homogenize *in situ* temperature are very slow, so that geophysical

fluids are rarely in thermodynamic equilibrium. We here introduce the notion of *potential temperature*, which offers a measure of temperature that removes the adiabatic lapse rate. With some qualifiers discussed below, turbulent mixing processes active in geophysical fluids lead to a nearly homogenous potential temperature. As such, potential temperature is a more practical thermodynamic tracer than *in situ* temperature.

24.3.1 Motivating the definition of potential properties

We observe that the processes of heating and cooling of the ocean occur predominantly near the ocean surface. In contrast, transport in the ocean interior is nearly adiabatic and isohaline (i.e., nearly isentropic). The physical picture is suggested whereby the surface ocean boundary layer experiences irreversible processes that set characteristics of water masses that move quasi-reversibly within the ocean interior. As a means to characterize and thus to label these *water masses*, oceanographers prefer to use properties that maintain constant values when moving within the quasi-isentropic ocean interior. Salinity is a good label for this purpose since it is only altered by mixing between waters of varying concentrations, and in turn it is materially constant in the absence of mixing.[5] This behavior constitutes a basic property of material tracers (tracers that measure the mass per mass of a constituent as discussed in Section 21.1). However, it is *not* a property of the *in situ* temperature, T, which changes even in the absence of mixing due to pressure effects. We are thus motivated to seek a thermodynamic property that evolves analogously to material tracers, so that it can be used as a second material label for fluid elements. A similar motivation stems from the analysis of atmospheric motions.

A thermodynamic property that remains constant when a fluid element is moved from one pressure to another, without the transfer of heat or matter and without any kinetic energy dissipation, is said to be a *potential property*. The *potential temperature* is the example that concerns us in this section. As we will see, in some special cases the potential temperature is directly proportional to the specific entropy. More practically, it offers a means to estimate the heat transport within a geophysical fluid.

Conservative Temperature, Θ, is another potential property discussed in Section 27.11, with Conservative Temperature defined as the potential enthalpy divided by a constant heat capacity. As detailed in *McDougall* (2003), Conservative Temperature provides a more convenient and accurate measure of heat transport in a geophysical fluid than potential temperature. As such, Θ is now more commonly used in applications than potential temperature, θ, (*McDougall et al.*, 2021).

24.3.2 Temperature changes from pressure changes

Motion of a fluid element, without exchange of heat (adiabatic) or matter (constant concentration), generally changes the pressure of the fluid element. In turn, this motion causes the *in situ* temperature to have a differential that is in proportion to the adiabatic lapse rate given by (Section 24.2)

$$\mathrm{d}T = \hat{\Gamma}\,\mathrm{d}p. \tag{24.30}$$

Consequently, and as already noted, the *in situ* temperature is not a useful thermodynamic variable to label fluid elements since it changes even in the absence of irreversible mixing processes.

[5] There are nuances concerning what we mean by "salinity", with details given by *IOC et al.* (2010) (in particular, see Sections A.8 and A.9). We are not directly concerned with these nuances in this book, though note that they are important for ocean measurements and the interpretation of salinity as used in numerical ocean models (*McDougall et al.*, 2021).

Instead, it is more useful to remove the adiabatic pressure effects. This is the key reason for introducing potential temperature.

FIGURE 24.1: Potential temperature is the *in situ* temperature that a fluid element of fixed material composition would have if isentropically displaced from its *in situ* pressure to a reference pressure, p_{R}. The schematic here depicts that displacement for a seawater fluid element with *in situ* temperature, T, salinity, $S = 1000\,C$, pressure, p, and specific entropy, $\mathcal{S}$. The element is moved to the ocean surface with the standard sea level atmospheric pressure providing the reference pressure.

24.3.3 Defining the potential temperature

Operationally, the potential temperature is based on removing adiabatic pressure effects from *in situ* temperature. That is, potential temperature is defined as the *in situ* temperature that a fluid element of fixed material composition would have if it were isentropically transported from its *in situ* pressure to a reference pressure p_{R}, with the reference pressure typically taken at the ocean/land surface (see Figure 24.1). Mathematically, the potential temperature, θ, is the reference temperature obtained via integration of $\mathrm{d}T = \hat{\Gamma}\,\mathrm{d}p$ for an isentropic *in situ* temperature change with respect to pressure

$$\int_{\theta}^{T} \mathrm{d}T' = \int_{p_{\mathrm{R}}}^{p} \hat{\Gamma}(T, p', C)\,\mathrm{d}p' \Longrightarrow T = \theta(T, p_{\mathrm{R}}, C) + \int_{p_{\mathrm{R}}}^{p} \hat{\Gamma}(T, p', C)\,\mathrm{d}p', \tag{24.31}$$

with $\hat{\Gamma}$ the lapse rate defined in terms of pressure changes (equation (24.26)). By definition, the *in situ* temperature, T, equals the potential temperature, θ, at the reference pressure, $p = p_{\mathrm{R}}$. Elsewhere, they differ by an amount determined by the adiabatic lapse rate. Furthermore, we see that

$$\left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}} = \left[\frac{\partial \theta}{\partial p}\right]_{C,\mathcal{S}} + \hat{\Gamma}. \tag{24.32}$$

However, by definition

$$\left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}} = \hat{\Gamma} \tag{24.33}$$

so that

$$\left[\frac{\partial \theta}{\partial p}\right]_{C,\mathcal{S}} = 0. \tag{24.34}$$

That is, by construction, the potential temperature depends explicity on the concentration, C, and *in situ* temperature, T, and has a parametric dependence on the reference pressure. It has no explicit dependence on the *in situ* pressure when holding tracer concentration and entropy

fixed. Finally, we emphasize that the potential temperature is a function of tracer concentration, C. Hence, the potential temperature generally changes if the tracer concentration changes. For example, potential temperature in the ocean changes if the salinity changes.

24.3.4 Potential temperature and specific entropy

An alternative definition of the potential temperature follows by noting that the entropy of a fluid element remains unchanged as it is reversibly moved to the reference pressure. Consequently, writing entropy as a function of the *in situ* temperature, pressure, and matter concentration as in equation (23.87)

$$\mathcal{S} = \mathcal{S}(T, p, C) \tag{24.35}$$

leads to the defining identity for potential temperature

$$\mathcal{S} = \mathcal{S}(T, p, C) = \mathcal{S}(\theta, p_{\mathrm{R}}, C). \tag{24.36}$$

This relation directly connects changes in entropy to changes in potential temperature

$$\mathrm{d}\mathcal{S} = \left[\frac{\partial \mathcal{S}(\theta, p_{\mathrm{R}}, C)}{\partial \theta}\right]_C \mathrm{d}\theta. \tag{24.37}$$

Consequently, the reversible transport of a fluid element with constant matter concentration ($\mathrm{d}C = 0$) occurs with both a constant specific entropy and constant potential temperature.

We can go even further than the relation (24.37) by recalling that equation (24.27) relates the differential of specific entropy to temperature and pressure

$$T\,\mathrm{d}\mathcal{S} = c_{\mathrm{p}}\,(\mathrm{d}T - \hat{\Gamma}\,\mathrm{d}p), \tag{24.38}$$

where $\hat{\Gamma}$ is the adiabatic lapse rate defined in terms of pressure changes (equation (24.26)), and we set $\mathrm{d}C = 0$. To relate $\mathrm{d}T - \hat{\Gamma}\,\mathrm{d}p$ to $\mathrm{d}\theta$ we write the potential temperature equation (24.31) in the form

$$\theta(T, p_{\mathrm{R}}, C) = T - \int_{p_{\mathrm{R}}}^{p} \hat{\Gamma}(T, p', C)\,\mathrm{d}p' = T - \Psi(T, p, C, p_{\mathrm{R}}), \tag{24.39}$$

so that the differentials are related by

$$\mathrm{d}\theta = \mathrm{d}T - \mathrm{d}\Psi. \tag{24.40}$$

We evaluate $\mathrm{d}\Psi$ using the chain rule and then specialize to the case of constant composition and with a fixed reference pressure

$$\mathrm{d}\Psi = \frac{\partial \Psi}{\partial T}\,\mathrm{d}T + \frac{\partial \Psi}{\partial p}\,\mathrm{d}p + \frac{\partial \Psi}{\partial C}\,\mathrm{d}C + \frac{\partial \Psi}{\partial p_{\mathrm{R}}}\,\mathrm{d}p_{\mathrm{R}} \tag{24.41a}$$

$$= \frac{\partial \Psi}{\partial T}\,\mathrm{d}T + \frac{\partial \Psi}{\partial p}\,\mathrm{d}p \tag{24.41b}$$

$$\equiv \int_{p_{\mathrm{R}}}^{p} \frac{\partial \hat{\Gamma}(T, p', C)}{\partial T}\,\mathrm{d}p' + \hat{\Gamma}(T, p, C)\,\mathrm{d}p. \tag{24.41c}$$

Evaluating this differentials at the reference pressure removes the integral so that

$$\mathrm{d}\Psi = \hat{\Gamma}(T, p_{\mathrm{R}}, C)\,\mathrm{d}p, \tag{24.42}$$

in which case the potential temperature differential is

$$\mathrm{d}\theta = \mathrm{d}T - \hat{\Gamma}(T, p_{\mathrm{R}}, C)\,\mathrm{d}p. \tag{24.43}$$

Making use of this relation in equation (24.38) renders an expression for the entropy differential in terms of the potential temperature differential

$$\mathrm{d}\mathcal{S} = c_{\mathrm{p}}\,\theta^{-1}\,\mathrm{d}\theta \qquad p = p_{\mathrm{R}} \text{ and } \mathrm{d}C = 0. \tag{24.44}$$

Although evaluated at the reference pressure, as part of exercise 27.4 we see that this relation holds for an ideal gas at all pressures. Furthermore, as part of exercise 27.5 we see that this relation also holds for all pressures in certain liquids.

24.4 Thermodynamic relations for a simple ideal gas

In an ideal gas, we ignore the potential energy of intermolecular interaction forces between molecules. Also, the molecules in an ideal gas are assumed to occupy zero volume (i.e., they are point particles), although they do collide elastically. As a result, the internal energy of an ideal gas is just due to translation, rotation, and vibration of molecules. We refer to a *simple ideal gas* as an ideal gas where the internal energy is a linear function of temperature. In this section we develop a variety of thermodynamic relations for a simple ideal gas atmosphere in exact hydrostatic balance. Although the real atmosphere is moving, and thus not in exact hydrostatic balance, and the real atmosphere is not a simple ideal gas, it turns out that many of the relations established here are rather accurate approximations to the real atmosphere. Furthermore, by exposing these relations for the ideal gas, we further our understanding of the more general thermodynamic relations established earlier in this chapter.

24.4.1 Equation of state

An ideal gas satisfies the following equation of state (see Section 17.3.2)

$$P\,V = n\,R^{\mathrm{g}}\,T, \tag{24.45}$$

where p is the pressure, V is the volume, n is the number of moles,

$$R^{\mathrm{g}} = 8.314 \text{ J mole}^{-1} \text{ K}^{-1} = 8.314 \text{ kg m}^2 \text{ s}^{-2} \text{ mole}^{-1} \text{ K}^{-1} \tag{24.46}$$

is the *universal gas constant*, and T is the absolute temperature in Kelvin (see Section 17.3.2). The number of moles equals to the mass, M, of the gas divided by the mass per mole, M_{mole}

$$n = M/M_{\mathrm{mole}}. \tag{24.47}$$

The mass density, $\rho = M/V$, is thus given by

$$\rho = \frac{p\,M_{\mathrm{mole}}}{T\,R^{\mathrm{g}}} \equiv \frac{p}{T\,R^{\mathrm{M}}}, \tag{24.48}$$

where

$$R^{\mathrm{M}} = R^{\mathrm{g}}/M_{\mathrm{mole}} \tag{24.49}$$

is the *specific gas constant* as defined by the universal gas constant normalized by the molar mass for the constituent. For air we have (Section 17.3.2)

$$M^{\text{air}} = 28.8 \times 10^{-3} \text{ kg mole}^{-1} \tag{24.50}$$

so that air's specific gas constant is

$$R^{\text{air}} = \frac{R^{\text{g}}}{M^{\text{air}}} = \frac{8.314 \text{ kg m}^2 \text{ s}^{-2} \text{ mole}^{-1} \text{ K}^{-1}}{28.8 \times 10^{-3} \text{ kg mole}^{-1}} = 2.938 \times 10^2 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1}. \tag{24.51}$$

The relation (24.48) is known as a *thermal equation of state*, or more succinctly just an equation of state (see Section 31.3 for more discussion). It shows that the mass density of an ideal gas is directly proportional to the pressure: increasing pressure increases density. In contrast, mass density is inversely proportional to the temperature: increases in temperature lead to lower mass density. This behavior for the ideal gas density is reflected in certain real gases and liquids.[6]

24.4.2 Internal energy

An ideal gas is comprised of molecules that interact only through elastic collisions. There are no inter-molecular forces. Furthermore, the volume of the individual molecules is ignored in comparison to the volume of empty space between the molecules, so they are approximated as point masses. Consequently, the internal energy for an ideal gas is independent of density and of the matter concentration. It is hence a function only of the temperature, which measures the kinetic energy of the elastic point molecules

$$\mathcal{I} = \mathcal{I}(T) \qquad \text{ideal gas.} \tag{24.52}$$

Consequently, the exact differential of internal energy for an ideal gas is

$$\mathrm{d}\mathcal{I} = c_{\text{v}} \, \mathrm{d}T. \tag{24.53}$$

The appearance of c_{v}, the constant volume specific heat capacity discussed in Section 23.7.1, arises in order for the ideal gas internal energy to satisfy the general equation (23.100). The heat capacity for an ideal gas is generally a function of temperature. However, for many applications it is sufficient to consider a simple ideal gas, in which c_{v} is a constant so that

$$\mathcal{I} = c_{\text{v}} \, T + \text{constant} \qquad \text{simple ideal gas.} \tag{24.54}$$

The arbitrary constant of integration is generally set to zero so that the internal energy vanishes at absolute zero.

24.4.3 Heat capacity

The heat capacity is a constant for a simple ideal gas (equation 24.54). Results from statistical mechanics show that the thermal/internal energy per molecule equals to $k_{\text{B}} \, T/2$ per excited molecular degree of freedom, where

$$k_{\text{B}} = 1.3806 \times 10^{-23} \text{ m}^2 \text{ kg s}^{-2} \text{ K}^{-1} \tag{24.55}$$

[6] A notable counter-example is water near its freezing point, which becomes more dense as temperature rises. This anomalous behavior is why a body of water freezes from the top down rather than from the bottom up.

is the *Boltzmann constant*. Dry air is mostly comprised of the diatomic molecules N_2 and O_2. Diatomic molecules at temperatures of the lower atmosphere have two rotational and three translational degrees of freedom,[7] so that $\mathcal{I}_{\text{molecule}} = 5\, k_{\text{B}}\, T/2$.

We convert this energy per molecule to an energy per mole of diatomic molecules by multiplying by Avogadro's number (equation (17.9))

$$\mathcal{I}_{\text{mole diatomic}} = 5\, A^{\text{v}}\, k_{\text{B}}\, T/2 = 5\, R^{\text{g}}\, T/2, \tag{24.56}$$

where the gas constant is given by

$$R^{\text{g}} = A^{\text{v}}\, k_{\text{B}} \tag{24.57a}$$
$$= \left(6.022 \times 10^{23}\ \text{mole}^{-1}\right)\left(1.3806 \times 10^{-23}\ \text{m}^2\ \text{kg s}^{-2}\ \text{K}^{-1}\right) \tag{24.57b}$$
$$= 8.314\ \text{kg m}^2\ \text{s}^{-2}\ \text{mole}^{-1}\ \text{K}^{-1}. \tag{24.57c}$$

Finally, dividing by the molar mass for dry air (equation (17.10))

$$M^{\text{air}} = 0.028\ \text{kg mole}^{-1} \tag{24.58}$$

leads to the simple ideal gas approximation to the dry air heat capacity

$$c_{\text{v}} = \frac{5\, R^{\text{g}}}{2\, M^{\text{air}}} = 742\ \text{m}^2\ \text{s}^{-2}\ \text{K}^{-1}. \tag{24.59}$$

The measured heat capacity for dry air at standard temperature (300 K) is 718 $\text{m}^2\ \text{s}^{-2}\ \text{K}^{-1}$, so the simple ideal gas estimate is only $(742 - 718)/718 = 3.3\%$ too large.

24.4.4 Enthalpy

The enthalpy is generally given by equation (23.73), which for a simple ideal gas takes the form

$$\mathcal{H} = \mathcal{I} + p/\rho = c_{\text{v}}\, T + \frac{T\, R^{\text{g}}}{M_{\text{mole}}} = T\left(c_{\text{v}} + R^{\text{M}}\right) \tag{24.60}$$

where $R^{\text{M}} = R^{\text{g}}/M_{\text{mole}}$ (equation (24.49)) is the specific gas constant for the gas. Recall that the constant pressure heat capacity is given by equation (23.101)

$$c_{\text{p}} = T\left[\frac{\partial \mathcal{S}}{\partial T}\right]_{p,C} = \left[\frac{\partial \mathcal{H}}{\partial T}\right]_{p,C}. \tag{24.61}$$

Consequently, for a simple ideal gas we have

$$c_{\text{p}} = c_{\text{v}} + R^{\text{M}} \qquad \text{and} \qquad \mathcal{H} = c_{\text{p}}\, T. \tag{24.62}$$

24.4.5 Thermal expansion coefficient

The thermal expansion coefficient for an ideal gas is given by

$$\alpha_{\text{T}} = -\frac{1}{\rho}\frac{\partial \rho}{\partial T} = \frac{1}{T}, \tag{24.63}$$

so that as temperature increases the thermal expansion decreases.

[7] At high temperatures, two vibrational degrees of freedom are also excited so that $\mathcal{I}_{\text{molecule}} = 7\, k_{\text{B}}\, T/2$ at high temperatures.

24.4.6 Fundamental thermodynamic relations

The fundamental thermodynamic relation, written in terms of internal energy (equation (23.56b)) and enthalpy (equation (23.73)), are given by

$$\mathrm{d}\mathcal{I} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\mathrm{s}} + \mu\,\mathrm{d}C \tag{24.64}$$

$$\mathrm{d}\mathcal{H} = T\,\mathrm{d}\mathcal{S} + \nu_{\mathrm{s}}\,\mathrm{d}p + \mu\,\mathrm{d}C. \tag{24.65}$$

For a simple ideal gas these relations take the form

$$c_{\mathrm{v}}\,\mathrm{d}T = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}\nu_{\mathrm{s}} + \mu\,\mathrm{d}C \tag{24.66}$$

$$c_{\mathrm{p}}\,\mathrm{d}T = T\,\mathrm{d}\mathcal{S} + \nu_{\mathrm{s}}\,\mathrm{d}p + \mu\,\mathrm{d}C. \tag{24.67}$$

24.4.7 Isothermal compressibility

The isothermal compressibility measures the change in volume when holding the temperature and matter concentration fixed and it is determined by the partial derivatives

$$-\frac{1}{V}\left[\frac{\partial V}{\partial p}\right]_{T,C} = \frac{1}{\rho}\left[\frac{\partial \rho}{\partial p}\right]_{T,C}. \tag{24.68}$$

For an ideal gas the compressibility is given by

$$-\frac{1}{V}\left[\frac{\partial V}{\partial p}\right]_{T,C} = \frac{1}{p}, \tag{24.69}$$

so that the compressibility decreases when pressure increases.

24.4.8 Sound speed

As studied in Chapter 49, sound travels through a fluid through compression and expansion of the fluid media. So we expect the sound speed to be related to the compressibility. But rather than the isothermal compressibility considered above, sound waves are largely adiabatic waves so that the entropy is constant. We are thus in need of the isentropic compressibility to compute the sound speed. That is, as defined by equation (23.104), the sound speed is the pressure derivative of density computed with entropy and matter concentration held fixed. We make use of the fundamental relations (24.66) and (24.67), with $\mathrm{d}\mathcal{S} = 0$ and $\mathrm{d}C = 0$ to have

$$\frac{c_{\mathrm{v}}}{c_{\mathrm{p}}} = \frac{p}{\rho}\left[\frac{\partial \rho}{\partial p}\right]_{\mathcal{S},C} = (p/\rho)\,c_{\mathrm{s}}^{-2} \Longrightarrow c_{\mathrm{s}}^2 = (p/\rho)(c_{\mathrm{p}}/c_{\mathrm{v}}) = T\,R^{\mathrm{M}}\,(c_{\mathrm{p}}/c_{\mathrm{v}}). \tag{24.70}$$

For an ideal diatomic gas, such as nitrogen and oxygen, the ratio $c_{\mathrm{p}}/c_{\mathrm{v}} = 7/5$. Taking $R^{\mathrm{M}} = 2.938 \times 10^2\ \mathrm{m}^2\ \mathrm{s}^{-2}\ \mathrm{K}^{-1}$ for air from equation (24.51) then leads to

$$c_{\mathrm{s}} \approx 350\ \mathrm{m\ s}^{-1} \quad \text{for } T = 300\ \mathrm{K}. \tag{24.71}$$

24.4.9 Adiabatic lapse rate

For an ideal gas, the thermal expansion coefficient is given by (equation (24.63)) $\alpha_{\mathrm{T}} = T^{-1}$ so that the lapse rates are

$$\hat{\Gamma} = \frac{1}{\rho\,c_{\mathrm{p}}} \qquad \text{and} \qquad \Gamma = -\frac{g}{c_{\mathrm{p}}}. \tag{24.72}$$

The measured specific heat capacity for a dry atmosphere at standard temperature (300 K) is

$$c_{\mathrm{p}} = 1005 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1} \tag{24.73}$$

so that the adiabatic lapse rate for a dry atmosphere is roughly

$$\Gamma_{\mathrm{d}} = -9.8 \text{ K}/(1000 \text{ m}). \tag{24.74}$$

Hence, temperature decreases by nearly 10 K when rising 1000 m in a dry and ideal gas atmosphere.

24.4.10 Geopotential thickness

We now establish basic relations for a static atmosphere satisfying the hydrostatic balance. These relations also hold to a very good approximation for the large-scale atmosphere given the dominance of approximate hydrostatic balance for these scales (see Section 28.2).

From the hydrostatic equation (25.56) we know that the pressure on a geopotential, Φ_1, equals to

$$p(\Phi_1) = \int_{\Phi_1}^{\infty} \rho(\Phi)\, \mathrm{d}\Phi \tag{24.75}$$

where we assumed that $p(\Phi_2 = \infty) = 0$. Equation (25.55) allows us to write the integrand as

$$\mathrm{d}\Phi = -\rho^{-1}\, \mathrm{d}p = -\frac{T\, R^{\mathrm{air}}\, \mathrm{d}p}{p}, \tag{24.76}$$

where the second equality assumed an ideal gas atmosphere. Vertical integration of equation (24.76) leads to the *hypsometric equation*, which provides the geopotential thickness between two pressure isosurfaces

$$\Phi(z_2) - \Phi(z_1) = -R^{\mathrm{air}} \int_{p_1}^{p_2} T\, \mathrm{d}(\ln p). \tag{24.77}$$

Recall that $\mathrm{d}p < 0$ if $\mathrm{d}z > 0$ since the hydrostatic pressure decreases when moving up in the atmosphere. We define the *geopotential height* according to

$$Z = \Phi/g, \tag{24.78}$$

where g is the gravitational acceleration at sea level. The geopotential height is close to the geometric height in the troposphere and lower stratosphere. The hypsometric equation (24.77) says that the geopotential thickness between two isobars is

$$Z_2 - Z_1 = \frac{R^{\mathrm{air}}}{g} \int_{p_2}^{p_1} T\, \mathrm{d}(\ln p). \tag{24.79}$$

Defining the layer mean temperature

$$\langle T \rangle = \frac{\int_{p_2}^{p_1} T\, \mathrm{d}(\ln p)}{\int_{p_2}^{p_1} \mathrm{d}(\ln p)} \tag{24.80}$$

and the layer mean *scale height*

$$H = \frac{R^{\mathrm{air}}\, \langle T \rangle}{g} \tag{24.81}$$

leads to the geopotential thickness

$$Z_2 - Z_1 = -H \ln(p_2/p_1) \tag{24.82}$$

The geopotential thickness is thus directly proportional to the mean temperature within the pressure layer, with thicker layers, for example, with higher mean temperatures.

We can invert the geopotential thickness relation (24.82) for the pressures to render

$$p_1 = p_2 \, e^{-(Z_1 - Z_2)/H}. \tag{24.83}$$

This relation, or more commonly its simplified version (24.87) discussed below, is sometimes referred to as the *law of atmospheres* or the *barometric law*. The scale height is a function of pressure through its dependence on the layer averaged temperature in equation (24.81). For the special case of an atmosphere with a constant temperature, T, then the scale height is a constant[8]

$$H_{\text{const}} = \frac{R^{\text{air}} \, T_{\text{const}}}{g}. \tag{24.84}$$

Setting $T_{\text{const}} = 300$ K and using the specific gas constant for air from equation (24.51) leads to the scale height

$$H_{\text{const}} = \frac{2.938 \times 10^2 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1} \times 300 \text{ K}}{9.8 \text{ m s}^{-2}} \approx 9 \times 10^3 \text{ m}. \tag{24.85}$$

It is furthermore convenient to set $Z_2 = 0$ with $p_2 = p_{\text{slp}}$ the sea level pressure, whose global average is

$$\langle p_{\text{slp}} \rangle = 101.325 \times 10^3 \text{ N m}^{-2}. \tag{24.86}$$

The pressure in an isothermal atmosphere thus decreases exponentially with geopotential height according to the scale height

$$p(Z) = \langle p_{\text{slp}} \rangle \exp(-Z/H_{\text{const}}). \tag{24.87}$$

24.4.11 Potential temperature

The fundamental thermodynamic relation for a simple ideal gas (24.67) takes on the following form for an isentropic change

$$c_{\text{p}} \, \text{d}T = \nu_{\text{s}} \, \text{d}p. \tag{24.88}$$

Dividing both sides by temperature and using the ideal gas relation

$$\frac{\nu_{\text{s}}}{T} = \frac{R^{\text{M}}}{p} \tag{24.89}$$

leads to

$$c_{\text{p}} \, \text{d}(\ln T) = R^{\text{M}} \, \text{d}(\ln p). \tag{24.90}$$

Since c_{p} and R^{M} are constants, we can integrate this relation from the reference pressure to an arbitrary pressure

$$c_{\text{p}} \int_{\theta}^{T} \text{d}(\ln T) = R^{\text{M}} \int_{p_{\text{R}}}^{p} \text{d}(\ln p), \tag{24.91}$$

[8] As we saw earlier in this chapter, a fluid has uniform temperature at thermodynamic equilibrium. However, the effects from turbulent motions, even very modest turbulent motions, readily break thermodynamic equilibrium. This topic was discussed on page 299 of *Maxwell* (1872), where he also credits input from Lord Kelvin.

which renders the explicit expression for the potential temperature of a simple ideal gas

$$\theta = T\left[\frac{p_{\mathrm{R}}}{p}\right]^{R^{\mathrm{M}}/c_{\mathrm{p}}} \qquad \text{where} \qquad c_{\mathrm{p}} = \frac{7\,R^{\mathrm{M}}}{2}, \tag{24.92}$$

with c_{p} the constant pressure heat capacity of a simple ideal gas of diatomic molecules (Section 24.4.3). In some treatments (e.g., Exercise 24.3) it is useful to introduce the *Exner function*

$$\Pi = \frac{c_{\mathrm{p}}\,T}{\theta} = c_{\mathrm{p}}\left[\frac{p}{p_{\mathrm{R}}}\right]^{R^{\mathrm{M}}/c_{\mathrm{p}}}. \tag{24.93}$$

In Exercise 24.2 we show that $\partial\theta/\partial p = 0$ for the ideal gas, thus exemplifying the removal of explicit pressure effects from the potential temperature. Furthermore, it follows from equation (24.92) that the potential temperature differential is related to temperature and pressure differentials via

$$\frac{\delta\theta}{\theta} = \frac{\delta T}{T} - \frac{\delta p}{p}. \tag{24.94}$$

In particular, if the differential is computed between points in space within a fluid at a particular time instance, then we are led to the relationship between spatial gradients

$$\frac{\nabla\theta}{\theta} = \frac{\nabla T}{T} - \frac{\nabla p}{p}. \tag{24.95}$$

24.4.12 Further study

Atmospheric sciences and dynamic meteorology books have thorough discussions of ideal gas thermodynamics. Some of the material in section 1.6 of *Holton* (1992) was used in the present section.

24.5 Exercises

EXERCISE 24.1: GEOPOTENTIAL HEIGHT

The *geopotential height* is the height above the earth of a chosen pressure surface.

(a) Show that an ideal gas atmosphere in exact hydrostatic balance with a uniform lapse rate

$$\frac{\mathrm{d}T}{\mathrm{d}z} = -|\Gamma| = \text{constant} \tag{24.96}$$

has a geopotential height at a pressure p given by

$$z = \frac{T_0}{|\Gamma|}\left[1 - \left[\frac{p_0}{p}\right]^{-R^{\mathrm{M}}\,|\Gamma|/g}\right], \tag{24.97}$$

where T_0 is the temperature at $z = 0$.

(b) For an isothermal atmosphere, obtain an expression for the geopotential height as a function of pressure, and show that this result is consistent with the expression (24.97) in the appropriate limit.

EXERCISE 24.2: POTENTIAL TEMPERATURE FOR AN IDEAL GAS
Show that $\partial\theta/\partial p = 0$ for the potential temperature of an ideal gas given by equation (24.92)

$$\theta = T \left[\frac{p_{\mathrm{R}}}{p} \right]^{R^{\mathrm{M}}/c_{\mathrm{p}}} . \tag{24.98}$$

Hint: remember that $\partial T/\partial p \neq 0$ since the partial derivative is computed with other variables fixed.

EXERCISE 24.3: THERMODYNAMIC RELATIONS FOR AN ATMOSPHERE
In this exercise, we establish some relations for an ideal gas atmosphere, and one relation holding for an arbitrary equation of state. We assume that the gravitational acceleration is constant throughout the full depth of the atmosphere. This assumption becomes questionable when integrating to the top of the atmosphere. We furthermore ignore differences in the horizontal cross-sectional area of a fluid column at the bottom and top of the atmosphere arising from the spherical nature of the planet. These two assumption are sufficient for our purposes.

(a) PRESSURE-HEIGHT IDENTITY: Prove the following identity and state your assumptions

$$\int_0^{p_{\mathrm{s}}} z \, \mathrm{d}p = \int_{z=0}^{z_{\mathrm{top}}} p \, \mathrm{d}z. \tag{24.99}$$

This identity will be of use for some of the following questions.

(b) IDEAL GAS $\mathcal{I}+\Phi$ INTEGRATED OVER DEPTH OF A HYDROSTATIC ATMOSPHERE: For an ideal gas atmosphere in exact hydrostatic balance, show that the integral of the gravitational potential energy plus internal energy from the surface to the top of the atmosphere is equal to the integral of the enthalpy of the atmosphere

$$\int_0^{z_{\mathrm{top}}} (\Phi + \mathcal{I}) \, \rho \, \mathrm{d}z = \int_0^{z_{\mathrm{top}}} \mathcal{H} \, \rho \, \mathrm{d}z, \tag{24.100}$$

where

$$\mathcal{H} = p \, \alpha + \mathcal{I} \tag{24.101}$$

is the enthalpy per mass,

$$\Phi = g \, z \tag{24.102}$$

is the simple form of the geopotential, which is also the gravitational potential energy per mass (Section 13.10.4), and $\mathcal{I}$ is the internal energy per mass. The height integral extends from the surface where $z = 0$, to the top of the atmosphere where $z = z_{\mathrm{top}}$.

(c) VERTICAL DERIVATIVE OF DRY STATIC ENERGY: For an ideal gas atmosphere in hydrostatic balance, show that

$$\frac{\mathrm{d}\sigma}{\mathrm{d}z} = \Pi \, \frac{\mathrm{d}\theta}{\mathrm{d}z}, \tag{24.103}$$

where

$$\sigma = \mathcal{H} + \Phi \tag{24.104}$$

is the dry static energy and

$$\Pi = c_{\mathrm{p}} \, (T/\theta) \tag{24.105}$$

is the *Exner function* introduced in equation (24.93).

(d) FIRST IDENTITY FOR HORIZONTAL PRESSURE GRADIENT: For an ideal gas atmosphere

(either hydrostatic or non-hydrostatic), derive the following expression for the pressure gradient acceleration

$$-\frac{1}{\rho}\,\nabla p = -\theta\,\nabla\Pi. \tag{24.106}$$

It then follows that for any instant in time, we have the relation between differentials

$$\rho^{-1}\,\mathrm{d}p = \theta\,\mathrm{d}\Pi. \tag{24.107}$$

(e) Second identity for horizontal pressure gradient: For an ideal gas atmosphere (either hydrostatic or non-hydrostatic), derive the following expression for the pressure gradient acceleration

$$-\frac{1}{\rho}\,\nabla p = -\frac{c_s^2}{\rho\,\theta}\,\nabla(\rho\,\theta), \tag{24.108}$$

where c_s is the sound speed.

(f) $\mathcal{I} + \Phi$ integrated over depth of a hydrostatic atmosphere: Show that for a hydrostatic atmosphere with an arbitrary equation of state

$$\int_0^{p_\mathrm{s}} (\Phi + \mathcal{I})\,\mathrm{d}p = \int_0^{p_\mathrm{s}} \mathcal{H}\,\mathrm{d}p. \tag{24.109}$$

That is, show that the relation in the first part of this problem holds even without making the ideal gas assumption.

exercise 24.4: Unit Knudsen number

Recall from Section 17.2.2 that the Knudsen number is the ratio $\mathrm{Kn} = L_\mathrm{mfp}/L_\mathrm{macro}$, where $L_\mathrm{macro} \approx 10^{-4}$ m is the macroscopic length scale used in the discussion of the continuum approximation, and L_mfp is the molecular mean free path (Section 17.3.3). Throughout this exercise make use of $p_\mathrm{stand} = 101.325 \times 10^3$ Pa for standard atmospheric pressure.

(a) Consider a mole of an isothermal and ideal gas atmosphere of $T = 300\mathrm{K}$ with a constant gravitational acceleration. At what pressure is the Knudsen number unity? Write your answer as a fraction of standard sea atmospheric pressure, p_stand.

(b) Compute the altitude corresponding to the above pressure, assuming the sea level pressure is p_slp and the geopotential is $\Phi = g\,z$. Hint: make use of results from Section 24.4.10.

(c) Assuming $p = p_\mathrm{stand}$, at what temperature is $\mathrm{Kn} = 1$? Hint: assume the ideal gas law holds regardless the temperature.

(d) Comment on what is the least atmospherically relevant assumption made during this exercise.

Part V

Dynamics of geophysical flows

Dynamics is the area of mechanics that examines the causes of motion. For a Newtonian system, such as a geophysical fluid, the cause of motion is understood when we understand the forces acting on the fluid. In this part of the book, we encounter a suite of theoretical concepts that form the foundations of geophysical fluid mechanics. Our presentation typically moves from the general to the specific, with each chapter written in a manner that allows it to be picked up without relying too much on other chapters. The *general to specific* presentation allows us to establish general principles based on foundational concepts and to then see how they manifest in specific contexts.

Forces of concern in geophysical fluid mechanics include the body force acting on a fluid element from the earth's gravity field along with the contact forces from pressure and friction that act between adjacent fluid elements. Additionally, by choosing to work in a non-inertial rotating terrestrial reference frame, we encounter body forces from the Coriolis and planetary centrifugal accelerations, just as encountered for geophysical particle mechanics in Part II of this book. Each of these forces play important roles in determining the diversity of geophysical fluid motion, and their analysis leads to dynamical insights into the nature and causes of fluid motion. We observe that forces in fluids are commonly inferred from kinematic properties of the motion, thus making use of the fluid kinematics from Part III.

SUMMARY OF THE DYNAMICS CHAPTERS

We start the development of dynamics by formulating the equations of motion (linear momentum and angular momentum) in Chapter 25. In subsequent chapters we study the forces appearing in these equations, including friction (Chapter 26), pressure (Chapter 29), and buoyancy (Chapter 31). Buoyancy is the vertical pressure force, arising from density inhomogeneities, that are not balanced by gravity. As such, our study of buoyancy focuses on vertical forces, which contrasts to our study of pressure form stresses in Chapter 29, which focus on horizontal forces.

When studying buoyancy in Chapter 31, we make use of an equation of state that provides the mass density of a fluid element as a function of thermodynamical properties such as temperature, pressure, and matter concentration. In Chapter 27 we study the flow of energy through the fluid, including both mechanical energy of the macroscopic fluid and the internal energy of the molecular degrees of freedom. We thus study how mechanical energy is exchanged with internal energy in the presence of work done by pressure and heat generated by friction.

Chapters 28 and 30 introduce a variety of approximate equations that allow us to focus on selected dynamical regimes by filtering away selected phenomena. It is here that we encounter the hydrostatic approximation and the Boussinesq approximation, both of which are commonly used for large-scale models of the ocean and atmosphere. Approximate balances are further examined in Chapter 32, where we study the mechanics of a rapidly rotating fluid. We here encounter the geostrophic balance, which is a diagnostic balance appropriate for describing large-scale geophysical flows in which the horizontal pressure acceleration is balanced by the Coriolis acceleration. Geostrophic balance is one of the variety of balances considered in Chapter 33, which introduces balanced flow regimes pertaining to horizontal motions. We close this part of the book in Chapter 34, which examines the physics of an Ekman boundary layer in which the Coriolis acceleration balances vertical friction.

Throughout the previous chapters in this part of the book, we assumed a constant effective gravitational acceleration. However, much of the observed motion of the ocean arises from the spatial-temporal variations of the gravity field that give rise to tides. Given this observation, we are motivated to to take a brief look at the case of a space and time dependent gravitational acceleration in Chapter 35.

Chapter 25

Momentum dynamics

We here formulate the fluid mechanical equations for linear and axial angular momentum for geophysical fluid motions. These equations of geophysical fluid dynamics (GFD) are based on Newton's laws of motion applied to a stratified fluid continuum moving on a rotating spherical planet where the rotation rate is constant in time. Relative to the point particle, the new dynamical feature afforded to the continuum concerns contact forces between fluid elements, which lead to pressure and frictional forces from mechanical interactions.

READER'S GUIDE TO THIS CHAPTER

We make liberal use of results from point particle mechanics studied in Part II as well as fluid kinematics from Part III. There are various places in this chapter where we consider integrals of vectors over finite regions, such as when forming the finite volume (weak form) momentum budget as well as the angular momentum budget. As written, such discussions hold for Cartesian tensors, such as for the planetary Cartesian coordinates from Chapter 13 or the tangent plane Cartesian coordinates from Section 25.5. More care than given here is needed for general tensors on general manifolds.

25.2 Linear momentum equation

We here summarize elements of classical continuum mechanics and in turn apply Newton's second law to derive the linear momentum budget for a fluid continuum. We present the momentum budget over both a finite volume region of the fluid (weak formulation) and for an infinitesimal fluid element (strong formulation).

25.2.1 Body forces

Forces acting on an arbitrary volume, $\mathcal{R}$, of a continuous media are of two general types. The first involves *external* or *body* forces, such as gravitation (including astronomical tidal forces), Coriolis, planetary centrifugal, and electromagnetic forces. These forces act throughout the extent of the media. Consequently, the total body force acting on a volume of fluid is the integral of the body force per unit mass, $\boldsymbol{f}_{\text{body}}$, multiplied by the mass of the media and then integrated over the volume

$$\boldsymbol{F}_{\text{body}} = \int_{\mathcal{R}} \boldsymbol{f}_{\text{body}}\, \rho\, \mathrm{d}V. \tag{25.1}$$

For example, the effective gravitational force (combination of central gravity plus planetary centrifugal) acting on a volume of fluid is given by

$$\boldsymbol{F}_{\text{effective gravity}} = \int_{\mathcal{R}} \boldsymbol{g}\, \rho\, \mathrm{d}V, \tag{25.2}$$

where $\boldsymbol{g} = -\nabla\Phi$ is the effective acceleration of gravity with Φ the geopotential (Section 13.10.4). Likewise, the Coriolis force acting on the volume is given by

$$\boldsymbol{F}_{\text{Coriolis}} = -2 \int_{\mathcal{R}} (\boldsymbol{\Omega} \times \boldsymbol{v})\, \rho\, \mathrm{d}V. \tag{25.3}$$

These body forces have the same appearance as for the point particle in Chapter 13, with the only difference being the material is now a continuous media rather than a point mass, thus requiring us to integrate over the region.

25.2.2 Contact forces

The second kind of forces are *internal* or *contact* forces, such as pressure forces and frictional forces. In some areas of continuum mechanics, contact forces are referred to as *tractions*. These forces act on a region of a continuous media through the area integrated stresses acting on the boundary enclosing the region. Mathematically, we compute the contact force exerted on the region by area integrating the *stress tensor* projected onto the normal direction along the region

boundary

$$\boldsymbol{F}_{\text{contact}} = \oint_{\partial\mathcal{R}} \mathbb{T} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{25.4}$$

where $\hat{\boldsymbol{n}}$ is the outward normal direction orienting the domain boundary with $\mathrm{d}\mathcal{S}$ the associated area element, and $\mathbb{T}$ is the second order stress tensor. We have more to say about the stress tensor in the following as well as in Chapter 26. For now, we must be satisfied regarding equation 25.4 as the definition of a contact force.

Contact forces affect continuous media and they do so through the nonzero spatial extent of elements within the media, with this spatial extent allowing for interactions between adjacent fluid elements. Point particles (Part II) do not experience contact forces since point particles have no spatial extent. Hence, contact forces represent a fundamentally new feature, conceptually and operationally, to the fluid dynamical equations relative to the equations of point particles.

Stresses from friction and pressure

As detailed in Chapter 26, there are two types of stress that concern us: diagonal stresses associated with reversible momentum exchange through pressure, and stresses associated with the irreversible exchange of momentum through friction. Hence, it is convenient to decompose the stress tensor components according to

$$\mathbb{T}^{ab} = \mathbb{\tau}^{ab} - p \, g^{ab}. \tag{25.5}$$

In this equation, p is the pressure, which is a force per unit area acting in a compressive manner on the area of a surface. The second order tensor, g^{ab}, is a chosen coordinate representation of the inverse metric tensor and it equals to the Kronecker or unit tensor when choosing Cartesian coordinates in Euclidean space (Section 9.1). The frictional stress tensor is written $\mathbb{\tau}^{ab}$. It is also known as the *deviatoric* stress tensor as it represents deviations from the static case when stress is due solely to pressure. The friction stress tensor generally has zero trace, with pressure comprising the trace portion of the full stress tensor.

Substitution of the stress tensor (25.5) into the contact force expression (25.4) leads to

$$\boldsymbol{F}_{\text{contact}} = \oint_{\partial\mathcal{R}} (\mathbb{\tau} \cdot \hat{\boldsymbol{n}} - p \, \hat{\boldsymbol{n}}) \, \mathrm{d}\mathcal{S}, \tag{25.6}$$

where the integral is taken over the bounding surface of the domain whose outward normal is $\hat{\boldsymbol{n}}$. Given this expression for contact forces acting on the boundary of a fluid domain, it is seen that positive pressure ($p > 0$) acts in the direction opposite to the surface's outward normal so that pressure always acts in a compressive manner. Deviatoric stresses create more general forces on the bounding surface, which can have compressive, expansive, shearing, and/or rotational characteristics.

Exchange of momentum between fluid elements

We mathematically represent the exchange of momentum between fluid elements via a symmetric stress tensor, with symmetry implied by statements about angular momentum conservation (detailed in Section 26.4). The divergence of the stress tensor then leads to a force acting on the fluid element. The forces arising from molecular viscosity provide an irreversible exchange of momentum that reduce the kinetic energy of fluid elements (Section 27.3.3). This process is dissipative and thus referred to as friction. Furthermore, when averaging over turbulent realizations of a fluid, the impacts on the mean flow are generally far larger than those associated with molecular viscosity, with these exchanges commonly parameterized via a symmetric stress tensor.

A gauge symmetry of pressure force

The contribution from pressure in the contact force (25.6) remains invariant if pressure is shifted by an arbitrary function of time

$$p(\boldsymbol{x}, t) \to p(\boldsymbol{x}, t) + F(t). \tag{25.7}$$

We see this invariance by noting that

$$\oint_{\partial\mathcal{R}} F(t)\, \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = F(t) \oint_{\partial\mathcal{R}} \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0, \tag{25.8}$$

where the final equality follows from a corollary of the divergence theorem as discussed in Section 2.7.3. Briefly, through the divergence theorem in Section 2.7.2 we know that

$$\oint_{\partial\mathcal{R}} p\, \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla p\, \mathrm{d}V, \tag{25.9}$$

so that if pressure is shifted by a spatial constant then the pressure gradient body force remains unchanged, as will the pressure contact force.

We refer to this invariance of the pressure force as a *gauge symmetry*. It means that motion of the fluid remains unchanged if pressure is modified by a spatial constant that can generally be a function of time.

25.2.3 Equation of motion

The linear momentum of a fluid region is given by

$$\boldsymbol{P} = \int_{\mathcal{R}} \boldsymbol{v}\, \rho\, \mathrm{d}V. \tag{25.10}$$

Applying Newton's law of motion to the continuum leads to the finite volume equation of motion

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} \boldsymbol{v}\, \rho\, \mathrm{d}V = \int_{\mathcal{R}} \rho\, \boldsymbol{f}_{\mathrm{body}}\, \mathrm{d}V + \oint_{\partial\mathcal{R}} \mathbb{T} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{25.11}$$

The time derivative can be material, as for a constant mass fluid region moving with the barycentric velocity. Or it could be Eulerian, as for a fixed region in space (see Section 21.2), or it could be a time derivative following an arbitrary fluid region. Applying the divergence theorem (Section 2.7.2) to the area integral yields

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} \rho\, \boldsymbol{v}\, \mathrm{d}V = \int_{\mathcal{R}} (\rho\, \boldsymbol{f}_{\mathrm{body}} + \nabla \cdot \mathbb{T})\, \mathrm{d}V, \tag{25.12}$$

where we brought the contact forces into the volume integral through exposing the divergence of the stress tensor.

General form of the equation of motion for a fluid element

Since the volume under consideration is arbitrary, the integral relation (25.12) is satisfied for an arbitrary region. We apply the result to an infinitesimal fluid element moving with the flow

$$\frac{\mathrm{D}(\rho\, \boldsymbol{v}\, \delta V)}{\mathrm{D}t} = \delta V\, (\rho\, \boldsymbol{f}_{\mathrm{body}} + \nabla \cdot \mathbb{T}). \tag{25.13}$$

Assuming the mass for the fluid element is constant then reveals the strong form of the equation of motion

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\, \boldsymbol{f}_{\text{body}} + \nabla \cdot \mathbb{T} \Longleftrightarrow \rho \frac{\mathrm{D}v_a}{\mathrm{D}t} = \rho\, f_a + \partial_b \mathbb{T}_{ba}. \tag{25.14}$$

This equation is a continuum expression of Newton's equation of motion, and it is sometimes referred to as *Cauchy's equation of motion*. The right expression exposes the Cartesian tensor labels, with the "body" label dropped for brevity.

Momentum equation for a rotating fluid in a gravitational field

We now specialize the momentum equation (25.14) to suit the needs of geophysical fluid mechanics. We first write the stress tensor in terms of the deviatoric component from friction and a diagonal component from pressure (equation (25.6))

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\, \boldsymbol{f}_{\text{body}} - \nabla p + \nabla \cdot \mathbb{\tau}. \tag{25.15}$$

Next, move to a rotating terrestrial reference frame and thus expose the Coriolis acceleration and the effective gravitational force (Section 13.11)

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\, \boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\, \nabla \Phi - \nabla p + \nabla \cdot \mathbb{\tau}. \tag{25.16}$$

This form of the equation of motion arises from extracting the rigid-body motion of the basis vectors to define the Coriolis acceleration (see Section 13.9). Any remaining changes to the basis vectors arise from motion of the fluid relative to the rigid-body rotating reference frame, and thus appear when expanding the material time derivative. The form (25.16) for the equation of motion offers a suitable starting point for studies of geophysical fluid dynamics. It sometimes goes by the name of *Navier-Stokes* equation. However, that name is more commonly applied to the non-rotating case with a specific form for the friction operator (see Section 26.8.7). We thus refer to equation (25.16) as Newton's law of motion for a rotating fluid.[1]

25.2.4 Euler equation for perfect fluid motion

The inviscid form of the momentum equation (25.15) is known as the *Euler equation* of perfect fluid mechanics

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\, \boldsymbol{f}_{\text{body}} - \nabla p, \tag{25.17}$$

where the body force is conservative. That is, the Euler equation is concerned just with fluid motion in the absence of dissipative processes. The inviscid form of the momentum equation (25.16) leads to the Euler equation in the presence of rotation and gravitation

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\, \boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\, \nabla \Phi - \nabla p. \tag{25.18}$$

We have many occasions in this book to ignore dissipation, in which case we work with a particular form of the Euler equation. We further comment on the Euler equation in Section 26.8.7.

[1] The Navier-Stokes equations were first derived by Claude-Louis Navier in 1822 and later independently derived by George Stokes in 1845.

25.2.5 Further study

Chapter 5 of *Aris* (1962) offers an insightful discussion of continuum mechanics as applied to a fluid. Section 2.2 *Vallis* (2017) provides a thorough derivation of the dynamical equations of motion for the atmosphere and ocean. We offer further discussion of the mathematics and physics of stress in fluids in Chapters 26 and 29.

25.3 Spherical coordinates

Geophysical fluids move on a rotating planet with the planet commonly assumed to have an oblate spherical geometry, though with the equations approximated by their spherical form using the geopotential vertical coordinate. To display the equations of motion, we make use of the acceleration as derived in Section 13.11.3 for the point particle, using the geopotential coordinate to measure radial distances from the center of the sphere, as well as the longitude and latitude angular coordinates defined by Figure 10.1. The point particle time derivative, which is computed following the particle, translates into a material time derivative for fluid elements. We are thus led to the spherical equations of motion in their full glory

$$\frac{\mathrm{D}u}{\mathrm{D}t} + \frac{u\,(w - v\tan\phi)}{r} + 2\,\Omega\,(w\cos\phi - v\sin\phi) = -\frac{1}{\rho\,r\cos\phi}\,\frac{\partial p}{\partial\lambda} + F^{\lambda} \tag{25.19}$$

$$\frac{\mathrm{D}v}{\mathrm{D}t} + \frac{v\,w + u^2\tan\phi}{r} + 2\,\Omega\,u\sin\phi = -\frac{1}{\rho\,r}\,\frac{\partial p}{\partial\phi} + F^{\phi} \tag{25.20}$$

$$\frac{\mathrm{D}w}{\mathrm{D}t} - \frac{u^2 + v^2}{r} - 2\,\Omega\,u\cos\phi = -g - \frac{1}{\rho}\,\frac{\partial p}{\partial r} + F^{r}, \tag{25.21}$$

where we introduced the spherical components to the friction acceleration

$$\boldsymbol{F} = F^{\lambda}\,\hat{\boldsymbol{\lambda}} + F^{\phi}\,\hat{\boldsymbol{\phi}} + F^{r}\,\hat{\boldsymbol{r}}, \tag{25.22}$$

which is determined by the divergence of the frictional stress tensor. We also note the spherical coordinate form for the gradient operator (Section 10.2.8)

$$\nabla = \frac{\hat{\boldsymbol{\lambda}}}{r\cos\phi}\,\frac{\partial}{\partial\lambda} + \frac{\hat{\boldsymbol{\phi}}}{r}\,\frac{\partial}{\partial\phi} + \hat{\boldsymbol{r}}\,\frac{\partial}{\partial r}, \tag{25.23}$$

as well as the material time derivative operator

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla = \frac{\partial}{\partial t} + \frac{u}{r\cos\phi}\,\frac{\partial}{\partial\lambda} + \frac{v}{r}\,\frac{\partial}{\partial\phi} + w\,\frac{\partial}{\partial r}. \tag{25.24}$$

We can write the spherical momentum equations in a bit more compact form by introducing the spherical coordinate velocity field (see equation (13.47))

$$\boldsymbol{v} = \boldsymbol{u} + \hat{\boldsymbol{r}}\,w = u\,\hat{\boldsymbol{\lambda}} + v\,\hat{\boldsymbol{\phi}} + w\,\hat{\boldsymbol{r}} \tag{25.25}$$

and the corresponding spherical coordinate acceleration

$$\boldsymbol{A}_{\text{sphere}} = \frac{\mathrm{D}u}{\mathrm{D}t}\,\hat{\boldsymbol{\lambda}} + \frac{\mathrm{D}v}{\mathrm{D}t}\,\hat{\boldsymbol{\phi}} + \frac{\mathrm{D}w}{\mathrm{D}t}\,\hat{\boldsymbol{r}}. \tag{25.26}$$

We also introduce the expression (13.84c) for the metric acceleration to render

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\,\nabla\Phi - \nabla p + \rho\,\boldsymbol{F}, \tag{25.27}$$

where we have the acceleration relative to the rotating frame

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \boldsymbol{A}_{\text{sphere}} + \frac{1}{r}\left[u \tan\phi\,(\hat{\boldsymbol{r}} \times \boldsymbol{v}) + w\,\boldsymbol{u} - \hat{\boldsymbol{r}}\,\boldsymbol{u}\cdot\boldsymbol{u}\right]. \tag{25.28}$$

For some purposes it is convenient to combine one piece of the metric acceleration to the Coriolis acceleration to yield

$$\boldsymbol{A}_{\text{sphere}} + \frac{1}{r}\left[w\,\boldsymbol{u} - \hat{\boldsymbol{r}}\,\boldsymbol{u}\cdot\boldsymbol{u}\right] + \left[2\,\boldsymbol{\Omega} + \frac{u\tan\phi\,\hat{\boldsymbol{r}}}{r}\right] \times \boldsymbol{v} = -\nabla\Phi - \rho^{-1}\,\nabla p + \boldsymbol{F}. \tag{25.29}$$

25.4 Vector-invariant velocity equation

The metric terms appearing in the momentum equation (25.29) are those terms proportional to r^{-1} that arise from spatial dependence of the spherical unit vectors.[2] An alternative formulation removes these terms in favor of the vorticity and kinetic energy. For that purpose we make use of the identity (equation (2.38)) for the nonlinear self-advection term

$$(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{v} + \nabla(\boldsymbol{v}\cdot\boldsymbol{v})/2, \tag{25.30}$$

where $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$ is the vorticity from Part VII of this book. We derive the corresponding *vector-invariant* form of the velocity equation using Cartesian coordinates and then invoke general coordinate invariance (Section 8.1) to extend the result to arbitrary coordinates.[3] Making use of equation (25.30) thus leads to the material acceleration

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \frac{\partial\boldsymbol{v}}{\partial t} + \boldsymbol{\omega} \times \boldsymbol{v} + \nabla(\boldsymbol{v}\cdot\boldsymbol{v})/2 \tag{25.31}$$

so that the momentum equation (25.16) becomes the vector-invariant velocity equation

$$\frac{\partial\boldsymbol{v}}{\partial t} + (2\,\boldsymbol{\Omega} + \boldsymbol{\omega}) \times \boldsymbol{v} = -\nabla(\Phi + \boldsymbol{v}\cdot\boldsymbol{v}/2) + (1/\rho)\,(-\nabla p + \nabla\cdot\mathbb{T}). \tag{25.32}$$

The name *vector-invariant* is motivated since the form of this equation remains unchanged when using Cartesian or spherical coordinates. However, this name seems rather unnecessary since when formulated using the tensor formalism from Chapters 8 and 9, any mathematical physics equation remains form invariant.

25.4.1 Dynamic pressure

The *velocity equation* (25.32) is mathematically equivalent to the momentum equation (25.16). Even so, it provides a more convenient means to derive Bernoulli's theorem in Section 27.9.3 and the vorticity equation in Chapter 41. Furthermore, it highlights certain physical processes affecting accelerations that are not obviously seen from the momentum equation. One such process is the *dynamic pressure*, which arises from the kinetic energy per mass appearing in the velocity equation

[2] The metric terms are referred to as *Christoffel symbols* in Section 9.11, which is the section where we derive the covariant derivative of a vector.

[3] See Section 4.4.4 of *Griffies* (2004) for a detailed derivation using general coordinates.

(25.32). Gradients in the kinetic energy per mass contribute a *dynamical pressure gradient* that accelerates the fluid down the kinetic energy gradient, from regions of high kinetic energy per mass to regions of low kinetic energy per mass. To help understand this process, consider a Boussinesq fluid (Chapter 30), in which case the density factor is a constant, $\rho = \rho_0$, so that we can write the accelerations from pressure and kinetic energy as

$$-(1/\rho_0)\,\nabla p - \nabla(\boldsymbol{v}\cdot\boldsymbol{v}/2) = -\rho_0^{-1}\,\nabla(p + \rho_0\,\boldsymbol{v}\cdot\boldsymbol{v}/2) \equiv -\rho_0^{-1}\,\nabla p_{\text{stagnation}}. \tag{25.33}$$

In this equation we defined the *stagnation pressure* (page 149 of *Kundu et al.* (2016)), also called the *total head* (Section 3.1 of *Saffman* (1992))

$$p_{\text{stagnation}} \equiv p + \rho_0\,\boldsymbol{v}\cdot\boldsymbol{v}/2, \tag{25.34}$$

which is the sum of the mechanical pressure, p, plus the dynamic pressure, $\rho_0\,\boldsymbol{v}\cdot\boldsymbol{v}/2$.

The stagnation pressure is the mechanical pressure required to keep the local acceleration unchanged *if* the dynamic pressure is set to zero as per a stagnant fluid. This situation arises in practice in a device known as a *Pitot tube* used to measure the speed of flow in a pipe, with the Pitot tube making use of the Bernoulli theorem formulated in Section 27.9. Stagnation points also arise at special points along solid objects within a moving fluid, such as wings. The dynamic pressure, $\rho_0\,\boldsymbol{v}\cdot\boldsymbol{v}/2$, provides an isotropic force per area in addition to mechanical pressure, p. Hence, the stagnation pressure is the total isotropic contact force per area, thus motivating some treatments to refer the stagnation pressure as the *total pressure*.[4]

25.4.2 Magnus acceleration

The acceleration, $-\boldsymbol{\omega}\times\boldsymbol{v}$, appearing in the velocity equation (25.32) couples vorticity and velocity. This acceleration is known as the *Magnus effect* or *Magnus acceleration*. Since it acts only when there is both motion and vorticity, it is sometimes referred to as a *vortex force*.[5] As discussed in Chapter 38, vorticity is a measure of the spin of a fluid element. Evidently, the Magnus acceleration deflects a spinning fluid element in a direction perpendicular to its trajectory in a manner analogous to the Coriolis acceleration.[6]

25.4.3 Nonlinear accelerations for some example flows

We here consider some example two-dimensional velocities to help garner insights into the nonlinear accelerations. First note that there are certain flows where the self-advection term vanishes identically so that

$$(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} = 0 \Longrightarrow \boldsymbol{\omega}\times\boldsymbol{v} + \nabla(\boldsymbol{v}\cdot\boldsymbol{v})/2 = 0. \tag{25.35}$$

One example is a zonal flow with a meridional shear

$$\boldsymbol{v} = u(y)\,\hat{\boldsymbol{x}}, \tag{25.36}$$

in which case

$$(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} = 0 \quad\text{and}\quad \boldsymbol{\omega} = -\partial_y u\,\hat{\boldsymbol{z}} \quad\text{and}\quad \boldsymbol{\omega}\times\boldsymbol{v} = -u\,\partial_y u\,\hat{\boldsymbol{y}} \quad\text{and}\quad \nabla(\boldsymbol{v}\cdot\boldsymbol{v}/2) = u\,\partial_y u\,\hat{\boldsymbol{y}}. \tag{25.37}$$

[4] In many applications, the mechanical pressure, p, is referred to as the *static pressure* so that the total/stagnation pressure is the sum of the static plus dynamic pressures. See section 4.9 of *Kundu et al.* (2016) for more discussion.

[5] Chapter 3 of *Saffman* (1992) pursues this interpretation in studying the forces acting on and by vortices.

[6] Besides causing a moving and spinning fluid element to deflect, the Magnus acceleration provides the mechanism whereby a solid spinning body immersed in a moving fluid is deflected, such as commonly experienced by spinning balls used for baseball, tennis, and cricket.

FIGURE 25.1: Illustrating the various nonlinear accelerations contributing to the velocity time tendency as per the vector-invariant velocity equation (25.32). Far left panel: the two-dimensional non-divergent velocity, $\boldsymbol{u} = \gamma\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}})$. Middle left panel: self-advection acceleration $-(\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = \gamma^2\boldsymbol{x}$. Middle right panel: Magnus acceleration $-\boldsymbol{\omega}\times\boldsymbol{u} = 2\,\gamma^2\,\boldsymbol{x}$. Far right panel: dynamic pressure gradient acceleration, $-\nabla(\boldsymbol{u}^2/2) = -\gamma^2\,\boldsymbol{x}$. Notice that the Magnus acceleration acts to the right of the flow, whereas the acceleration from the dynamic pressure gradient partially opposes the Magnus acceleration. The sum of the Magnus acceleration and dynamic pressure gradient acceleration equals to the acceleration from self-advection. In each panel we set $\gamma = 1$ and used arbitrary units.

An example flow with a nonzero self-advection is given by the two-dimensional flow of an ideal vortex

$$\boldsymbol{u} = \hat{\boldsymbol{z}}\times\nabla\psi = \gamma\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}), \tag{25.38}$$

where $\gamma > 0$ is a constant with dimensions of inverse time.[7] This flow has zero horizontal divergence, $\nabla\cdot\boldsymbol{u} = 0$, and constant vorticity

$$\hat{\boldsymbol{z}}\cdot\boldsymbol{\omega} = \zeta = 2\,\gamma. \tag{25.39}$$

The accelerations from self-advection, Magnus, and dynamic pressure are given by

$$-(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} = \gamma^2\,\boldsymbol{x} \quad\text{and}\quad -\boldsymbol{\omega}\times\boldsymbol{v} = 2\,\gamma^2\,\boldsymbol{x} \quad\text{and}\quad -\nabla(\boldsymbol{u}\cdot\boldsymbol{u}/2) = -\gamma^2\,\boldsymbol{x}. \tag{25.40}$$

We depict these three accelerations, along with the velocity field, in Figure 25.1. Notice how the Magnus acceleration acts to the right of the flow, whereas the acceleration from the dynamic pressure gradient partially opposes the Magnus acceleration.

25.5 The tangent plane approximation

Spherical coordinates are suited for the study of planetary fluid dynamics for cases where the fluid samples the earth's curvature. However, spherical coordinates remain more complicated to work with than Cartesian coordinates. We are thus led to consider the utility of an idealized tangent plane configuration as part of a hierarchy of theoretical models to help understand geophysical fluid motion. This motivation leads to the f-plane and β-plane approximations, which are the two cases of the tangent plane approximation. We here expose these equations, with further use encountered later in the book. As formulated here, it is important to note that the tangent plane approximation is not based on assuming a locally flat sphere. Rather, the tangent plane approximation as based on assuming a locally flat geopotential. We further comment on this subtle distinction in Sections 25.5.2 and 25.5.5.

[7] We made use of this velocity in Section 19.7 in our study of kinematics in two-dimensional flow.

25.5.1 Basics of the tangent plane approximation

Consider a position at latitude $\phi = \phi_0$ and introduce a local Cartesian set of coordinates according to

$$(x, y, z) = (R_{\mathrm{e}}\, \lambda \cos\phi_0, R_{\mathrm{e}}\, (\phi - \phi_0), z) \tag{25.41}$$

$$(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}}) = (\hat{\boldsymbol{\lambda}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{r}}). \tag{25.42}$$

Use of these Cartesian coordinates leads to the following inviscid (i.e., no friction) equations of motion local to $\phi = \phi_0$

$$\frac{\mathrm{D}u}{\mathrm{D}t} + 2\,(\Omega^y\, w - \Omega^z\, v) = -\frac{1}{\rho}\,\frac{\partial p}{\partial x} \tag{25.43a}$$

$$\frac{\mathrm{D}v}{\mathrm{D}t} + 2\,(\Omega^z\, u - \Omega^x\, w) = -\frac{1}{\rho}\,\frac{\partial p}{\partial y} \tag{25.43b}$$

$$\frac{\mathrm{D}w}{\mathrm{D}t} + 2\,(\Omega^x\, v - \Omega^y\, u) = -\frac{1}{\rho}\,\frac{\partial p}{\partial z} - g, \tag{25.43c}$$

with rotational vector components

$$\boldsymbol{\Omega} = \Omega\,(\cos\phi_0\, \hat{\boldsymbol{y}} + \sin\phi_0\, \hat{\boldsymbol{z}}). \tag{25.44}$$

Note the absence of metric terms due to the use of Cartesian coordinates on a flat geometry.

25.5.2 Tangent plane is a geopotential approximation

As formulated above, the tangent plane approximation originates from the geopotential vertical coordinate system rather than the spherical coordinates (Section 13.11.3). In geopotential coordinates, the effective gravitational acceleration (central gravity plus planetary centrifugal) is aligned with the local vertical direction. Correspondingly, the resulting tangent plane equations have the effective gravitational force aligned in the $\hat{\boldsymbol{z}}$ direction. This very convenient property of the geopotential coordinate system was discussed in Section 13.10.4, with particular attention given by Figure 13.4.

In contrast, when studying motion in a rotating tank, such as in Section 28.4, it is convenient to separately account for the gravitational acceleration and rotating reference frame's centrifugal acceleration, so that both accelerations appear explicitly in the fluid equation of motion. It is thus important to distinguish the tangent plane equations (which absorb the rotating reference frame's centrifugal acceleration into the effective gravity acceleration) from the equations used for a rotating fluid in a laboratory tank (which separately account for gravity and centrifugal).[8]

25.5.3 Traditional approximation and the f-plane

The *traditional approximation* is discussed in Section 28.1.3, where we justify retaining only the local vertical component of the rotation vector for the study of large-scale planetary flows, thus resulting in

$$\mathrm{D}\boldsymbol{u}/\mathrm{D}t + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\rho^{-1}\,\nabla_z p \quad \text{and} \quad \mathrm{D}w/\mathrm{D}t = -\rho^{-1}\,\partial_z p - g. \tag{25.45}$$

The f-plane makes further use of a constant Coriolis parameter

$$f = 2\,\Omega \sin\phi_0 \equiv f_0. \tag{25.46}$$

[8] As noted by *Durran* (1993), confusion can arise when forgetting this distinction.

The f-plane approximation is the simplest model for a rotating fluid on a locally flat geopotential, and as such it provides an end member in the hierarchy of theoretical models for rotating geophysical fluid flows.

25.5.4 β-plane approximation

As seen in Section 52.3, *Rossby waves* are planetary scale waves that sample the earth's curvature. The essential ingredient for their existence is the latitudinal dependence of the Coriolis parameter. To capture Rossby waves on a tangent plane requires the meridional gradient of the Coriolis parameter, with a linear dependence sufficient

$$f = f_0 + R_{\text{e}}^{-1} \, (2 \, \Omega \, \cos \phi_0) \, (y - y_0). \tag{25.47}$$

The β-plane approximation only depends on the meridional gradient of the Coriolis parameter, in which case we more succintly write

$$f = f_0 + \beta \, y \tag{25.48}$$

$$\beta = \partial f / \partial y = (2 \, \Omega / R_{\text{e}}) \cos \phi_0, \tag{25.49}$$

thus ignoring the constant $-(2 \, \Omega \, \cos \phi_0) \, y_0 / R_{\text{e}}$. The β-plane approximation is formally valid so long as the horizontal scale of motion, L, is not too large, in which case we require

$$\beta \, L \ll |f_0|. \tag{25.50}$$

25.5.5 Comments and caveats

We emphasized that the tangent plane assumes a locally flat geopotential, so that the gravitational acceleration remains locally vertical. Additionally, for the traditional approximation we retain only the local vertical component of the planetary rotation vector, which leads to a simpler expression for the Coriolis acceleration. It is tempting to extrapolate the traditional tangent plane to an infinite plane. However, doing so certainly breaks the assumption built into the truncated Taylor series used to mathematically justify the tangent plane. Furthermore, it leads to the unphysical situation of an infinite flat rotating plane without a centrifugal acceleration to distinguish a center of rotation. Additionally, an infinite β-plane leads to an unbounded rotation rate.

25.6 Exact hydrostatic balance

We are mostly interested in moving fluids within this book. Even so, it is useful to expose the signature of a static fluid supporting the trivial solution, $\boldsymbol{v} = 0$. The equation of motion (25.16) has an exact static solution so long as the pressure gradient force balances the effective gravitational force

$$\nabla p = -\rho \, \nabla \Phi, \tag{25.51}$$

and where the frictional stress tensor has zero divergence. Equation (25.51) constitutes the *exact hydrostatic balance*. As justified in Section 28.2, the hydrostatic balance is a very good approximation for the vertical momentum equation in large-scale geophysical fluids even when those fluids are moving. We will thus commonly make the *hydrostatic approximation* for moving fluids. For the current considerations, we are interested in a static fluid, in which case the hydrostatic balance (25.51) is an exact solution to the equation of motion.

25.6.1 Properties of exact hydrostatic balance

We make the following observations of the exact hydrostatic balance.

- Since ∇p is directly proportional to $\nabla\Phi$, surfaces of constant pressure (*isobars*) in a static fluid correspond to surfaces of constant geopotential.

- Since the curl of the pressure gradient vanishes, a static fluid maintains its density gradients parallel to geopotential gradients
$$\nabla\rho \times \nabla\Phi = 0, \tag{25.52}$$
which in turn means that density surfaces are parallel to geopotentials so that
$$\rho = \rho(\Phi) \qquad \text{static fluid.} \tag{25.53}$$
For the geopotential $\Phi = g\,z$, a static fluid is realized if the density depends only on the vertical position
$$\rho = \rho(z) \qquad \text{static fluid with } \Phi = g\,z. \tag{25.54}$$
If the density gradient has any component perpendicular to $\nabla\Phi$, then pressure forces will affect fluid flow thus implying that the fluid is not in an exact hydrostatic balance.

- Projecting both sides of equation (25.51) onto an infinitesimal space increment, $\mathrm{d}\boldsymbol{x}$, renders
$$\mathrm{d}\boldsymbol{x}\cdot\nabla p = -\rho\,\mathrm{d}\boldsymbol{x}\cdot\nabla\Phi \Longrightarrow \frac{\mathrm{d}p}{\mathrm{d}\Phi} = -\rho. \tag{25.55}$$
Hence, the difference in hydrostatic pressure between any two geopotentials is given by the integral
$$p(\Phi_2) - p(\Phi_1) = -\int_{\Phi_1}^{\Phi_2} \rho(\Phi)\,\mathrm{d}\Phi. \tag{25.56}$$
If $\Phi = g\,z$ then we recover
$$p(z_2) - p(z_1) = -g\int_{z_1}^{z_2} \rho(z)\,\mathrm{d}z, \tag{25.57}$$
so that the difference in hydrostatic presure between two geopotentials is given by the weight per horizontal area of fluid between the two geopotentials. This relation is illustrated for an infinitesimally thin layer in Figure 25.2.

25.6.2 Comparison to approximate hydrostatic balance

A static fluid in a gravitational field exhibits hydrostatic balance whereby pressure at a point is a function solely of the geopotential, in which case $p = p(z)$ when $\Phi = g\,z$. Correspondingly, $\mathrm{d}p/\mathrm{d}z = -\rho\,g$, which means that we determine hydrostatic pressure at a point by computing the weight per horizontal area of fluid above that point. Likewise, density is just a function of geopotential since $\nabla\rho\times\nabla\Phi = 0$.

For an approximate hydrostatic fluid, pressure is a function of space and time, $p = p(\boldsymbol{x}, t)$, as is density, $\rho = \rho(\boldsymbol{x}, t)$. Hence, we are no longer ensured that pressure and density isolines are parallel. However, the approximate hydrostatic fluid retains a vertical pressure gradient given by
$$\frac{\partial p}{\partial z} = -\rho\,g \quad \text{approximate hydrostatic.} \tag{25.58}$$

FIGURE 25.2: Illustrating the forces acting in a hydrostatically balanced fluid layer placed in a geopotential field $\Phi = g\, z$ with g constant. The layer has an infinitesimal thickness $\mathrm{d}z > 0$, density ρ, and horizontal cross-sectional area $\mathrm{d}A$. The pressure force acting on the top and bottom of the layer are compressive. Hence, the pressure force at the top of the layer acts downward, $\boldsymbol{F}^{\mathrm{press}}(z + \mathrm{d}z) = -\hat{\boldsymbol{z}}\, p(z + \mathrm{d}z)\, \mathrm{d}A$, whereas the pressure force at the bottom of the layer acts upward, $\boldsymbol{F}^{\mathrm{press}}(z) = +\hat{\boldsymbol{z}}\, p(z)\, \mathrm{d}A$. In a hydrostatically balanced fluid, the difference in pressure across the layer is exactly balanced by the weight per area of fluid within the layer. Consequently, $p(z + \mathrm{d}z) - p(z) = -g\, \rho(z)\, \mathrm{d}z$, so that pressure at the top of the layer is less than that at the bottom.

Hence, column by column, the pressure at a point in an approximate hydrostatic fluid is determined by the weight per horizontal area of fluid above that point. This key property is thus shared between fluids in exact and approximate hydrostatic balance. In Chapter 28 we have much more to say about fluid flows maintaining approximate hydrostatic balance.

25.7 Axial angular momentum

Following our discussion of a point particle in Section 14.6, the axial angular momentum of a fluid element is given by

$$L^z = (\rho\, \delta V)\, r_\perp\, (u + r_\perp\, \Omega) \equiv (\rho\, \delta V)\, l^z \tag{25.59}$$

where

$$l^z = r_\perp\, (u + r_\perp\, \Omega) \tag{25.60}$$

is the axial angular momentum per unit mass, and the distance to the polar rotation axis,

$$r_\perp = r \cos\phi \tag{25.61}$$

is the moment-arm for determining the torques acting on a fluid element. Making use of the zonal momentum equation (25.19), as well as the material time derivative of the moment arm

$$\frac{\mathrm{D}r_\perp}{\mathrm{D}t} = \frac{\mathrm{D}r}{\mathrm{D}t} \cos\phi - r\, \frac{\mathrm{D}\phi}{\mathrm{D}t} \sin\phi = w \cos\phi - v \sin\phi, \tag{25.62}$$

we find the material time change

$$\begin{aligned}
\frac{\mathrm{D}l^z}{\mathrm{D}t} &= (u + 2\,\Omega\, r_\perp)\, \frac{\mathrm{D}r_\perp}{\mathrm{D}t} + r_\perp\, \frac{\mathrm{D}u}{\mathrm{D}t} && (25.63\mathrm{a})\\
&= (u + 2\,\Omega\, r_\perp)\, \frac{\mathrm{D}r_\perp}{\mathrm{D}t} + (u + 2\,\Omega\, r_\perp)\, (v \sin\phi - w \cos\phi) - \frac{1}{\rho}\, \frac{\partial p}{\partial \lambda} && (25.63\mathrm{b})\\
&= (u + 2\,\Omega\, r_\perp)\, \left[\frac{\mathrm{D}r_\perp}{\mathrm{D}t} + v \sin\phi - w \cos\phi\right] - \frac{1}{\rho}\, \frac{\partial p}{\partial \lambda} && (25.63\mathrm{c})\\
&= -\frac{1}{\rho}\, \frac{\partial p}{\partial \lambda}, && (25.63\mathrm{d})
\end{aligned}$$

FIGURE 25.3: A ring of inviscid air circulating around a constant latitude circle over a smooth planet. This ring conserves is axial angular momentum. Consequently, axial angular momentum conserving motion of the ring induces a zonal acceleration if the ring alters its distance from the rotation axis, $r_\perp$, by moving meridionally or vertically.

so that

$$\rho \frac{\mathrm{D}l^z}{\mathrm{D}t} = -\frac{\partial p}{\partial \lambda} \Longrightarrow \frac{\partial(\rho\, l^z)}{\partial t} + \nabla \cdot (\rho\, l^z\, \boldsymbol{v}) = -\frac{\partial p}{\partial \lambda}. \tag{25.64}$$

In the absence of a zonal pressure gradient, the axial angular momentum for a fluid element is materially invariant just like for the point particle discussed in Section 14.6. The physical constraints for motion of the point particle, as described in Section 14.7, also hold for the fluid element. In particular, we can equate the zonal Coriolis acceleration to the zonal acceleration induced by axial angular momentum conservation. For example, a fluid element initially at rest in a fluid with zero zonal pressure gradient will zonally accelerate when moved meridionally (e.g., as from a meridional pressure gradient) according to the needs of axial angular momentum conservation.

25.7.1 Axial angular momentum conserving motion of a ring of air

Atmospheric and oceanic flows rarely experience a zero zonal pressure gradient. However, on a smooth spherical planet without meridional boundaries there is a zero zonally integrated zonal pressure gradient

$$\oint_{\text{ring}} \frac{\partial p}{\partial \lambda}\, \mathrm{d}\lambda = 0. \tag{25.65}$$

Hence, a constant mass material ring of fluid circling the smooth planet (Figure 25.3) will preserve its axial angular momentum in the absence of friction

$$\frac{\mathrm{d}}{\mathrm{d}t} \oint_{\text{ring}} \rho\, l^z\, \mathrm{d}V = \oint_{\text{ring}} \rho \frac{\mathrm{D}l^z}{\mathrm{D}t}\, \mathrm{d}V = -\oint_{\text{ring}} \frac{\partial p}{\partial \lambda}\, \mathrm{d}V = 0. \tag{25.66}$$

We now consider some thought experiments to illustrate the zonal fluid motion induced by axial angular momentum conservation. Each example has an analog in the point particle thought experiments considered in Section 14.7.

Consider a latitudinal ring of constant mass inviscid fluid circling the earth at latitude ϕ_{A} and radial position r_{A}. If the ring is at rest in the rotating terrestrial reference frame, the angular

momentum per mass for this ring is due to just the rigid-body motion of the planet,

$$l^z = \Omega\,(r_{\rm A}\cos\phi_{\rm A})^2. \tag{25.67}$$

Altering either the latitude (to $\phi_{\rm B}$) or radial position (to $r_{\rm B}$) induces a corresponding zonal velocity, $u_{\rm B} \neq 0$, that maintains fixed axial angular momentum

$$l^z = \Omega\,(r_{\rm A}\cos\phi_{\rm A})^2 = r_{\rm B}\cos\phi_{\rm B}\,(u_{\rm B} + \Omega\, r_{\rm B}\cos\phi_{\rm B}), \tag{25.68}$$

which means that

$$u_{\rm B} = \Omega\,\frac{(r_{\rm A}\cos\phi_{\rm A})^2 - (r_{\rm B}\cos\phi_{\rm B})^2}{r_{\rm B}\cos\phi_{\rm B}}. \tag{25.69}$$

For example, moving the ring vertically to a radial distance, $r_{\rm B} \neq r_{\rm A}$, while maintaining a constant latitude, $\phi_{\rm B} = \phi_{\rm A}$, induces a zonal velocity

$$u_{\rm B} = \Omega\cos\phi_{\rm A}\,\frac{r_{\rm A}^2 - r_{\rm B}^2}{r_{\rm B}}. \tag{25.70}$$

If the new radial position is less than the original, so that $r_{\rm A}^2 > r_{\rm B}^2$, then axial angular momentum conservation induces an eastward zonal velocity ($u_{\rm B} > 0$); i.e., westerly winds. The opposite happens for an increase in the radial position. If we instead change the latitudinal position of the ring ($\phi_{\rm A} \neq \phi_{\rm B}$) while keeping the radial position fixed ($r_{\rm A} = r_{\rm B}$), then axial angular momentum conservation induces the zonal velocity

$$u_{\rm B} = r_{\rm A}\,\Omega\,\frac{\cos^2\phi_{\rm A} - \cos^2\phi_{\rm B}}{\cos\phi_{\rm B}}. \tag{25.71}$$

Since $-\pi/2 \leq \phi \leq \pi/2$, we know that $\cos\phi \geq 0$ on the sphere, and $\cos\phi$ decreases moving poleward in either hemisphere. Hence, poleward latitudinal motion that preserves axial angular momentum induces eastward flow ($u_{\rm B} > 0$), whereas eqatorward latitudinal motion induces westward flow ($u_{\rm B} > 0$).

25.7.2 Realistic atmospheric axial angular momentum cycle

How realistic is it to have coherent rings of inviscid air circulating around the planet at all latitudes? To answer this question we insert some numbers for a ring of radius $R_{\rm e}$ that starts with zero relative velocity at the equator, $\phi_{\rm A} = 0$, in which case equation (25.71) reduces to

$$u_{\rm B} = r_{\rm A}\,\Omega\,\frac{\sin^2\phi_{\rm B}}{\cos\phi_{\rm B}}. \tag{25.72}$$

The westerly winds induced by axial angular momentum conserving motion have the following speeds at a selection of latitudes

$$u(10^\circ) = 14\ {\rm m\ s^{-1}} \qquad u(20^\circ) = 58\ {\rm m\ s^{-1}} \qquad u(30^\circ) = 134\ {\rm m\ s^{-1}}. \tag{25.73}$$

The values at higher latitudes grow unbounded since $\cos\phi \to 0$ as the poles are approached. So there is a problem with an idealized theory of atmospheric circulation based on axial angular momentum conserving rings of air.

Further investigation reveals that inviscid axial angular momentum conserving ideas extend only so far as the *Hadley circulation*, which extends only to the middle latitudes. There are two missing ingredients needed for a more realistic theory: (i) frictional dissipation between the

atmosphere and land, which occurs within the planetary boundary layer; (ii) baroclinic eddies that contribute to poleward and vertical transport of angular momentum. It is outside of our scope to detail these physical processes and the corresponding atmospheric circulation. A pedagogical summary can be found in Section 10.3 of *Holton* (1992) and Section 8.2 of *Marshall and Plumb* (2008).

25.7.3 Further study

In Section 29.5 we consider the zonally integrated axial angular momentum budget for the ocean with sloping solid-earth bottom boundary as well as the upper surface (ocean) boundary. In particular, we see how boundary form stresses (Section 29.1) affect the angular momentum in addition to boundary frictional stresses. That ocean analysis is analogous to that for the atmosphere given in Section 10.3 of *Holton* (1992).

25.8 Exercises

EXERCISE 25.1: CONDITIONS FOR UNIFORM FLOW WITHOUT GRAVITY AND ROTATION
Consider the Euler equation (25.18) in the absence of rotation (zero Coriolis) and gravitation (free space fluid)

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\nabla p. \tag{25.74}$$

Ignore all boundaries throughout this exercise, and assume density is a uniform constant.

(a) What equation does the pressure need to satisfy to ensure $\boldsymbol{v} \equiv \boldsymbol{v}_0$, where $\boldsymbol{v}_0$ is a constant in space and time?

(b) What equation does the pressure need to satisfy to ensure $\partial_t(\nabla \cdot \boldsymbol{v}) = 0$?

EXERCISE 25.2: DIAGNOSING THE PRESSURE FOR A GIVEN FLOW
Consider a two-dimensional perfect fluid with constant density, ρ, that satisfies the Euler equation in the absence of planetary rotation

$$\rho \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = -\nabla_z p. \tag{25.75}$$

Provide a suitable pressure (to within a constant) that corresponds to the following steady (i.e., time independent) velocity fields, with $\gamma > 0$ a constant having dimensions inverse time, and $\boldsymbol{x} = \hat{\boldsymbol{x}}\, x + \hat{\boldsymbol{y}}\, y$ the horizontal position vector. Consider the following hints: (i) check your physical dimensions, (ii) check that $\nabla \times [(\boldsymbol{u} \cdot \nabla)\boldsymbol{u}] = 0$, (iii) check that $\nabla \cdot \boldsymbol{u} = 0$, which is required since ρ is a constant.

(a) $\boldsymbol{u} = \gamma\, \boldsymbol{x}$

(b) $\boldsymbol{u} = -\gamma\, \hat{\boldsymbol{z}} \times \boldsymbol{x}$

(c) $\boldsymbol{u} = \gamma\, (x\, \hat{\boldsymbol{x}} - y\, \hat{\boldsymbol{y}})$.

EXERCISE 25.3: THEOREM OF STRESS MEANS (*Aris* (1962) EXERCISE 5.12.2)
Make use of Cauchy's equation of motion (25.14) and the divergence theorem to prove the *theorem of stress means*

$$\oint_{\partial\mathcal{R}} \Psi\, \mathbb{T}_{pq}\, \hat{n}_q \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \left[\mathbb{T}_{pq}\, \partial_q \Psi + \rho\, \Psi \left(\frac{\mathrm{D}v_p}{\mathrm{D}t} - f_p \right) \right] \mathrm{d}V, \tag{25.76}$$

where Ψ is an arbitrary differentiable function, and $\hat{n}_q$ is the q'th component of the outward normal vector on $\partial\mathcal{R}$. This theorem finds use in certain formulations of continuum mechanics. Assume Cartesian tensors.

EXERCISE 25.4: AREA OF A STEADY 1D LAMINAR JET EMANATING FROM A DOWNWARD NOZZLE
Consider a steady state laminar jet of constant density and inviscid water emanating from a downward facing nozzle with a constant prescribed volume flow rate, Q (dimensions volume per time). Ignore surface tension and assume the air pressure acting on the surface of the jet is constant all along the jet. You can solve this exercise by making use of the steady vertical momentum equation and the steady mass continuity equation.

(a) Explain why we can set $\mathrm{d}p/\mathrm{d}z = 0$ within the jet once it leaves the nozzle.

(b) Determine an expression for the area of the jet, $A(z)$, as a function of distance, z, from the nozzle, with the nozzle placed at $z = 0$ and $z < 0$ a position beneath the nozzle. In addition to z, your expression will contain Q, g, and $A(0)$.

(c) Is the area of the jet getting smaller or larger as the water moves downward away from the nozzle? Does this answer agree with your experience?

(d) If the downward speed of water at the nozzle is $w(0) = 0.5$ m s^{-1}, then at what vertical position, z, is the area of the jet four times different than at $z = 0$?

EXERCISE 25.5: ROSSBY EFFECT
Consider a horizontal region of fluid whose velocity is rotationally symmetric and depth independent

$$\boldsymbol{u} = \boldsymbol{\Gamma} \times \boldsymbol{r}, \tag{25.77}$$

where

$$\boldsymbol{\Gamma} = \Gamma(r)\, \hat{\boldsymbol{z}} \tag{25.78}$$

is an angular velocity, $\hat{\boldsymbol{z}}$ is the vertical direction, and r is the radial distance to the origin. Furthermore, let $\Gamma(r)$ vanish for radial distances $r \geq R$ for some radius R. Let the fluid be moving on a β-plane with Coriolis parameter $f = f_0 + \beta\, y = f_0 + \beta\, r \sin\vartheta$, where ϑ is the polar angle relative to the x-axis (see Section 10.3 for definition of polar coordinates). Derive an integral expression for the Coriolis acceleration integrated over this fluid region. Discuss the direction of the acceleration.

You may find the following hints of use.

- The resulting integrated Coriolis acceleration is solely in the $\hat{\boldsymbol{y}}$ direction, and it vanishes when $\beta = 0$.
- The answer is given in *Rossby* (1948), and is sometimes known as the *Rossby effect*.
- We further consider such interactions between rotating fluid motion and the Coriolis parameter in Section 39.5.4 when studying the *beta drift* of axially symmetric vortices. There, we find that the beta drift leads to a northwestward drift rather than the northward drift from the Rossby effect. The reason for the discrepency is that *Rossby* (1948) ignored pressure

effects that set up a secondary flow that induces westward drift, in addition to Rossby's northward drift. For this exercise, we ignore these pressure effects.

EXERCISE 25.6: CENTER OF MASS TRANSPORT THEOREM

Consider a field, ψ, that satisfies the standard conservation law

$$\rho \, \frac{\mathrm{D}\psi}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}, \tag{25.79}$$

within a region, $\mathcal{R}(\boldsymbol{v})$, that moves with the fluid flow. We here derive some results that hold for Cartesian coordinates in Euclidean space.

(a) Prove the transport theorem valid for Cartesian tensors

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \psi \, \boldsymbol{x} \, \rho \, \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{J} + \rho \, \psi \, \boldsymbol{v}) \, \mathrm{d}V - \oint_{\partial\mathcal{R}(\boldsymbol{v})} \boldsymbol{x} \, (\hat{\boldsymbol{n}} \cdot \boldsymbol{J}) \, \mathrm{d}\mathcal{S}. \tag{25.80}$$

Hint: multiply both sides of equation (25.79) by x_m.

(b) Offer an interpretation of equation (25.80). Hint: first consider the special case that the total ψ-stuff, defined by $\Psi \equiv \int_{\mathcal{R}(\boldsymbol{v})} \psi \, \rho \, \mathrm{d}V$, is constant when following the flow. Further hint: consider the more specialized case of $\psi = 1$ and $\boldsymbol{J} = 0$, and then make use of Exercise 20.2.

Chapter 26

Stress in fluids

As a continuous region of matter, a fluid element experiences two kinds of forces: *external* or *body* forces and *internal* or *contact* forces. Body forces act throughout the fluid element and arise from sources external to the matter acted upon. The accumulated effects from body forces within a fluid region result from volume integrating the body forces over the region. In geophysical fluid mechanics, we are concerned with body forces from the effective gravitational acceleration (central gravity plus planetary centrifugal) plus the body force from the Coriolis acceleration. Body forces are also experienced by the point particles studied in Part II in this book.

Contact forces act on a fluid element due to intermolecular forces within the fluid media. Contact forces signal a fundamental distinction between the dynamics of a fluid element (an infinitesimal portion of a continuous media) and the dynamics of a point particle (a 0-dimensional mathematical construct). Contact forces give rise to the local exchange of dynamical properties between fluid elements. Dividing the contact force by the area upon which it acts leads to the *Cauchy stress vector*. As a force per unit area, stresses are associated with two directions: the direction of the force and the direction normal to the area acted upon by the force. Correspondingly, stresses acting on a fluid element are naturally organized into a second order *stress tensor*.[1] Details of the stress tensor govern the dynamic response of a continuous media to kinematic and thermodynamic properties of the media. Consequently, the general equations of continuum mechanics posed by Cauchy find their specialization at the point of prescribing the stress tensor, with this specification known as a *constitutive relation*.

Contact forces, which are given by the Cauchy stress times an area element, satisfy Newton's third law, also known as the action/reaction law (e.g., see beginning of Chapter 11). Hence, the net contact force acting on a finite region arises just from the contact forces acting at the region boundary. This property of contact forces means that a mechanically isolated region of a continuous media (i.e., a region unaffected by external forces or boundary contact forces) does not spontaneously translate its center of mass. Similarly, symmetry of the stress tensor means that an isolated region does not spontaneously alters its angular momentum.

Surface tension is a stress that acts on the boundaries of a fluid media, such as the boundary between oil and water or, more relevant to our study of geophysical flows, the boundary between air and water. Surface tension is unique in this chapter in that it does *not* satisfy Newton's third. As shown in Section 26.11, surface tension is generally negligible for length scales larger than a few centimeters. Even so, the effects of surface tension are important if studying physical processes associated with air-sea interactions, such as tracer, heat, and momentum exchange through bubbles, droplets, and capillary waves (we study capillary waves in Section 50.10).

[1] In the language of continuum mechanics, we here work exclusively with the *Cauchy stress tensor*. See Section 1.22 of *Tromp* (2024) for more details.

CHAPTER GUIDE

We introduced contact forces in Chapter 25 when deriving the fluid equations of motion. In the present chapter we dive deeper a study of contact forces and their corresponding stresses. We also discuss conditions placed on stress and velocity at boundaries. We organize fluid stresses into a second order Cauchy stress tensor and further decompose this stress into isoptropic (pressure) stresses and tangential (viscous) stresses. Understanding the mathematical and physical aspects of stress is important for the suite of fluid models studied in this book. Because the subject involves vectors and tensors, it can require more patience than analogous chapters that discuss scalar fields. To make the formalism less mathematically intense, we employ Cartesian tensors as discussed in Chapters 1 and 2. Results can be generalized to arbitrary coordinates through the general tensor analysis detailed in Chapter 9.

There are various places in this chapter where we consider integrals of vectors over finite regions, such as when forming the finite volume (weak form) momentum budget or angular momentum budget. Such discussions hold only for Cartesian tensors, with integration of general tensors requiring more care.

26.1 Loose threads

- Schematic of viscous transfer as in Figure 12.6 of *Kundu et al.* (2016)
- More on existence and uniqueness of Navier-Stokes as per *Doering and Gibbon* (1995).

26.2 Cauchy's stress principle and Newton's laws

We here develop some general properties of contact forces and the associated stresses. For that purpose, consider an arbitrary smooth closed region, $\mathcal{R}$, of fluid with volume $V = \int_{\mathcal{R}} \mathrm{d}V$ and mass $M = \int_{\mathcal{R}} \rho \, \mathrm{d}V$ (Figure 26.1). Furthermore, let $\partial\mathcal{R}$ be the bounding surface for the region, and let $\hat{\boldsymbol{n}}$ be the outward normal at a point on the boundary.

26.2.1 Cauchy's stress principle

The bounding surface of the region experiences mechanical interactions with the surrounding fluid continuum and these interactions lead to contact forces acting on the boundary. Let $\boldsymbol{\tau}$ be the stress vector (force per unit area) acting at a point on $\partial\mathcal{R}$. Cauchy's stress principle asserts that the stress vector is a function of the position, time, and boundary normal

$$\boldsymbol{\tau} = \boldsymbol{\tau}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}). \tag{26.1}$$

The dependence on the boundary normal in equation (26.1) means that the stress acting on a surface is generally a function of the orientation of that surface. This form of the stress trivially holds for an exactly hydrostatic fluid where the stress vector is proportional to the pressure (Section 25.6). Furthermore, the stress from pressure is oriented along the inward normal, thus reflecting the purely compressive nature of pressure

$$\boldsymbol{\tau} = -p(\boldsymbol{x}, t)\, \hat{\boldsymbol{n}} \qquad \text{static fluid in hydrostatic balance.} \tag{26.2}$$

Cauchy's stress principle is sensible for points within the fluid media, and its relevance has been supported by experimental studies over the time since Cauchy made this assertion in the 1820s. Furthermore, it holds for pressure and viscous stresses at the interface between fluid media

or at solid-earth boundaries. However, Cauchy's stress principle does not hold for surface tension, which is proportional to the curvature of the surface separating two fluid media (e.g., atmosphere and ocean), where curvature involves spatial gradients of the normal vector. As discussed in Section 26.11, surface tension is important for length scales on the order of centimeters, and as such play a minor role in this book. Hence, with the single exception of surface tension, we rely on Cauchy's stress principle to formulate the fluid dynamical equations.

26.2.2 Newton's third law and local equilibrium of stresses

Newton's second law says that in an inertial reference frame, unbalanced forces acting on a physical system affect a time change to the linear momentum. Consider a region, $\mathcal{R}(\boldsymbol{v})$, whose fluid elements follow the barycentric velocity. Newton's second law then states that the material time evolution of the region's linear momentum is given by

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{v}\, \rho \, \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{f}\, \rho \, \mathrm{d}V + \oint_{\partial \mathcal{R}(\boldsymbol{v})} \boldsymbol{\tau} \, \mathrm{d}\mathcal{S}, \tag{26.3}$$

where $\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{f}\, \rho \, \mathrm{d}V$ is the domain integrated body force (from central gravity, planetary centrifugal, and Coriolis). To develop a general property for the contact forces, consider this balance for a region whose size gets infinitesimally small. Assuming the integrands for the two volume integrals are well behaved (i.e., smooth and bounded) as the region size goes to zero, we see that the volume integrals are proportional to L^3, where L is a length scale measuring the size of the region (e.g., side for a cubical region or diameter for a spherical region). In the same manner, we assume the stresses are well behaved in the case of an infinitesimal region. However, the integral of the contact forces goes to zero at the slower rate that is proportional to L^2. Self-consistency for the balance (26.3) over a region of infinitesimal size thus requires the contact forces to satisfy the limiting behavior

$$\lim_{L \to 0} \frac{1}{L^2} \oint_{\partial \mathcal{R}(\boldsymbol{v})} \boldsymbol{\tau} \, \mathrm{d}\mathcal{S} = 0. \tag{26.4}$$

This behavior means that contact forces at a point in the fluid must be in local equilibrium. Equation (26.4) is sometimes referred to as *Cauchy's fundamental lemma*.

A direct implication of the local equilibrium statement is that stress vectors that respect Cauchy's principle (26.1) satisfy

$$\boldsymbol{\tau}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = -\boldsymbol{\tau}(\boldsymbol{x}, t, -\hat{\boldsymbol{n}}). \tag{26.5}$$

For example, the stress vector on one side of a surface is equal and oppositely directed to the stress vector acting on the other side. This equation is an expression of Newton's third law of mechanics (the action/reaction law; see Section 11.5), here written in terms of the stresses acting in a continuous media. It is of fundamental importance throughout our study of contact forces and their associated stresses acting within the fluid and at boundaries. We thus see how an application of Newton's second law, the linear momentum principle (26.3) for a continuous media, leads to a statement of Newton's third law in the form of equation (26.5) holding for contact forces.

As an example of the above ideas, the simplest stress we consider in this chapter is that from pressure, with pressure acting solely in a compressive manner so that the stress vector takes the form

$$\boldsymbol{\tau}^{\mathrm{press}}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = -p(\boldsymbol{x}, t)\, \hat{\boldsymbol{n}}. \tag{26.6}$$

This stress trivially satisfies the Newton's third law relation (26.5) since

$$\boldsymbol{\tau}^{\text{press}}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = -\boldsymbol{\tau}^{\text{press}}(\boldsymbol{x}, t, -\hat{\boldsymbol{n}}). \tag{26.7}$$

FIGURE 26.1: Schematic of the net body force, $\boldsymbol{F}_{\text{body}}$, acting on a finite region of fluid, plus the accumulation of stress vectors, $\boldsymbol{\tau}$, acting on the region boundaries. The net body force is determined by a volume integral of the body force (gravity, centrifugal, and Coriolis) at each point within the volume. In contrast, since the stresses are in local equilibrium, the volume integral of the stress divergence reduces to an area integral of the stress over the region boundary. Stress arises from pressure (compressive and normal) and strains (which then lead to viscous stresses when there is viscosity). The area integrated contribution from pressure to horizontal accelerations is referred to as *form stress*. The form stress coming from the bottom boundary is called the *topographic form stress*. The form stress appearing at the air-sea boundary is the *atmospheric form stress* if considering ocean dynamics and *oceanic form stress* if considering atmospheric dynamics. We study form stress in Chapter 29.

26.2.3 Comments on the local equilibrium relation

The local equilibrium relation (26.4), and the corresponding expression of Newton's third law, (26.5), might suggest that stresses cannot lead to motion. However, that suggestion is incorrect since stresses integrated over a finite region can lead to a net force that causes motion. Since contact forces within the domain interior cancel pointwise, the local equilibrium relation (26.4) says that the net contact force acting on the region arises only from the area integrated stresses acting on the region boundary. Local or pointwise mechanical equilibrium does not imply mechanical equilibrium for finite regions.

To further emphasize the above point, consider an ocean region bounded at its bottom by the solid earth and its upper surface by a massive atmosphere. Variations (divergences) in stresses over finite regions within the ocean fluid lead to accelerations; e.g., ocean circulation. However, when integrated over the full ocean domain, all stresses cancel from the interior of the fluid. Consequently, the net contact force acting on the full ocean domain reduces to the contact force acting just on the ocean boundaries. The boundary contact forces arise from mechanical interactions with the solid-earth and the overlying atmosphere. The center of mass for the ocean basin remains static if the accumulation of forces sum to zero, which includes the contact forces acting over its boundaries plus the volume integrated body forces from effective gravity (central gravity plus planetary centrifugal) and Coriolis.

In Figure 26.2 we illustrate the net pressure force acting on an arbitrary fluid domain. Pressure acts solely in a compressive manner as directed along the inward normal to the domain. Area

integration over a domain boundary renders the net pressure force acting on the domain

$$\boldsymbol{F}^{\text{pressure}} = -\oint_{\partial\mathcal{R}} p\,\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\int_{\mathcal{R}} \nabla p\,\mathrm{d}V, \tag{26.8}$$

where the second equality follows from application of Gauss's divergence theorem for a scalar field (Section 2.7.2). When decomposed according to coordinate axes, the pressure force acting on the boundary has a component in both the vertical and horizontal directions, thus contributing to both vertical and horizontal accelerations. The vertical accelerations are closely balanced by the weight of fluid, with exact balance in the case of a hydrostatic fluid. The horizontal stresses from pressure are known as *form stress*. This name arises since the stress depends on the form, or shape, of the surface on which pressure acts.

FIGURE 26.2: Schematic of contact forces from pressure acting on the boundaries to an ocean domain. Pressure forces are directed according to minus the local normal since pressure is a compressive force aligned with the inward normal direction. As with all contact forces, the pressure forces acting in the interior of the ocean are locally in mechanical equilibrium. Hence, when integrated over the global domain the net pressure forces only arise at the domain boundaries. That is, the net pressure force acting on the full ocean domain arises only at the interface between the solid-earth and the ocean, plus the interface between the atmosphere and the ocean. Note that the pressure force has a component in both the vertical and horizontal directions as per the orientation of the local normal vector. Further boundary stresses arise from viscous exchange, which generally have components perpendicular to the boundary normal; i.e., tangential to the boundary. Such stresses also satisfy Newton's third law.

26.2.4 Historical comments

We find it useful to quote from *Truesdell* (1952), who provides the following description of Cauchy's stress principle as given by equation (26.1).

> Upon any imagined closed surface, $\mathcal{S}$, there exists a distribution of stress vectors, $\boldsymbol{\tau}$, whose resultant and moment are equivalent to those of the actual forces of material continuity exerted by the material outside $\mathcal{S}$ upon that inside.

Worded in this manner, we can understand the relation between Newton's third law and Cauchy's stress principle. The profound nature of Cauchy's stress principle is further articulated, again from *Truesdell* (1952).

> [Cauchy's stress principle] has the simplicity of genius. Its profound originality can be grasped only when one realizes that a whole century of brilliant geometers had treated very special elastic problems in very complicated and sometimes incorrect ways without ever hitting upon this basic idea, which immediately became the foundation of the mechanics of distributed media.

26.3 The stress tensor

Cauchy's stress principle reduces the mathematical complexity of describing stress vectors. A further implication of this principle leads to *Cauchy's theorem*, which states that the stress vector, which is a function of space, time, and normal direction, can be expressed in terms of a stress tensor (a function of space and time) projected into the direction of the normal. The purpose of this section is to provide arguments supporting this theorem, with these arguments largely following the original from Cauchy in 1827.

For this purpose, consider the tetrahedron fluid region shown in Figure 26.3, where three of the four sides are aligned according to the Cartesian coordinate axes and the fourth side has an outward normal, $\hat{\boldsymbol{n}} = (\hat{n}_1, \hat{n}_2, \hat{n}_3)$, projecting into all three directions. The results developed for this rather contrived region using Cartesian coordinates also hold for an arbitrary region using arbitrary coordinates. The reason for this generality is that once we derive a tensorially correct result using one choice of coordinates, such as Cartesian used here, we can make use of general tensor analysis (Chapters 8 and 9) to move from specific coordinates to arbitrary coordinates.

In the limit that the tetrahedron size goes to zero, local equilibrium of the contact forces means that

$$-\sum_{m=1}^{3} \boldsymbol{\tau}_{(m)}\, \mathrm{d}A_m + \boldsymbol{\tau}_{\hat{\boldsymbol{n}}}\, \mathrm{d}A = 0, \tag{26.9}$$

where we use the shorthand expression for the outward normal directed stress vector

$$\boldsymbol{\tau}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = \boldsymbol{\tau}_{\hat{\boldsymbol{n}}}. \tag{26.10}$$

In equation (26.9), $\boldsymbol{\tau}_{(m)}\, \mathrm{d}A_m$ (no implied summation) is the contact force vector acting on the face with outward normal parallel to the corresponding coordinate axis and $\boldsymbol{\tau}_{\hat{\boldsymbol{n}}}\, \mathrm{d}A$ is the contact force acting on the slanted face with outward normal $\hat{\boldsymbol{n}}$. The minus sign arises for the summation term since the outward normals for these three faces point in the negative coordinate directions, and our convention is for $\boldsymbol{\tau}_{(m)}$ to align with the positive coordinate directions. The areas for each face are related to the slanted face area through

$$\mathrm{d}A_m = \hat{n}_m\, \mathrm{d}A, \tag{26.11}$$

so that the local equilibrium relation (26.9) becomes

$$\boldsymbol{\tau}_{\hat{\boldsymbol{n}}} = \sum_{m=1}^{3} \hat{n}_m\, \boldsymbol{\tau}_{(m)}. \tag{26.12}$$

Equation (26.12) can be organized into a matrix-vector equation

$$\begin{bmatrix} (\tau_{\hat{n}})_1 \\ (\tau_{\hat{n}})_2 \\ (\tau_{\hat{n}})_3 \end{bmatrix} = \begin{bmatrix} \hat{n}_1 & \hat{n}_2 & \hat{n}_3 \end{bmatrix} \begin{bmatrix} \tau_{(1)1} & \tau_{(1)2} & \tau_{(1)3} \\ \tau_{(2)1} & \tau_{(2)2} & \tau_{(2)3} \\ \tau_{(3)1} & \tau_{(3)2} & \tau_{(3)3} \end{bmatrix}, \tag{26.13}$$

where each matrix element is the n-component of the m-stress $\boldsymbol{\tau}_{(m)}$. We introduce a less cumbersome notation by writing

$$\begin{bmatrix} (\tau_{\hat{n}})_1 \\ (\tau_{\hat{n}})_2 \\ (\tau_{\hat{n}})_3 \end{bmatrix} = \begin{bmatrix} \hat{n}_1 & \hat{n}_2 & \hat{n}_3 \end{bmatrix} \begin{bmatrix} \mathbb{T}_{11} & \mathbb{T}_{12} & \mathbb{T}_{13} \\ \mathbb{T}_{21} & \mathbb{T}_{22} & \mathbb{T}_{23} \\ \mathbb{T}_{31} & \mathbb{T}_{32} & \mathbb{T}_{33} \end{bmatrix}, \tag{26.14}$$

FIGURE 26.3: Cauchy's tetrahedron region of fluid with stresses acting on the four faces. Note that the stresses are not necessarily directed normal to the faces. Local equilibrium of stresses means that the accumulation of these four stresses around the region adds to zero as the region volume goes to zero.

so that $\mathbb{T}_{mn}$ measures the force per area in the n-direction along a surface whose outward normal points in the m-direction, as depicted in Figure 26.4. Making use of $\mathbb{T}_{mn}$ in the expression (26.12) leads to

$$(\boldsymbol{\tau}_{\hat{\boldsymbol{n}}})_n = \sum_{m=1}^{3} \hat{n}_m \, \mathbb{T}_{mn}, \tag{26.15}$$

which can be written more succinctly as

$$\boldsymbol{\tau}_{\hat{\boldsymbol{n}}} = \hat{\boldsymbol{n}} \cdot \mathbb{T}. \tag{26.16}$$

We thus see that the stress vector that acts on a surface that is oriented according to a normal vector, $\hat{\boldsymbol{n}}$, equals to the projection of the *stress tensor*, $\mathbb{T}$, onto the normal vector. We emphasize that $\boldsymbol{\tau}_{\hat{\boldsymbol{n}}}$ is a vector with components within the tangent plane of the surface, as well as normal to the surface. Exposing functional dependence reveals

$$\boldsymbol{\tau}_{\hat{\boldsymbol{n}}}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = \hat{\boldsymbol{n}} \cdot \mathbb{T}(\boldsymbol{x}, t), \tag{26.17}$$

which manifests Cauchy's theorem. Namely, the stress vector $\boldsymbol{\tau}_{\hat{\boldsymbol{n}}}$, which is a function of $(\boldsymbol{x}, t, \hat{\boldsymbol{n}})$, has been decomposed into a stress tensor, $\mathbb{T}$, which is a function of $(\boldsymbol{x}, t)$, as well as the projection of the stress tensor into a direction $\hat{\boldsymbol{n}}$.

How do we know that $\mathbb{T}_{mn}$ form the components to a tensor rather than just being elements of a 3×3 matrix? To answer this question we note that each component of $\mathbb{T}$ is a force per area, with force a vector and area orientable by its outward normal. As it is built from vectors, which are first order tensors, we suspect that $\mathbb{T}$ should be a proper second order tensor. This suspicion is supported by the quotient rule from tensor analysis (Section 8.1.1). Namely, the quotient rule means that equation (26.15) indeed yields $\mathbb{T}_{mn}$ that are components to a second order tensor. As components to a second order tensor, the tensor components, $\mathbb{T}_{mn}$, transform under a coordinate transformation according to the rules developed in Chapter 1 for Cartesian tensors and in Chapter 9 for general tensors. Through the power of tensor analysis, we thus see that our considerations, based on the rather contrived tetrahedron region in Figure 26.3, hold for an arbitrary region described by an arbitrary coordinate system.

FIGURE 26.4: Illustrating the components to the stress tensor, $\mathbb{T}_{mn}$ and how they are organized according to the coordinate axes. The component $\mathbb{T}_{mn}$ is the stress that points in the n-direction along the face with outward normal in the m-direction.

26.4 Angular momentum and the stress tensor

The linear momentum principle afforded by Newton's law of motion allowed us to deduce the local equilibrium property (26.4) of the stress. We here derive a constraint placed on the stress tensor that is imposed by studying angular momentum. Phenomenologically, we observe that geophysical fluids, as with most common fluids, experience torques only as the moments of body forces acting throughout the volume of a fluid region, or as moments of contact forces acting on the surface bounding the fluid region. We now make use of this observation to deduce symmetry of the stress tensor.[2]

26.4.1 Basic formulation

Consider a constant mass fluid element that has a Cartesian position $\boldsymbol{x}$ relative to an arbitrary origin. The angular momentum of the fluid element with respect to the origin is

$$\boldsymbol{L} = \rho\,\delta V\,(\boldsymbol{x}\times\boldsymbol{v}), \tag{26.18}$$

and its material time evolution is

$$\frac{\mathrm{D}\boldsymbol{L}}{\mathrm{D}t} = \rho\,\delta V\,\boldsymbol{x}\times\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t}, \tag{26.19}$$

which follows since $\mathrm{D}(\rho\,\delta V)/\mathrm{D}t = 0$, $\mathrm{D}\boldsymbol{x}/\mathrm{D}t = \boldsymbol{v}$, and $\boldsymbol{v}\times\boldsymbol{v} = 0$. Making use of Cauchy's form for the equation of motion (25.14)

$$\rho\,\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\,\boldsymbol{f} + \nabla\cdot\mathbb{T} \tag{26.20}$$

[2]Page 11 of *Batchelor* (1967) and Section 5.13 of *Aris* (1962) offer brief discussions of fluids in which internal force couplets lead to torques distinct from those considered here, and in which the stress tensor has an anti-symmetric component. *Dahler and Scriven* (1961) provide a more thorough account of such *polar materials*. Internal sources of angular momentum are studied in solid mechanics, with Section 5.3 of *Malvern* (1969) offering a discussion.

allows us to write the angular momentum evolution as

$$\frac{\mathrm{D}\boldsymbol{L}}{\mathrm{D}t} = \delta V\, \boldsymbol{x} \times (\rho \boldsymbol{f} + \nabla \cdot \mathbb{T}). \tag{26.21}$$

The first term arises from body forces (e.g., central gravity, planetary centrifugal, and Coriolis) and the second term arises from the divergence of stresses. Expanding the stress divergence term renders

$$\left[\frac{\mathrm{D}L_m}{\mathrm{D}t}\right]_{\text{stress}} = \delta V\, \epsilon_{mnp}\, x_n\, (\nabla \cdot \mathbb{T})_p \tag{26.22a}$$

$$= \delta V\, \epsilon_{mnp}\, x_n\, \partial_q \mathbb{T}_{pq} \tag{26.22b}$$

$$= \delta V\, \epsilon_{mnp}\, [\partial_q (x_n\, \mathbb{T}_{pq}) - (\partial_q x_n)\, \mathbb{T}_{pq}] \tag{26.22c}$$

$$= \delta V\, \epsilon_{mnp}\, [\partial_q (x_n\, \mathbb{T}_{pq}) - \mathbb{T}_{pn}], \tag{26.22d}$$

where the final equality follows since $\partial_q x_n = \delta_{qn}$. Bringing this result back into the full expression (26.21) leads to

$$\frac{\mathrm{D}L_m}{\mathrm{D}t} = \delta V\, \epsilon_{mnp}\, [\rho\, x_n\, f_p + \partial_q (x_n\, \mathbb{T}_{pq}) - \mathbb{T}_{pn}]. \tag{26.23}$$

26.4.2 Physical interpretation

To facilitate a physical interpretation of the terms appearing in equation (26.23), integrate over an arbitrary Lagrangian region (region moving with the barycentric velocity, $\boldsymbol{v}$) so that

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}(\boldsymbol{v})} L_m = \int_{\mathcal{R}(\boldsymbol{v})} \epsilon_{mnp}\, [\rho\, x_n\, f_p + \partial_q (x_n\, \mathbb{T}_{pq}) - \mathbb{T}_{pn}]\, \mathrm{d}V. \tag{26.24}$$

As noted earlier, the first term on the right hand side arises from torques due to body forces acting over the region

$$\int_{\mathcal{R}(\boldsymbol{v})} \epsilon_{mnp}\, (\rho\, x_n\, f_p)\, \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x} \times \boldsymbol{f})_m\, \rho\, \mathrm{d}V. \tag{26.25}$$

The second term on the right hand side of equation (26.24) can be transferred into a surface integral using the divergence theorem

$$\int_{\mathcal{R}(\boldsymbol{v})} \epsilon_{mnp}\, \partial_q (x_n\, \mathbb{T}_{pq})\, \mathrm{d}V = \int_{\partial\mathcal{R}(\boldsymbol{v})} \epsilon_{mnp}\, x_n\, \mathbb{T}_{pq}\, \hat{n}_q\, \mathrm{d}\mathcal{S} = \int_{\partial\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x} \times \boldsymbol{\tau})_m\, \mathrm{d}\mathcal{S}, \tag{26.26}$$

where $\hat{n}_q$ is the $q'th$ component of the normal vector on the region boundary, $\partial\mathcal{R}(\boldsymbol{v})$, and

$$\tau_p = \mathbb{T}_{pq}\, \hat{n}_q \tag{26.27}$$

is the $p'th$ component to the stress vector that is normal to $\hat{\boldsymbol{n}}$ (see equation (26.16)). Hence, the second term is the contribution to angular momentum evolution due to torques arising from the moment of contact forces acting on the region boundary.

26.4.3 Symmetry of the stress tensor

As noted at the start of this section, geophysical fluids have their angular momentum affected by torques arising from the moment of body forces acting throughout the fluid region, plus the

moment of contact forces acting on the region boundary. There is a third term in equation (26.23) that does not fit into either category, and it is given by the volume integral

$$-\int_{\mathcal{R}(\boldsymbol{v})} \epsilon_{mnp}\, \mathbb{T}_{pn}\, \mathrm{d}V = \int_{\mathcal{R}(\boldsymbol{v})} \epsilon_{mpn}\, \mathbb{T}_{pn}\, \mathrm{d}V \equiv \int_{\mathcal{R}(\boldsymbol{v})} T_m^{\times}\, \mathrm{d}V, \tag{26.28}$$

where we defined

$$T_m^{\times} = \epsilon_{mpn}\, \mathbb{T}_{pn}. \tag{26.29}$$

This term contributes a volume source to angular momentum and yet it is *not* associated with body forces. We might refer to it as a *torque density* (torque source per volume). As already noted, such torque sources are *not* relevant for geophysical fluids, in which case we conclude that geophysical fluids are affected only by symmetric stress tensors

$$\mathbb{T}_{mn} = \mathbb{T}_{nm} \Longrightarrow \epsilon_{mnp}\, \mathbb{T}_{np} = 0. \tag{26.30}$$

Symmetry of the stress tensor is a central property of the stresses acting on most fluids, including geophysical fluids. We thus only consider symmetric stress tensors throughout this book.

To further support the above conclusion concerning a symmetric stress tensor, consider a particular component of the torque density, such as the vertical

$$T_3^{\times} = \epsilon_{3pn}\, \mathbb{T}_{pn} = \mathbb{T}_{12} - \mathbb{T}_{21}, \tag{26.31}$$

with the corresponding torque applied to a fluid element given by

$$T_3^{\times}\, \delta V = (\mathbb{T}_{12} - \mathbb{T}_{21})\, \delta x\, \delta y\, \delta z. \tag{26.32}$$

What sort of angular acceleration is induced by this torque when computed relative to the fluid element center? To answer this question, assume the fluid element is moving as a rigid body so that we can compute its angular acceleration by dividing the torque by the moment of inertia for the fluid element. The moment of inertia depends on the shape of the element, which is unspecified. Even so, we can estimate the moment of inertia computed relative to a vertical axis through the center of the element

$$I_3 = \alpha\, [(\delta x)^2 + (\delta y)^2]\, \rho\, \delta x\, \delta y\, \delta z, \tag{26.33}$$

where α is a dimensionless geometric factor. Dividing the torque (26.32) by the moment of inertia thus leads to an estimate of the angular acceleration

$$\text{angular acceleration} \approx \frac{T_3^{\times}}{I_3} \approx \frac{\mathbb{T}_{12} - \mathbb{T}_{21}}{[(\delta x)^2 + (\delta y)^2]\, \rho\, \alpha}. \tag{26.34}$$

Now consider the continuum limit, found as δx and δy are reduced to zero. In the absence of an unspecified counteracting torque, a finite angular acceleration in the continuum limit (where $(\delta x)^2 + (\delta y)^2 \to 0$) is ensured only if the stress tensor is symmetric so that the numerator vanishes.

26.5 Forces and torques in an exact hydrostatic fluid

In this section we return to the study of a static fluid in a gravitational field originally considered in Section 25.6. The exact solution is known as *exact hydrostatic balance*, which distinguishes it from the approximate hydrostatic balance appropriate for moving geophysical fluids under certain scaling regimes (Section 28.2). For a static fluid, all forces and all torques sum to zero at any

point. Similarly, the integrated forces and integrated torques acting on any finite fluid region also vanish. The static fluid, although trivial dynamically, offers useful practice in applying the formalism of continuum mechanics to a system where we know the answer. Furthermore, there are interesting and important applications of these ideas, such as in the building of dams and underwater structures, both of which we certainly hope will remain static!

26.5.1 Force balance

The force balance in an exact hydrostatic fluid was addressed in Section 25.6 where we deduced the following relation between the pressure gradient and geopotential gradient

$$\nabla p = -\rho \, \nabla \Phi. \tag{26.35}$$

This equality holds at every point within the fluid, and as such it is a strong form of the hydrostatic balance.[3] Integrating over a finite fluid region, $\mathcal{R}$, and using the divergence theorem for scalar fields, (2.73), renders the finite volume or weak form of hydrostatic balance

$$\int_{\mathcal{R}} \rho \, \nabla \Phi \, \mathrm{d}V = -\int_{\mathcal{R}} \nabla p \, \mathrm{d}V = -\oint_{\partial \mathcal{R}} p \, \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{26.36}$$

Expanding the above relations for the special case of $\Phi = g\, z$ leads to the differential statements

$$0 = \hat{\boldsymbol{x}} \cdot \nabla p = \hat{\boldsymbol{y}} \cdot \nabla p \qquad \text{and} \qquad \rho \, g = -\hat{\boldsymbol{z}} \cdot \nabla p, \tag{26.37}$$

with the first two equations implying that the exact hydrostatic pressure is only a function of z. The corresponding weak form of hydrostatic balance reads

$$g \, M = -\int_{\mathcal{R}} \nabla p \cdot \hat{\boldsymbol{z}} \, \mathrm{d}V = -\oint_{\partial \mathcal{R}} p \, (\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}}) \, \mathrm{d}\mathcal{S}, \tag{26.38}$$

where $M = \int_{\mathcal{R}} \rho \, \mathrm{d}V$ is the mass in the fluid region, and the weak form of horizontal balances are

$$0 = \int_{\mathcal{R}} \nabla p \cdot \hat{\boldsymbol{x}} \, \mathrm{d}V = \oint_{\partial \mathcal{R}} p \, (\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{x}}) \, \mathrm{d}\mathcal{S} \tag{26.39a}$$

$$0 = \int_{\mathcal{R}} \nabla p \cdot \hat{\boldsymbol{y}} \, \mathrm{d}V = \oint_{\partial \mathcal{R}} p \, (\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{y}}) \, \mathrm{d}\mathcal{S}. \tag{26.39b}$$

We emphasize that these finite volume balances hold for any arbitrarily shaped region within a static fluid.

26.5.2 Pressure force balance for a homogeneous fluid

To further our understanding of the pressure force balances in a static fluid, consider a constant density static ocean sitting under a massless atmosphere, in which case the hydrostatic pressure is

$$p = -\rho \, g \, z, \tag{26.40}$$

where $z < 0$ for the ocean. Now examine the pressure forces acting on the three sides of the triangle in Figure 26.5. This geometry is simple enough to explicitly compute the pressure forces, thus confirming the general properties in equations (26.38), (26.39a), and (26.39b).

[3] Recall the discussion of weak and strong formulation in Section 18.2. In brief, the weak formulation provides integral relations whereas the strong formulation provides differential relations.

The outward normal vectors along the three triangle faces are given by

$$\hat{\boldsymbol{n}}_{\mathrm{A}} = +\hat{\boldsymbol{y}} \qquad \text{and} \qquad \hat{\boldsymbol{n}}_{\mathrm{B}} = -\hat{\boldsymbol{z}} \qquad \text{and} \qquad \hat{\boldsymbol{n}}_{\mathrm{C}} = \hat{\boldsymbol{z}}\cos\varphi - \hat{\boldsymbol{y}}\sin\varphi, \tag{26.41}$$

where

$$\tan\varphi = \frac{z_2 - z_1}{y_2 - y_1} = \frac{\Delta z}{\Delta y} \tag{26.42}$$

is the slope of the hypotenuse relative to the horizontal. The integrated pressure force along the vertical face is thus given by

$$\boldsymbol{F}_{\mathrm{A}}^{\mathrm{press}} = -\int p\,\hat{\boldsymbol{n}}_{\mathrm{A}}\,\mathrm{d}\mathcal{S} = \hat{\boldsymbol{y}}\,\Delta x \int_{z_1}^{z_2} \rho\,g\,z\,\mathrm{d}z = \hat{\boldsymbol{y}}\,(\rho\,g/2)\,(z_2 + z_1)\,\Delta z\,\Delta x, \tag{26.43}$$

where Δx is the thickness of the triangle in the $\hat{\boldsymbol{x}}$ direction into the page. Note that $\boldsymbol{F}_{\mathrm{A}}^{\mathrm{press}}$ points in the $-\hat{\boldsymbol{y}}$ direction since $z_2 + z_1 < 0$. Likewise, the integrated pressure force along the horizontal face is given by

$$\boldsymbol{F}_{\mathrm{B}}^{\mathrm{press}} = -\int p\,\hat{\boldsymbol{n}}_{\mathrm{B}}\,\mathrm{d}\mathcal{S} = -\hat{\boldsymbol{z}}\,\Delta x \int_{y_1}^{y_2} \rho\,g\,z_1\,\mathrm{d}y = -\hat{\boldsymbol{z}}\,\rho\,g\,z_1\,\Delta y\,\Delta x, \tag{26.44}$$

which points upward since $z_1 < 0$.

The integrated pressure force along the sloped hypotenuse face, C, requires a bit of trigonometry. For this purpose we make use of the formalism from Section 20.4.3, in which the vertical position along the hypotenuse is written

$$z = \eta(y) = z_2 - (y_2 - y)\tan\varphi, \tag{26.45}$$

so that the horizontal projection of the surface area is given by equation (29.4)

$$\mathrm{d}\mathcal{S} = |\nabla(z - \eta)|\,\mathrm{d}x\,\mathrm{d}y = \frac{\mathrm{d}x\,\mathrm{d}y}{|\cos\varphi|}. \tag{26.46}$$

Hence, the integrated pressure force on the hypotenuse is given by

$$\begin{aligned}
\boldsymbol{F}_{\mathrm{C}}^{\mathrm{press}} &= -\int p\,\hat{\boldsymbol{n}}_{\mathrm{C}}\,\mathrm{d}\mathcal{S} && (26.47\mathrm{a})\\
&= \frac{\hat{\boldsymbol{n}}_{\mathrm{C}}}{\cos\varphi}\,\Delta x \int_{y_1}^{y_2} \rho\,g\,\eta(y)\,\mathrm{d}y && (26.47\mathrm{b})\\
&= (\hat{\boldsymbol{z}} - \hat{\boldsymbol{y}}\tan\varphi)\,\rho\,g\,\Delta x\,[z_2\,\Delta y - y_2\,\Delta z - (1/2)\,(y_1 + y_2)\,\Delta y\,\tan\varphi] && (26.47\mathrm{c})\\
&= (\hat{\boldsymbol{z}} - \hat{\boldsymbol{y}}\tan\varphi)\,\rho\,g\,\Delta x\,[z_2\,\Delta y - y_2\,\Delta z + (y_1 + y_2)\,\Delta z/2] && (26.47\mathrm{d})\\
&= (\hat{\boldsymbol{z}} - \hat{\boldsymbol{y}}\tan\varphi)\,\rho\,g\,\Delta x\,\Delta y\,(z_1 + z_2)/2. && (26.47\mathrm{e})
\end{aligned}$$

Bringing these results together renders the net pressure forces in the two directions

$$\hat{\boldsymbol{y}}\cdot(\boldsymbol{F}_{\mathrm{A}}^{\mathrm{press}} + \boldsymbol{F}_{\mathrm{B}}^{\mathrm{press}} + \boldsymbol{F}_{\mathrm{C}}^{\mathrm{press}}) = (\rho\,g\,\Delta x/2)\,[(z_1 + z_2)\,\Delta z - \tan\varphi\,(z_1 + z_2)\,\Delta y] = 0 \tag{26.48a}$$

$$\hat{\boldsymbol{z}}\cdot(\boldsymbol{F}_{\mathrm{A}}^{\mathrm{press}} + \boldsymbol{F}_{\mathrm{B}}^{\mathrm{press}} + \boldsymbol{F}_{\mathrm{C}}^{\mathrm{press}}) = \rho\,g\,\Delta x\,\Delta y\,\Delta z/2 = M\,g, \tag{26.48b}$$

where the mass of the triangle is given by

$$M = \rho\,\Delta x\,\Delta y\,\Delta z/2. \tag{26.49}$$

We thus see that the area integrated horizontal pressure forces vanish, whereas the area integrated

vertical pressure force balances the weight of the fluid. Again, these results are expected given the general expressions (26.38), (26.39a), and (26.39b) of force balance. Even so, being able to explictly compute the pressure forces acting around a region, and to confirm the general force balances, is a useful means to become familiar with hydrostatic pressure.

FIGURE 26.5: A right triangle region of fluid in a static ocean where $z < 0$. The positions for the three corners are shown as (y_1, z_1), (y_2, z_1), and (y_2, z_2), along with the pressure forces acting on the three sides. In exact hydrostatic balance, the area integrated pressure force acting over the triangle boundary vanishes, $-\oint_{\partial\mathcal{R}} p\,\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0$. If the density of the fluid is assumed constant, then we can analytically compute the force balance as detailed in Section 26.5.2.

26.5.3 Torque balance

Torques arise in the presence of force *couplets*, which in turn lead to time changes in the angular momentum. In our discussion of the stress tensor in Section 26.4, we saw that a symmetric stress tensor removes volume sources of torque; i.e., there are no internal sources of force couplets. So the only means to impart a nonzero torque is for force couplets to arise from body forces (forces originating outside of the fluid region) and from contact forces that act between fluid elements within the region. In this section, we show that for a static fluid then the net torque vanishes both at an arbitrary point in the fluid as well as when integrated over an arbitrary region.

Strong form: zero torques acting on a fluid element

The torque is the moment of a force computed about a chosen origin. For a static geophysical fluid, the torque acting on a fluid element is given by the moment of the pressure force plus the moment of the effective gravity force (central gravity plus planetary centrifugal)

$$\boldsymbol{x} \times \boldsymbol{f}\,\rho\,\delta V = \boldsymbol{x} \times (-\rho^{-1}\,\nabla p - \nabla\Phi)\,\rho\,\delta V. \tag{26.50}$$

As seen in Section 26.5.1, the pressure and effective gravitational forces exactly balance at each point with a static fluid so that $\nabla p = -\rho\,\nabla\Phi$. Hence, there can be no torques at each point since there are no net forces at each point.

Weak form: zero torques acting on a finite fluid region

To show that the torque vanishes for a finite fluid region, we can merely integrate the fluid element result (26.50) over the finite region. Since the integral of zero is still zero, there are no torques on the region. An alternative approach makes use of the weak formulation by following the discussion in Section 26.4.2. In this approach, we start by writing the time change in angular momentum acting on a static fluid region

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \boldsymbol{L} = \int_{\mathcal{R}} [\boldsymbol{x}\times(-\rho\,\nabla\Phi)]\,\mathrm{d}V + \oint_{\partial\mathcal{R}} [\boldsymbol{x}\times(-\hat{\boldsymbol{n}}\,p)]\,\mathrm{d}\mathcal{S}. \tag{26.51}$$

Note that although the discusssion in Section 26.4.2 focused on a Lagrangian region, $\mathcal{R}(\boldsymbol{v})$, there is no distinction here between Lagrangian and Eulerian since the fluid is static.

The pressure contribution in equation (26.51) is written in its contact force form, which is appropriate for a weak formulation. However, to compare its contribution to the torque with that from effective gravity requires us to convert the area integral to a volume integral. For that purpose we use Cartesian tensor notation and expose full details

$$\begin{aligned}
\oint_{\partial\mathcal{R}} (\hat{\boldsymbol{n}}\times\boldsymbol{x})_a\,p\,\mathrm{d}\mathcal{S} &= \epsilon_{abc}\oint_{\partial\mathcal{R}} \hat{n}_b\,x_c\,p\,\mathrm{d}\mathcal{S} && \text{permutation symbol (Section 1.4.1)} && (26.52a)\\
&= \epsilon_{abc}\int_{\mathcal{R}} \partial_b(x_c\,p)\,\mathrm{d}V && \text{divergence theorem} && (26.52b)\\
&= \epsilon_{abc}\int_{\mathcal{R}} (\delta_{bc}\,p + x_c\,\partial_b p)\,\mathrm{d}V && \text{product rule} && (26.52c)\\
&= \epsilon_{abc}\int_{\mathcal{R}} x_c\,\partial_b p\,\mathrm{d}V && \epsilon_{abc}\,\delta_{bc} = 0 && (26.52d)\\
&= -\epsilon_{acb}\int_{\mathcal{R}} x_c\,\partial_b p\,\mathrm{d}V && \epsilon_{abc} = -\epsilon_{acb} && (26.52e)\\
&= -\int_{\mathcal{R}} (\boldsymbol{x}\times\nabla p)_a\,\mathrm{d}V && \text{vector cross product notation.} && (26.52f)
\end{aligned}$$

This result then brings the angular momentum equation (26.51) to the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \boldsymbol{L} = \int_{\mathcal{R}} [\boldsymbol{x}\times(-\rho\,\nabla\Phi - \nabla p)]\,\mathrm{d}V. \tag{26.53}$$

At this point we can invoke the strong form force balance in equation (26.35), thus revealing that the integrand on the right hand side vanishes at each point in the fluid. However, this approach is no different than starting from the strong formulation of the torques in equation (26.50) and integrating over a finite region. An alternative approach, remaining fully within the weak formulation, states that if the region's angular momentum remains constant, then that defines a region experiencing zero net torque. This approach is the same as taken for the force balance, whereby we say that a fluid region experiencing no acceleration is one that has zero net forces acting on it. Hence, for a region with time invariant angular momentum we are led to the finite volume (weak form) torque balance

$$\int_{\mathcal{R}} [\boldsymbol{x}\times(\rho\,\nabla\Phi + \nabla p)]\,\mathrm{d}V = 0 \Longrightarrow \int_{\mathcal{R}} (\boldsymbol{x}\times\rho\,\nabla\Phi)\,\mathrm{d}V = -\int_{\partial\mathcal{R}} (\boldsymbol{x}\times\hat{\boldsymbol{n}}\,p)\,\mathrm{d}\mathcal{S}, \tag{26.54}$$

with this balance the direct analog for torques of the weak form of the force balances given by equations (26.38), (26.39a), and (26.39b).

26.6 Flux-form Eulerian momentum equation

We often find it useful to consider Cauchy's form of the momentum equation (26.20) in its flux-form Eulerian expression. Making use of Cartesian tensors, we expand the material time derivative acting on the velocity and introduce the mass conservation equation (20.6) so that

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\,[\partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v}] \tag{26.55a}$$

$$= \rho\,[\partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v}] + \boldsymbol{v}\,(\partial_t \rho + \nabla\cdot(\rho\,\boldsymbol{v})] \tag{26.55b}$$

$$= \partial_t(\rho\,\boldsymbol{v}) + \nabla\cdot[\rho\,\boldsymbol{v}\otimes\boldsymbol{v}], \tag{26.55c}$$

where $\boldsymbol{v}\otimes\boldsymbol{v}$ is the outer product of the velocity vector and it has Cartesian tensor components written as

$$(\boldsymbol{v}\otimes\boldsymbol{v})_{mn} = v_m\,v_n. \tag{26.56}$$

Consequently, the momentum equation (26.20) takes on the flux-form Eulerian expression

$$\partial_t(\rho\,\boldsymbol{v}) + \nabla\cdot[\rho\,\boldsymbol{v}\otimes\boldsymbol{v}] = \rho\,\boldsymbol{f} + \nabla\cdot\mathbb{T}. \tag{26.57}$$

Alternatively, we can move the advection of momentum term onto the right hand side so that

$$\partial_t(\rho\,\boldsymbol{v}) = \rho\,\boldsymbol{f} + \nabla\cdot[\mathbb{T} - \rho\,\boldsymbol{v}\otimes\boldsymbol{v}], \tag{26.58}$$

which takes on the component form

$$\partial_t(\rho\,v_m) = \rho\,f_m + \partial_n[\mathbb{T}_{mn} - \rho\,v_m\,v_n]. \tag{26.59}$$

In this form we see that momentum advection can be interpreted as a stress that modifies the linear momentum per volume at a point in space. We refer to the stress,

$$\mathbb{T}^{\text{kinetic}}_{mn} = -\rho\,(\boldsymbol{v}\otimes\boldsymbol{v})_{mn} = -\rho\,v_m\,v_n, \tag{26.60}$$

as the *mechanical stress* or *kinetic stress*, which arises from the mechanical interactions between moving fluid elements. The turbulent contribution to the mechanical stress is known as the *Reynolds stress*.

For a rotating fluid in a gravity field we set the body force to

$$\rho\,\boldsymbol{f} = -2\,\rho\,\boldsymbol{\Omega}\times\boldsymbol{v} - \rho\nabla\Phi, \tag{26.61}$$

and the divergence of the stress tensor is

$$\nabla\cdot\mathbb{T} = -\nabla p + \rho\,\boldsymbol{F}, \tag{26.62}$$

with $\boldsymbol{F}$ the frictional acceleration (see Section 26.8). In this case, Cauchy's equation (26.57) takes on the form

$$\frac{\partial(\rho\,\boldsymbol{v})}{\partial t} + \nabla\cdot(\rho\,\boldsymbol{v}\otimes\boldsymbol{v}) + 2\,\rho\,\boldsymbol{\Omega}\times\boldsymbol{v} = -\nabla p - \rho\,\nabla\Phi + \rho\,\boldsymbol{F}. \tag{26.63}$$

26.7 Linear momentum for arbitrary regions

Consider the budget of linear momentum for an arbitrary region, $\mathcal{R}$, moving in an arbitrary manner within the fluid. For this purpose we make use of the Leibniz-Reynolds Transport Theorem

(21.37)

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \varphi \,\mathrm{d}V\right] = \int_{\mathcal{R}} \frac{\partial \varphi}{\partial t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \varphi\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{26.64}$$

where $\boldsymbol{v}^{(b)}$ is the velocity of the region boundary, $\partial\mathcal{R}$, with $\hat{\boldsymbol{n}}$ the outward normal along the boundary. Applying this result to a component of the linear momentum per volume, $\varphi = \rho\, v_m$ (again, assuming Cartesian tensors), and making use of the flux-form Eulerian momentum equation (26.59) leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, v_m \,\mathrm{d}V\right] = \int_{\mathcal{R}} \partial_t(\rho\, v_m)\,\mathrm{d}V + \oint_{\partial\mathcal{R}} (\rho\, v_m)\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{26.65a}$$

$$= \int_{\mathcal{R}} [\rho\, f_m + \partial_n(\mathbb{T}_{mn} - \rho\, v_m\, v_n)]\,\mathrm{d}V + \oint_{\partial\mathcal{R}} (\rho\, v_m)\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{26.65b}$$

$$= \int_{\mathcal{R}} \rho\, f_m\,\mathrm{d}V + \oint_{\partial\mathcal{R}} (\mathbb{T}_{mn} - \rho\, v_m\, v_n)\,\hat{n}_n\,\mathrm{d}\mathcal{S} + \oint_{\partial\mathcal{R}} (\rho\, v_m)\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{26.65c}$$

$$= \int_{\mathcal{R}} \rho\, f_m\,\mathrm{d}V + \oint_{\partial\mathcal{R}} [\mathbb{T}_{mn} + \rho\, v_m\,(v_n^{(b)} - v_n)]\,\hat{n}_n\,\mathrm{d}\mathcal{S}. \tag{26.65d}$$

We can write this relation as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, \boldsymbol{v}\,\mathrm{d}V\right] = \int_{\mathcal{R}} \rho\, \boldsymbol{f}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} [\mathbb{T} + \rho\, \boldsymbol{v} \otimes (\boldsymbol{v}^{(b)} - \boldsymbol{v})] \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{26.66}$$

We conclude that the evolution of linear momentum over an arbitrary region is affected by the volume integrated body force acting over the region, plus the impacts from stresses acting on the region boundary. Notably, the stresses have a contribution from the advection of linear momentum across the region boundary, with advection computed relative to motion of the boundary. In Section 26.10 we specialize the budget (26.66) to an infinitesimally thin interface. That analysis is then used to develop stress conditions for a surface within a single fluid media, and the stress condition at the boundary between two fluids.

We refer to a *Lagrangian region* as one that moves so that the surface velocity and barycentric velocity satisfy $\boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v} \cdot \hat{\boldsymbol{n}}$, in which case the mechanical stress is eliminated from the finite volume momentum budget (26.66). Recall from our discussion of Lagrangian regions in Section 20.3.1, we denote a Lagrangian region by writing $\mathcal{R}(\boldsymbol{v})$ to emphasize that the region moves with the barycentric fluid velocity, $\boldsymbol{v}$. For this case the linear momentum is only affected by body forces as well as stresses contained in the stress tensor

$$(\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} = 0 \Longrightarrow \frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}(\boldsymbol{v})} \rho\, \boldsymbol{v}\,\mathrm{d}V\right] = \int_{\mathcal{R}(\boldsymbol{v})} \rho\, \boldsymbol{f}\,\mathrm{d}V + \oint_{\partial\mathcal{R}(\boldsymbol{v})} \mathbb{T} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{26.67}$$

This relation is Reynold's transport theorem (Section 21.2.6) as applied to linear momentum.

26.8 Constitutive relation between stress and strain rate

Thus far we have offered a rather general treatment of stress, developing its properties according to the conservation of linear momentum and angular momentum. We now develop *constitutive relations*, which relate stress to properties of the fluid as well as properties of the fluid flow.

26.8.1 Thermodynamic pressure and mechanical pressure

Consider a fluid in which the stress on an area element is always normal to the area element and is independent of the orientation. This fluid is in hydrostatic balance and the corresponding stress tensor and stress vector are written

$$\mathbb{T}_{mn} = -p\,\delta_{mn} \Longleftrightarrow \mathbb{T}\cdot\hat{\boldsymbol{n}} = -p\,\hat{\boldsymbol{n}}, \tag{26.68}$$

where p is the hydrostatic pressure field. Since the pressure introduced here arises from purely mechanical considerations, we refer to it as the *mechanical pressure*. For a compressible fluid at rest, we can identify the mechanical pressure with the *thermodynamic pressure* encountered in our study of equilibrium thermodynamics (Chapter 23). Furthermore, if we assume that local thermodynamic equilibrium is maintained for fluid elements within a moving fluid, then we are motivated to continue making this identification between mechanical pressure and thermodynamical pressure (see Section 4.5 of *Kundu et al.* (2016) or Section 1.10 of *Salmon* (1998)). However, we note that there is no fully deductive theory supporting this equality of pressures. The reader in search of a deductive theory will need to start by studying nonequilibrium statistical mechanics, which is outside our scope.

When the fluid flow is non-divergent (Chapter 22), we lose the equality between mechanical pressure and thermodynamical pressure, even when the fluid is at rest. The reason is that a non-divergent fluid flow is unable to do pressure work on a fluid element since the flow cannot change the fluid element's volume. Hence, for non-divergent flow there is no connection between pressure and changes to internal energy as per the first law of thermodynamics (Section 23.2). A non-divergent flow only has access to the mechanical pressure as revealed through the measurement of stresses. Furthermore, the mechanical pressure instantaneously conforms to the needs of non-divergence throughout the fluid (see Section 30.3 and Section 39.4). Correspondingly, energetic consistency requires us to make use of the geopotential in the equation of state for *in situ* density in an oceanic Boussinesq fluid (in which the velocity is non-divergent), rather than the thermodynamic pressure. We explore this point in Section 30.8.

26.8.2 Couette flow and the frictional stress tensor

Couette flow arises when fluid is placed between two long and straight concentric cylinders that can rotate. Relative motion between the two cylinders leads to fluid motion. For example, if the inner surface rotates, then fluid next to the cylinder wall will move with the cylinder. Any normal stresses on the fluid imparted by the cylinders are directed toward the cylinder axis and so cannot render any tangential motion. This elegant experiment proves that fluid motion can be induced by purely tangential stresses. Furthermore, the tangential stress imparted by the inner cylinder transfers through the fluid to the outer cylinder. Indeed, if the inner cylinder rotates at a constant rate, then eventually the whole fluid-cylinder system rotates as a solid body. Couette flow thus exhibits how real fluids can support tangential stresses in response to tangential strains, thus providing a clear distinction from a perfect fluid where only normal stresses (i.e., pressure) are supported.

As evidenced by the Couette flow, a moving fluid has a more complex stress relation than a static fluid. In particular, the presence of tangential stresses in the fluid provides evidence for an additional piece to the stress tensor that we write as

$$\mathbb{T}_{mn} = -p\,\delta_{mn} + \mathbb{\tau}_{mn} \Longleftrightarrow \mathbb{T} = -p\,\mathbb{I} + \mathbb{\tau}. \tag{26.69}$$

The pressure term remains isotropic as for a fluid at rest, thus imparting normal stresses. The

additional tensor, $\mathbb{\tau}$, is referred to as the *frictional stress tensor* or sometimes the *viscous stress tensor*.[4] The friction tensor captures the irreversible exchanges of momentum between moving (relative to one another) fluid elements, such as in Couette flow, with the irreversible momentum exchange supported by fluid viscosity. Viscosity is assumed to be identically zero in a perfect fluid, so that a perfect fluid can only support normal stresses from pressure even when the perfect fluid has relative motion.

As noted above, we assume the frictional stress tensor vanishes when there is zero relative motion within the fluid.[5] The physical idea is that fluid strains are needed to generate friction between fluid elements to support the transfer of momentum through the presence of viscosity. The determination of frictional stresses from kinematic properties (such as strain) requires a constitutive relation. The constitutive relation commonly used for geophysical fluids follows that for a *Newtonian fluid*, which is a particular type of *Stokesian fluid* whose frictional stresses are assumed to be linearly proportional to the strain rate.

The diagonal stresses, $\mathbb{T}_{11}$, $\mathbb{T}_{22}$, and $\mathbb{T}_{33}$, are known as the *direct stresses* or *normal stresses*, whereas the off-diagonal stresses are *shear stresses*. The sum of the direct stresses forms the trace of the stress tensor and is given by

$$\mathbb{T}_{qq} = \mathbb{T}_{11} + \mathbb{T}_{22} + \mathbb{T}_{33} = -3\,p + \mathbb{\tau}_{qq}. \tag{26.70}$$

If $\mathbb{\tau}_{qq} = 0$ then it is known as the *deviatoric friction tensor*. As argued in Section 26.8.6, a deviatoric friction tensor is consistent with the assumption of equal mechanical and thermodynamical pressures.

26.8.3 D'Alembert's theorem for perfect fluids

Consider a finite impermeable solid body placed in a steady fluid flow, with the flow assumed to be uniform upstream and downstream. A particular realization is an arbitrarily long pipe flow with a solid object in the middle of the pipe. *D'Alembert's theorem* says that the force exerted by a perfect fluid on the solid body has no component along the direction of the pipe's central axis. A proof of this theorem, as provided in Section 13 of *Meyer* (1971), makes use of basic insights into momentum balances.

D'Alembert's theorem suggests a behavior that is contrary to common experience, whereby an object placed in a real fluid flow experiences a net force in the direction of the flow, so that there is a transfer of momentum between the fluid and the solid body. Consequently, D'Alembert's theorem became known as *D'Alembert's paradox*, thus motivating research during the 19th and early 20th centuries to understand stresses acting between a fluid and solid. It further put into question the ability to consider a fluid with arbitrarily small, but nonzero, viscosity as approximately a perfect fluid, where the viscosity identically vanishes.

The nonzero viscosity present in real fluid supports tangential stresses, in addition to normal (pressure) stresses present in perfect fluids. It is the tangential stresses, no matter how small in magnitude (but nonzero), that lead to a net force on the solid body. These ideas highlight the subtle nature of taking the limit of vanishing viscosity. Namely, a real fluid, no matter how small its viscosity (so long as it is nonzero), displays fundamentally distinct behavior relative to the perfect fluid. We return to this point in Section 26.8.7 when discussing the relation between the Navier-Stokes equation and the Euler equation.

[4] The viscous tensor is distinct from the viscosity tensor, which is a fourth order tensor not considered in this book. Section 4.5 of *Kundu et al.* (2016) and Chapter 17 in *Griffies* (2004) for a discussion of the viscosity tensor.

[5] This assumption follows those for a Stokes fluid as discussed in Section 5.21 of *Aris* (1962).

26.8.4 Guidance from Galilean invariance

Consider a fluid in uniform motion in free space. Boosting the reference frame allows us to move to a reference frame where the fluid is static. Through Galilean invariance (Section 18.9) we expect the dynamics to remain unchanged. Since we assume friction vanishes when the fluid is static (as per a Stokesian fluid), Galilean invariance implies that the frictional stresses vanish when the fluid undergoes uniform motion in any direction.

Uniform motion of fluid elements is reflected in zero velocity gradients, which offers a key insight into how friction depends on strains. Namely, these considerations suggest that the friction tensor is a function of gradients in the velocity field, $\partial_m v_n$. Furthemore, as the stress tensor must be symmetric (Section 26.4), the simplest expression for the friction tensor is one that is linearly proportional to the strain rate tensor introduced in Section 19.4. Fluids that satisfy a linear constitutive relation between stress and the strain rate are known as *Newtonian fluids*. Furtheremore, this constitutive relation takes the same mathematical form as *Hooke's Law* used in the study of elastic materials or simple harmonic oscillators (see Section 15.6).

26.8.5 A comment on Rayleigh drag

Rayleigh drag is a particular form of friction that makes use of the acceleration

$$\boldsymbol{F}_{\text{Rayleigh}} = -\gamma\, \boldsymbol{v}, \tag{26.71}$$

where $\gamma > 0$ is an inverse time scale. Rayleigh drag is *not* Galilean invariant since it decelerates all flows, even uniformly moving flows, towards rest where rest is defined by the laboratory frame. Furthermore, Rayleigh drag is not equal to the divergence of a frictional stress tensor, and so it does not arise from a contact stress. Even so, it has found some use for rudimentary purposes, particularly when aiming to derive analytic expressions for how friction acts on flows in a bulk sense. We provide an example in the study of Ekman dynamics in Section 34.2.3.

26.8.6 Constitutive relation for Newtonian fluids

There are many details involved with deriving the Newtonian fluid constitutive relation, with discussions provided in Section G of *Serrin* (1959), Chapter 5 of *Aris* (1962), Section 3.1 of *Segel* (1987), and Section 4.5 of *Kundu et al.* (2016) for general fluids, and Chapter 17 and 18 of *Griffies* (2004) for stratified fluids with particular focus on the ocean. We here offer a taste of these considerations by starting with the constitutive relation

$$\mathbb{T}_{mn} = \rho\,(2\,\nu\,\mathbb{S}_{mn} + \lambda\,\nabla\cdot\boldsymbol{v}\,\delta_{mn}), \tag{26.72}$$

with $\mathbb{S}_{mn}$ the components to the strain rate tensor introduced in Section 19.4.4 and whose trace equals to the velocity divergence

$$\mathbb{S}_{qq} = \nabla\cdot\boldsymbol{v}. \tag{26.73}$$

The first contribution to the frictional stress (26.72) includes the strain tensor multiplied by the *first kinematic viscosity*, $\nu > 0$ (dimensions of squared length per time). The second contribution arises just from flow divergence as scaled by a *second kinematic viscosity*, λ. The sum

$$\nu_{\text{bulk}} = \rho\,(\lambda + 2\,\nu/3) \tag{26.74}$$

is known as the *bulk viscosity*, which, as discussed in the following, will be set to zero. Finally, one sometimes finds it more convenient to work with the *dynamic viscosity*

$$\mu_{\text{vsc}} = \rho\,\nu. \tag{26.75}$$

Note that we set ρ to the constant Boussinesq reference density, ρ_0 (Chapter 30), when working with a Boussinesq fluid.

Deviatoric friction tensor

As noted in Section 26.8.1, the pressure appearing in the stress tensor is a mechanical pressure that equals to minus one-third the trace of the stress tensor when the fluid is at rest

$$\mathbb{T}_{qq}^{\text{static}} = -3\,p. \tag{26.76}$$

We assume that the frictional stress tensor does *not* alter this trace, so that the frictional stress tensor has zero trace and is known as a *deviatoric friction tensor*[6]

$$\mathbb{T}_{qq} = 0 = 3\,\nu_{\text{bulk}}\,\nabla\cdot\boldsymbol{v} \Longrightarrow \lambda = -2\,\nu/3, \tag{26.77}$$

so that the total stress tensor is given by

$$\mathbb{T}_{mn} = -\delta_{mn}\,p + 2\,\mu_{\text{vsc}}\,\mathbb{S}_{mn}^{\text{dev}} \quad \text{with} \quad \mathbb{S}_{mn}^{\text{dev}} = \mathbb{S}_{mn} - \delta_{mn}\,\mathbb{S}_{qq}/3, \tag{26.78}$$

where $\mathbb{S}^{\text{dev}}$ is the *deviatoric strain rate tensor*. We next offer arguments for why the friction tensor used for geophysical flows should have zero trace.

Equality of the mechanical and thermodynamic pressures

The frictional stress tensor (26.72) is not the precise form typically used in geophysical fluid modeling. Instead, the velocity divergence term is generally dropped even for compressible flows, and the viscosity is anisotropic and more generally takes the form of a fourth order *viscosity tensor* (see Chapter 17 and 18 of *Griffies* (2004) for the ocean). Furthermore, what is generally respected in most geophysical applictions is the deviatoric nature of the friction tensor. That property is maintained since it is consistent with our assumption in Section 26.8.1 that the mechanical pressure equals to the thermodynamic pressure.

To see this equality between the pressures, introduce the mechanical pressure, p^{mech}, according to the trace of the stress tensor

$$\mathbb{T}_{qq} = -3\,p^{\text{mech}}. \tag{26.79}$$

That is, mechanical pressure is minus one-third the trace of the stress tensor whether the fluid is at rest or in motion. We can, in principle, measure this pressure by measuring the stresses. If we now return to the general form of the stress tensor

$$\mathbb{T}_{mn} = -\delta_{mn}\,p + \rho\,(\lambda\,\nabla\cdot\boldsymbol{v}\,\delta_{mn} + 2\,\nu\,\mathbb{S}_{mn}), \tag{26.80}$$

with p here given by the thermodynamic pressure, then the trace is

$$\mathbb{T}_{qq} = -3\,p + \rho\,(3\,\lambda + 2\,\nu)\,\nabla\cdot\boldsymbol{v}. \tag{26.81}$$

[6] A second order tensor in 3-dimensions, $\mathbb{D}$, has a *deviator* with components given by $\mathbb{D}_{mn}^{\text{dev}} = \mathbb{D}_{mn} - (1/3)\,\delta_{mn}\,\mathbb{D}_{qq}$. By construction, the trace of the deviator vanishes: $\mathbb{D}_{qq}^{\text{dev}} = 0$.

Setting the two traces (26.79) and (26.81) equal then leads to

$$p - p^{\text{mech}} = \nu_{\text{bulk}} \, \nabla \cdot \boldsymbol{v}. \tag{26.82}$$

In principle, one can measure the difference in pressures, but in practice this measurement is rather difficult. Stokes assumed $p - p^{\text{mech}} = 0$ by taking a zero bulk viscosity, and he used arguments from kinetic theory of gases to support that choice.[7] This choice is generally taken for geophysical fluid applications, largely based on the assumption of local thermodynamic equilibrium mentioned in Section 26.8.1, and by noting that the flows are predominantly close to divergence-free.

Local thermodynamical equilibrium is not a good assumption in supersonic flows, in which case $p - p^{\text{mech}} \neq 0$ and the bulk viscosity is nonzero. Correspondingly, the divergence term and the second kinematic viscosity, $\lambda \neq -2\,\nu/3$, are important. Additionally, the second viscosity is important when concerned with the damping of acoustic waves. Neither topics are considered in this book so that we have no further concern for the second viscosity.

Frictional force per volume

Taking the mechanical and thermodynamic pressures equal, so that the second kinematical viscosity satisfies equation (26.77), renders the frictional force per volume as given by the divergence of the frictional stress tensor

$$\rho \, F_n = \partial_m \mathbb{T}_{mn} = 2 \, \partial_m (\mu_{\text{vsc}} \, \mathbb{S}^{\text{dev}}_{mn}). \tag{26.83}$$

The special case of a Boussinesq ocean with $\nabla \cdot \boldsymbol{v} = 0$

For a Boussinesq ocean (Chapter 30), the viscous friction (26.83) simplifies to

$$\rho_0 \, F_n = 2 \, \rho_0 \, \partial_m (\nu \, \mathbb{S}_{mn}). \tag{26.84}$$

To reach this equality we set the dynamic viscosity to $\mu_{\text{vsc}} = \rho_0 \, \nu$, with ρ_0 the constant Boussinesq reference density. Furthermore, as studied in Chapter 30, the Boussinesq ocean has a non-divergent flow field so that $\nabla \cdot \boldsymbol{v} = \partial_m v_m = 0$, in which case

$$\mathbb{S}^{\text{dev}}_{mn} = \mathbb{S}_{mn} \quad \text{if } \nabla \cdot \boldsymbol{v} = 0. \tag{26.85}$$

Finally, for the case of a constant kinematic viscosity, we have the Boussinesq result reducing to the Laplacian form, which is seen by

$$\begin{aligned}
\nu^{-1} \, F_n &= 2 \, \partial_m \mathbb{S}_{mn} && \text{(26.86a)}\\
&= \partial_m (\partial_n v_m + \partial_m v_n) && \text{(26.86b)}\\
&= \partial_m (\partial_n v_m) + \partial_m (\partial_m v_n) && \text{(26.86c)}\\
&= \partial_n (\partial_m v_m) + \nabla^2 v_n && \text{(26.86d)}\\
&= \nabla^2 v_n, && \text{(26.86e)}
\end{aligned}$$

so that

$$\boldsymbol{F} = \nu \, \nabla^2 \boldsymbol{v}. \tag{26.87}$$

The relatively simple form of the Laplacian friction operator is commonly used for scale analysis, such as when introducing the Reynolds number in Section 26.9.

[7] As noted in Section 62 of *Serrin* (1959), Stokes later admitted to having little confidence in this assumption.

26.8.7 Navier-Stokes and Euler equations

The *Navier-Stokes* equation is a special form of the momentum equation found by assuming a Newtonian fluid constitutive relation. In this case the Navier-Stokes momentum equation (25.16), in the presence of rotation and gravity, takes on the form

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\,\nabla\Phi - \nabla p + \nabla \cdot (2\,\mu_{\mathrm{vsc}}\,\mathbb{S}^{\mathrm{dev}}), \tag{26.88}$$

where we set the friction tensor equal to $\mathbb{T} = 2\,\mu_{\mathrm{vsc}}\,\mathbb{S}^{\mathrm{dev}}$. Quite often when examining the mathematical properties of the Navier-Stokes equation, one assumes the flow to be non-divergent, in which case $\mathbb{S}^{\mathrm{dev}} = \mathbb{S}$ since $\mathbb{S}_{qq} = \nabla \cdot \boldsymbol{v} = 0$. A further simplification occurs by assuming a constant density, ρ, and constant kinematic viscosity, ν, in which case the friction tensor reduces to the Laplacian form (26.87) so that the Navier-Stokes equation becomes

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\Phi - \rho^{-1}\,\nabla p + \nu\,\nabla^2\boldsymbol{v}. \tag{26.89}$$

This form, or even simpler when ignoring rotation and gravity, is commonly studied by mathematicians concerned with existence and uniqueness properties of fluid flow solutions (e.g., see *Doering and Gibbon* (1995)). When assuming the fluid to be perfect, so that there are no viscous forces, the momentum equation is referred to as the *Euler equation*[8]

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\Phi - \rho^{-1}\,\nabla p. \tag{26.90}$$

It is tempting to consider the Euler equations to be a continuous limit of the Navier-Stokes equation as the viscosity goes to zero. However, there is a key distinction between the two equations. Namely, the Navier-Stokes equations admit solutions that display statistically equilibriated turbulent motions, whereby energy cascades to the small scales through vortex stretching in three dimensional flows. This energy is ultimately dissipated by viscosity at the small spatial scales, and this mechanism holds no matter how small the viscosity, so long as it is nonzero. In contrast, for the Euler equations, with identically zero viscosity, energy cannot be dissipated at the small scales so that an equilibrium turbulent cascade is unavailable.

Another fundamental distinction between the Euler equation and Navier-Stokes equation concerns the boundary conditions. For the Navier-Stokes equation, the presence of a second order operator (the Laplacian), weighted by the viscosity, signals a very distinct behavior of the flow next to boundaries. The Euler equation can only maintain a no-normal flow condition at a boundary, with the kinematics detailed in Section 20.4. Yet the viscous fluid described by the Navier-Stokes equation must satisfy an additional boundary condition. Evidence based on research in the 19th and 20th centuries suggests that fluids, such as air and water, adhere to solid boundaries and thus satisfy the *no-slip* boundary condition. This boundary condition has basic implications for how stress acts between fluids and solids. We have more to say concerning this boundary condition in Section 26.10.[9]

[8] Note that some authors refer to the Euler equations only in the case of a perfect fluid that has no body force, so that both rotation and gravitation vanish.

[9] See also the comments and footnote on page 86 of *Segel* (1987) as well as pages 83-84 of *Meyer* (1971).

26.8.8 Laplacian friction in terms of vorticity and divergence

The Laplacian friction operator with a constant viscosity is afforded the following decomposition

$$\begin{aligned}
\nu^{-1} F_n &= \partial_m(\partial_m v_n) && (26.91a)\\
&= \partial_m(\partial_m v_n - \partial_n v_m + \partial_n v_m) && (26.91b)\\
&= \partial_m(\partial_m v_n - \partial_n v_m) + \partial_n(\partial_m v_m) && (26.91c)\\
&= -2\,\partial_m \mathbb{R}_{mn} + \partial_n \nabla\cdot\boldsymbol{v} && (26.91d)\\
&= \partial_m(\epsilon_{mnp}\,\omega_p) + \partial_n \nabla\cdot\boldsymbol{v} && (26.91e)\\
&= -\epsilon_{nmp}\,\partial_m\omega_p + \partial_n \nabla\cdot\boldsymbol{v} && (26.91f)\\
&= -(\nabla\times\boldsymbol{\omega})_n + \partial_n \nabla\cdot\boldsymbol{v}. && (26.91g)
\end{aligned}$$

In the fourth equality we introduced the rotation tensor (19.52)

$$\mathbb{R}_{mn} = (1/2)\,(\partial_n v_m - \partial_m v_n), \tag{26.92}$$

which is related to the vorticity, $\boldsymbol{\omega} = \nabla\times\boldsymbol{v}$, via equation (19.55)

$$\mathbb{R}_{mn} = -\epsilon_{mnp}\,\omega_p/2. \tag{26.93}$$

These manipulations have served to decompose the Laplacian viscous acceleration, with a constant viscosity, into the two terms

$$\boldsymbol{F} = \nu\left[-\nabla\times\boldsymbol{\omega} + \nabla(\nabla\cdot\boldsymbol{v})\right]. \tag{26.94}$$

The Laplacian friction acceleration is thus due to the curl of the vorticity plus gradients in the velocity divergence. Many geophysical flows are dominated by vorticity, with the divergence relatively small. Indeed, the Boussinesq ocean discussed in Chapter 30 has $\nabla\cdot\boldsymbol{v} = 0$, in which case frictional acceleration arises only when the vorticity has a nonzero curl. Correspondingly, irrotational flows (where $\boldsymbol{\omega} = 0$) that are also non-divergent have zero Laplacian frictional acceleration.

26.8.9 Frictional stresses in a sheared flow

As a means to connect the above ideas in this section to the Couette flow discussed in Section 26.8.2, consider a non-divergent velocity that only has a zonal component with a vertical shear (Figure 26.6)

$$\boldsymbol{v} = u(z)\,\hat{\boldsymbol{x}}. \tag{26.95}$$

In this case the only nonzero components to the strain rate tensor are due to the vertical shear, $\mathbb{S}_{13} = \mathbb{S}_{31} = \partial_z u/2$. Now consider a horizontal area whose outward normal is parallel to the $\hat{\boldsymbol{z}}$ direction. The frictional force acting on that area is given by the area integral of the frictional stress

$$\boldsymbol{F}_{\text{area}} = \int \mathbb{T}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int \mathbb{T}\cdot\hat{\boldsymbol{z}}\,\mathrm{d}x\,\mathrm{d}y = \rho_0\,\frac{\hat{\boldsymbol{x}}}{2}\,\nu\,A\,\frac{\partial u}{\partial z}, \tag{26.96}$$

where $A = \int \mathrm{d}x\,\mathrm{d}y$ is the horizontal area, and where we used the constant reference density, ρ_0, for a Boussinesq fluid. Hence, the zonal stress arises from the nonzero vertical shear.

Momentum is deposited in regions where there is a divergence in the stress, in which case momentum is transferred from regions of high vertical shear to low vertical shear. At a point, the momentum is affected by the divergence of the friction stress at that point. For $\boldsymbol{v} = u(z)\,\hat{\boldsymbol{x}}$ we have

$$\left[\frac{\partial(\rho\,v_m)}{\partial t}\right]_{\text{viscous}} = \partial_n \mathbb{T}_{nm} \Longrightarrow \left[\frac{\partial(\rho\,u)}{\partial t}\right]_{\text{viscous}} = \partial_z\left(\mu_{\text{vsc}}\,\partial_z u\right), \tag{26.97}$$

so that zonal momentum is preferentially deposited to or removed from regions with high vertical curvature in the zonal velocity. Spatial variations in the dynamic viscosity, $\mu_{\text{vsc}} = \rho_0 \nu$, also contribute to friction.

FIGURE 26.6: Sample profile of zonal velocity possessing a vertical shear: $\boldsymbol{v} = u(z)\,\hat{\boldsymbol{x}}$ and with a no-slip boundary condition at $z = 0$. The resulting zonal frictional stress arises from the nonzero vertical shear in the presence of viscosity.

26.8.10 The net stress tensor

Combining the frictional stress tensor with pressure and kinetic stress yields the flux-form momentum equation (26.63)

$$\frac{\partial(\rho\,\boldsymbol{v})}{\partial t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{v} + \rho\,\nabla\Phi = \nabla \cdot \mathbb{T}^{\text{net}}, \tag{26.98}$$

where we introduced the net stress tensor

$$\mathbb{T}^{\text{net}} = -p\,\mathbb{I} - \rho\,\boldsymbol{v} \otimes \boldsymbol{v} + \mathbb{\tau} = \begin{bmatrix} -p - \rho\,u^2 + \tau_{11} & -\rho\,u\,v + \tau_{12} & -\rho\,u\,w + \tau_{13} \\ -\rho\,u\,v + \tau_{12} & -p - \rho\,v^2 + \tau_{22} & -\rho\,v\,w + \tau_{23} \\ -\rho\,u\,w + \tau_{13} & -\rho\,v\,w + \tau_{23} & -p - \rho\,w^2 + \tau_{33} \end{bmatrix}. \tag{26.99}$$

The left hand side of the momentum equation (26.98) includes the local time tendency plus the body forces from Coriolis and effective gravity. The right hand side is the divergence of the net stress tensor, with this tensor combining the pressure stress, kinetic stress, and frictional stress. Varieties of the net stress tensor appear in subsequent chapters of this book, with details dependent on the chosen approximations.

26.8.11 Properties under time reversal[10]

Make an animation of a dynamical system over a period of time, and then play the animation backwards in time. Is there anything about the time reversed animation to indicate it is not physically realizable? If not, then the dynamical system possesses symmetry under the reversal of time. We considered this question in Section 14.3 for the motion of a point particle. Here we ask the same question for the perfect fluid satisfying the Euler equation (26.90) in a rotating reference frame, in which we show there is time symmetry. We then show that time reversal symmetry is broken by viscous friction in the Navier-Stokes equation (26.89).

[10]This subsection was inspired by the discussion on page 77 of *Meyer* (1971), with the added feature here of the Coriolis acceleration.

Perfect fluid satisfying the rotating Euler equation

Consider a particular solution, $\boldsymbol{v}(\boldsymbol{x},t)$, to the Euler equation in a rotating reference frame in either free space (i.e., no boundaries) or with static material boundaries where the flow satisfies the no normal flow boundary condition, $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} = 0$. What transformation properties for the pressure, $p(\boldsymbol{x},t)$, density, $\rho(\boldsymbol{x},t)$, geopotential, $\Phi(\boldsymbol{x},t)$, and rotation, $\boldsymbol{\Omega}$, are sufficient for $\boldsymbol{v}^*(\boldsymbol{x},t^*) = -\boldsymbol{v}(\boldsymbol{x},-t)$ to be a solution? That is, by running time backwards, and changing the sign of the velocity, does this flow also satisfy the Euler equations?

In the following, we retain the space position unchanged. Hence, for brevity, we suppress the $\boldsymbol{x}$ dependence just focus on time, in which case we have the Euler equation (26.90) is written as

$$\rho(t)\,\frac{\mathrm{D}\boldsymbol{v}(t)}{\mathrm{D}t} + 2\,\rho(t)\,\boldsymbol{\Omega}\times\boldsymbol{v}(t) = -\rho(t)\,\nabla\Phi(t) - \nabla p(t). \tag{26.100}$$

We can ensure time reversal symmetry by assuming the following properties

$$\boldsymbol{v}^*(\boldsymbol{x},t) = -\boldsymbol{v}(\boldsymbol{x},-t) \qquad \text{velocity reverses direction} \tag{26.101a}$$
$$p^*(\boldsymbol{x},t^*) = p(\boldsymbol{x},-t) \qquad \text{pressure retains same sign} \tag{26.101b}$$
$$\rho^*(\boldsymbol{x},t^*) = \rho(\boldsymbol{x},-t) \qquad \text{density retains same sign} \tag{26.101c}$$
$$\Phi^*(\boldsymbol{x},t^*) = \Phi(\boldsymbol{x},-t) \qquad \text{geopotential retains same sign} \tag{26.101d}$$
$$\boldsymbol{\Omega}^* = -\boldsymbol{\Omega}. \qquad \text{rotation reverses direction.} \tag{26.101e}$$

That is, if the rotating Euler equation is satisfied by $\boldsymbol{v}(\boldsymbol{x},t)$, $p(\boldsymbol{x},t)$, $\rho(\boldsymbol{x},t)$, $\Phi(\boldsymbol{x},t)$, and $\boldsymbol{\Omega}$, then the rotating Euler equation is also satisfied by $-\boldsymbol{v}(\boldsymbol{x},-t)$, $p(\boldsymbol{x},-t)$, $\rho(\boldsymbol{x},-t)$, $\Phi(\boldsymbol{x},-t)$, and $-\boldsymbol{\Omega}$. More explicitly, we verify time reversal symmetry by writing out the terms in the Euler equation

$$\frac{\mathrm{D}\boldsymbol{v}^*(t^*)}{\mathrm{D}t^*} = \frac{\mathrm{D}\boldsymbol{v}(-t)}{\mathrm{D}t} \tag{26.102a}$$
$$\rho^*(t^*)\,\boldsymbol{\Omega}^*\times\boldsymbol{v}^*(t^*) = \rho(-t)\,\boldsymbol{\Omega}\times\boldsymbol{v}(-t) \tag{26.102b}$$
$$\rho^*(t^*)\,\Phi^*(t^*) = \rho(-t)\,\Phi(-t) \tag{26.102c}$$
$$\nabla p^*(t^*) = \nabla p(-t), \tag{26.102d}$$

so that satisfying the Euler equation (26.100) implies that also

$$\rho(-t)\,\frac{\mathrm{D}\boldsymbol{v}(-t)}{\mathrm{D}(-t)} + 2\,\rho(-t)\,\boldsymbol{\Omega}\times\boldsymbol{v}(-t) = -\rho(-t)\,\nabla\Phi(-t) - \nabla p(-t). \tag{26.103}$$

Note that a special case for the density condition (26.101c) is realized by a barotropic fluid[11], in which

$$\rho(\boldsymbol{x},t) = \rho[p(\boldsymbol{x},t)]. \tag{26.104}$$

The geopotential condition (26.101c) generally holds for static geopotentials, $\Phi = g\,z$, so that the gravity field does not care about the time direction. This property of gravity is characteristic of conservative forces. As noted in Section 14.3, the condition on rotation arises since the Coriolis acceleration is a function of the velocity.

Real fluid satisfying the rotating Navier-Stokes equation

Real fluids are not time reversible. For example, water leaving a tea pot does turn around and reenter the pot. Also, if air were a perfect fluid then one could only survive through breathing

[11] Barotropic fluids have a functional relation $\rho = \rho(p)$, and are discussed in Section 41.2.3.

in a cross-wind since otherwise we would breath in the same air we just breathed out. Even though perfect fluids suffer from unrealistic features, it is of interest to expose symmetries of the Euler equations and to then study how these symmetries are broken. To see how dissipation breaks time reversal symmetry, consider the Laplacian viscous friction acceleration appearing in the Navier-Stokes equation (26.89)

$$\boldsymbol{F} = \nu \nabla^2 \boldsymbol{v}, \tag{26.105}$$

where $\nu > 0$ is the kinematic viscosity. So long as the viscosity stays positive, we see that frictional acceleration changes sign under the transformation $\boldsymbol{v}^*(t^*) = -\boldsymbol{v}(-t)$, so that the friction operator becomes an anti-dissipation operator when time is reversed. As such, time reversed motion in the presence of viscous friction (again, with $\nu > 0$) is distinct from time forward motion. That is, friction breaks time reversal symmetry so that the Navier-Stokes equations are not time symmetric, meaning that we can distinguish between motion that is forward in time versus motion that is backward in time.

26.8.12 Comments and further study

There are more elaborate constitutive relations between the frictional stress tensor and strain rate tensor than those considered in this section. The most general form for a Newtonian fluid introduces a fourth-order viscosity tensor as in Section 4.5 of *Kundu et al.* (2016) and Chapter 17 in *Griffies* (2004). We also recommend the presention of stress in Chapter 5 of *Aris* (1962).

Geophysical fluids such as air and water are generally well treated using Newtonian constitutive relations. However, there are some geophysical turbulence theories that propose a non-Newtonian constitutive relation for part of their closures, whereby the constitutive relation makes use of products of the strain rate tensor for computing stress. *Anstey and Zanna* (2017) offer a compelling approach with a subgrid scale stress tensor that is non-Newtonian and furthermore contains a non-zero trace, thus resulting in a modification to the mechanical pressure. Additional nonlinear relations can arise when the viscous tensor is a function of the flow, such as with the Smagorinsky scheme commonly used for Large Eddy Simulations (LES) (see *Smagorinsky* (1993) or Chapter 18 of *Griffies* (2004)).

26.9 Reynolds number and flow regimes

How important is friction relative to other terms in the momentum equation? In particular, how does it compare to the material acceleration? We consider that question in the context of the non-rotating and constant density Navier-Stokes equations with a constant viscosity, ρ,

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} = -\rho^{-1} \nabla p + \nu \nabla^2 \boldsymbol{v}. \tag{26.106}$$

26.9.1 Non-dimensional Navier-Stokes

We non-dimensionalize the Navier-Stokes equation (26.106) to garner an understanding of relative magnitudes of the various terms. For that purpose, introduce the dimensional scales and corresponding non-dimensional fields

$$L = \text{length scale} \qquad U = \text{velocity scale} \qquad P = \text{pressure scale} \qquad T = \text{time scale}, \tag{26.107}$$

so that equation (26.106) takes the form

$$\frac{\partial \widehat{\boldsymbol{v}}}{\partial \widehat{t}} + \frac{U\,T}{L}\,(\widehat{\boldsymbol{v}} \cdot \widehat{\nabla})\,\widehat{\boldsymbol{v}} = -\frac{T\,P}{\rho\,U\,L}\,\widehat{\nabla}\widehat{p} + \frac{T\,\nu}{L^2}\,\widehat{\nabla}^2\widehat{\boldsymbol{v}}, \tag{26.108}$$

where the hat fields are non-dimensional and defined according to

$$\nabla = L^{-1}\,\widehat{\nabla} \qquad \partial_t = T^{-1}\,\partial_{\widehat{t}} \qquad \boldsymbol{v} = U\,\widehat{\boldsymbol{v}} \qquad p = P\,\widehat{p}. \tag{26.109}$$

26.9.2 Ratio of inertial to frictional accelerations

We are concerned with three dimensional flows with only a single length and velocity scale, L and U. For the time scale we assume that it is determined by the fluid particle time scale, which is the *advective time*

$$T = L/U. \tag{26.110}$$

Furthermore, we assume that the scale of mechanical pressure is comparable to the dynamical stress induced by the flow itself, thus leading to the *dynamical pressure scaling*[12]

$$P = \rho\,U^2. \tag{26.111}$$

These assumed scales for time and pressure bring the non-dimensionl Navier-Stokes equation (26.108) into the rather tidy form

$$\frac{\partial \widehat{\boldsymbol{v}}}{\partial \widehat{t}} + (\widehat{\boldsymbol{v}} \cdot \widehat{\nabla})\,\widehat{\boldsymbol{v}} = -\widehat{\nabla}\widehat{p} + \frac{1}{\mathrm{Re}}\,\widehat{\nabla}^2\widehat{\boldsymbol{v}}. \tag{26.112}$$

Flow regimes of the non-dimensional Navier-Stokes equation are specified by the non-dimensional number, $\mathrm{Re} = L\,U/\nu$, which is the *Reynolds number*. By definition, the Reynolds number is the ratio of scales for material (inertial) acceleration to frictional acceleration

$$\mathrm{Re} = \frac{\text{inertial accelerations}}{\text{frictional accelerations}} = \frac{U/T}{\nu\,U/L^2} = \frac{L^2/T}{\nu} = \frac{L\,U}{\nu}. \tag{26.113}$$

26.9.3 Reynolds numbers for some example flows

Laboratory experiments with flow around and within various objects indicates the following regimes of flow as a function of the Reynolds number:

$$\mathrm{Re} \sim \left[\begin{array}{ll} \leq 10^2 & \text{laminar} \\ 10^2 - 10^3 & \text{quasi-periodic flow} \\ 10^3 - 10^4 & \text{transition to turbulence} \\ \geq 10^4 & \text{fully turbulent.} \end{array}\right. \tag{26.114}$$

These numbers are fuzzy given dependence on the geometry of the objects placed in the flow and their characteristic length scale. What is more general concerns the behavior of the flow, with a transition from laminar to turbulent typically occuring as the flow moves from relatively low to high Reynolds number.

For a given molecular kinematic viscosity, the Reynolds number is dependent on the velocity and length scales. Let us consider some examples. First, place a finger into a flowing stream of

[12] When considering flows close to geostrophic balance in Sections 34.3.2 and 44.7.4, we find that pressure scales as $\rho\,f\,U\,L$, where f is the Coriolis parameter, which is distinct from the $\rho\,U^2$ scaling found for flows not feeling the Coriolis acceleration.

water, such as in a gentle mountain creek. Let the length scale for the finger be 10^{-2} m and the stream flow at a speed of $U \approx 0.1 - 1$ m s^{-1}. With the kinematic viscosity of water given by (page 75 of *Gill* (1982))

$$\nu_{\text{water}} = 10^{-6} \text{ m}^2 \text{ s}^{-1}, \tag{26.115}$$

our finger poking into the mountain stream is associated with a flow Reynolds number on the order of

$$\text{Re}_{\text{finger in stream}} = 10^3 - 10^4. \tag{26.116}$$

Evidently, mountain stream flow around a finger is at the lower end of the turbulent regime. We thus expect to see slightly turbulent whirls and eddies downstream from the finger.

Now consider an oceanographic length scale given by a Gulf Stream ring (see Figure 32.1) in which $L \approx 10^5$ m. Assuming the flow speed is on the same order as the mountain stream (good assumption) leads to a huge Reynolds number for Gulf Stream flow

$$\text{Re}_{\text{Gulf Stream}} = 10^{10} - 10^{11}. \tag{26.117}$$

For the atmosphere, we take $L = 10^6$ m for a typical atmospheric weather system, $U = 10$ m s^{-1} for the speed, and

$$\nu_{\text{air}} = 1.4 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}, \tag{26.118}$$

for the kinematic viscosity of air at standard pressure (page 75 of *Gill* (1982)). Given the larger length and velocity scales, the Reynolds number for large-scale atmospheric circulation features is

$$\text{Re}_{\text{weather system}} = 10^{12}. \tag{26.119}$$

Note that these large Reynolds numbers are associated with horizontal scales of geophysical flows. Vertical motions have much smaller L and U, so that the Reynolds number for vertical motions are significantly smaller than horizontal scales.

The above values for the Reynolds number from horizontal geophysical motions are huge relative to typical values found in engineering flows, with the large values arising from the large length scales of the flows. Large Reynolds numbers signal the minor role that molecular friction plays in large-scale geophysical fluid flows. Even so, molecular friction is the process leading to mechanical energy dissipation at the small scales. A fundamental feature of large Reynolds number flow is the presence of turbulent motions. Turbulent flows are highly nonlinear and affect a transfer of mechanical energy across length and time scales. This cascade leads to the dissipation of mechanical energy at the small scales. It is at the small scales that flow curvature can be large enough for the relatively tiny values of molecular viscosity to dissipate the energy, thus preventing an *ultraviolet catastrophe*; i.e., preventing the unbounded pile up of mechanical energy at the smallest scales.[13]

The ocean and atmosphere exhibit a huge variety of turbulent regimes, from the macroturbulence of quasi-geostrophic eddies to the microturbulence of boundary layers. Turbulence is not directly considered in this book. However, certain of its implications are identified in various places given that it is so basic to the ocean and atmosphere flows. *Vallis* (2017) offers a pedagogical entry point for the physics and maths of geophysical turbulence.

[13] Ultraviolet refers to the high wavenumber end of the flow spectrum. The name refers to the violet part of the visible electromagnetic spectrum, which has a higher wavenumber than the infrared part of the spectrum.

26.10 Stress on an interface

In this section we study the stress acting on an interface. This analysis applies to an arbitrary surface within a single media as well as for the boundary interface separating a liquid and a gas (air-sea boundary) or between a fluid and a rigid boundary (air-land or ocean-land). We ignore the effects from surface tension discussed in Section 26.11 since we are interested in length scales on the order of meters or larger (see in particular Section 26.11.5).

26.10.1 General formulation

Formulation of the stress boundary conditions follows from applying the finite volume momentum equation (26.66) to a cylindrical region straddling a moving interface such as that shown in Figure 26.7. The sides of the cylinder have thickness h and the top and bottom have area $\delta\mathcal{S}$. In the limit that the cylinder thickness goes to zero, the volume integrals in equation (26.66) vanish under the assumption of a smooth velocity field on both sides of the interface as well as smooth body forces. We are thus left with the constraint that the area integrated contact forces must vanish when integrated around the cylinder boundary

$$\oint_{\partial\text{cylinder}} [\mathbb{T} + \rho\,\boldsymbol{v}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v})]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \oint_{\partial\text{cylinder}} [-p\,\mathbb{I} + \mathbb{T} + \rho\,\boldsymbol{v}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v})]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0. \tag{26.120}$$

The end-caps on the cylinder vanish as $h\to 0$, in which case we have no constraint based on the stresses acting on the end-caps. Instead, the $h\to 0$ limit leads us to conclude that the contact force on one side of the interface is equal and opposite to that on the other side. This condition is a direct statement of the Newton's third law as manifest via the local equilibrium of stresses discussed in Section 26.2.2. For the stresses acting on the interface in Figure 26.7 we have

$$[-p_{\mathrm{A}}\,\mathbb{I} + \mathbb{T}_{\mathrm{A}} + \rho_{\mathrm{A}}\,\boldsymbol{v}_{\mathrm{A}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}})]\cdot\hat{\boldsymbol{n}}_{\mathrm{A}} + [-p_{\mathrm{B}}\,\mathbb{I} + \mathbb{T}_{\mathrm{B}} + \rho_{\mathrm{B}}\,\boldsymbol{v}_{\mathrm{B}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}})]\cdot\hat{\boldsymbol{n}}_{\mathrm{B}} = 0. \tag{26.121}$$

Setting $\hat{\boldsymbol{n}} = \hat{\boldsymbol{n}}_{\mathrm{B}} = -\hat{\boldsymbol{n}}_{\mathrm{A}}$ leads to

$$[-p_{\mathrm{A}}\,\mathbb{I} + \mathbb{T}_{\mathrm{A}} + \rho_{\mathrm{A}}\,\boldsymbol{v}_{\mathrm{A}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}})]\cdot\hat{\boldsymbol{n}} = [-p_{\mathrm{B}}\,\mathbb{I} + \mathbb{T}_{\mathrm{B}} + \rho_{\mathrm{B}}\,\boldsymbol{v}_{\mathrm{B}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}})]\cdot\hat{\boldsymbol{n}}, \tag{26.122}$$

which is an expanded expression of Newton's third law given by equation (26.5). Recall that we are ignoring surface tension, which means there is no pressure jump across the interface (see Section 26.11). Hence, setting $p_{\mathrm{A}} = p_{\mathrm{B}}$ allows us to cancel pressure thus leaving an interface stress condition involving just the frictional stress and kinetic stress

$$[\mathbb{T}_{\mathrm{A}} + \rho_{\mathrm{A}}\,\boldsymbol{v}_{\mathrm{A}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}})]\cdot\hat{\boldsymbol{n}} = [\mathbb{T}_{\mathrm{B}} + \rho_{\mathrm{B}}\,\boldsymbol{v}_{\mathrm{B}}\otimes(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}})]\cdot\hat{\boldsymbol{n}}, \tag{26.123}$$

which is sometimes more suitably written as

$$(\mathbb{T}_{\mathrm{A}} - \mathbb{T}_{\mathrm{B}})\cdot\hat{\boldsymbol{n}} = \boldsymbol{v}_{\mathrm{B}}\,[\rho_{\mathrm{B}}\,(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}})\cdot\hat{\boldsymbol{n}}] - \boldsymbol{v}_{\mathrm{A}}\,[\rho_{\mathrm{A}}\,(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}})\cdot\hat{\boldsymbol{n}}]. \tag{26.124}$$

Recall from Section 26.3 that $\mathbb{T}_{\mathrm{A}}\cdot\hat{\boldsymbol{n}}$ and $\mathbb{T}_{\mathrm{B}}\cdot\hat{\boldsymbol{n}}$ pick out that portion of the frictional stress tensor that acts on a surface whose outward normal is $\hat{\boldsymbol{n}}$. We now consider some examples to unpack the boundary condition (26.124).

FIGURE 26.7: An infinitesimal cylindrical region used in formulating the stress boundary condition at an interface. The interface can be one that separates two fluid regions with densities ρ_{A} and ρ_{B}. It can also represent the boundary between a fluid (region A) and solid (region B). The interface generally moves with velocity $\boldsymbol{v}^{(b)}$. We orient the interface through the outward normals according to (recall h is infinitesimal) $\hat{\boldsymbol{n}} = \hat{\boldsymbol{n}}_{\mathrm{B}} = -\hat{\boldsymbol{n}}_{\mathrm{A}}$, so that the outward normal for region A points into region B whereas the outward normal for region B points into region A. For this particular interface, the normal direction has a nonzero projection in the vertical, $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} \neq 0$, thus allowing us to define the interface vertical position according to $z = \eta(x, y, t)$. This interface represents an idealized geometry useful to formulate the stress condition at the boundary between fluid media, such as the air-sea interface, fluid-land interface, or interior fluid interface (e.g., buoyancy surface). The single geometric assumption is that there are no overturning motions so that $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} \neq 0$, with this assumption based on convenience. The stress condition is general and so does not require this assumption.

26.10.2 Solid material boundary

Consider a solid material boundary through which no matter crosses. Let region B be the solid side of the interface and region A the fluid side (region A is either the ocean or atmosphere). The material nature of the boundary means that no matter crosses it, in which case (see Section 20.4.2)

$$(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}}) \cdot \hat{\boldsymbol{n}} = (\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}}) \cdot \hat{\boldsymbol{n}} = 0. \tag{26.125}$$

A nonzero $\boldsymbol{v}^{(b)}$ corresponds here to a moving solid boundary, such as the region next to the grounding line of an ice-shelf. More commonly, in geophysical fluid applications we have $\boldsymbol{v}^{(b)} = 0$ for solid boundaries. In either case, there is no contribution from the kinetic stress so that the stress condition (26.123) reduces to

$$\mathbb{T}_{\mathrm{A}} \cdot \hat{\boldsymbol{n}} = \mathbb{T}_{\mathrm{B}} \cdot \hat{\boldsymbol{n}} \Longleftrightarrow \mathbb{T}_{\mathrm{A}} \cdot \hat{\boldsymbol{n}}_{\mathrm{A}} = -\mathbb{T}_{\mathrm{B}} \cdot \hat{\boldsymbol{n}}_{\mathrm{B}}. \tag{26.126}$$

This identity is consistent with
