$$\mathbb{T}_{\mathrm{A}} \cdot \hat{\boldsymbol{n}} = \boldsymbol{\tau}^{\text{friction A}}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}) = -\boldsymbol{\tau}^{\text{friction A}}(\boldsymbol{x}, t, -\hat{\boldsymbol{n}}) = \mathbb{T}_{\mathrm{B}} \cdot \hat{\boldsymbol{n}} = \boldsymbol{\tau}^{\text{friction B}}(\boldsymbol{x}, t, \hat{\boldsymbol{n}}), \tag{26.127}$$

which expresses Newton's third law in the form of Cauchy's principle in equation (26.5). Hence, the frictional force imparted by the land on the fluid is equal and opposite to that imparted by the fluid on the land.

26.10.3 No-slip condition at a static boundary

At solid boundaries, the kinematic boundary condition from Section 20.4.1 sets the normal component of the velocity to zero[14]

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{kinematic no-flux condition on static material boundary.} \tag{26.128}$$

However, kinematic is unable to specify the tangential component of the velocity along a solid boundary. What is it?

[14] For convenience we here assume the solid boundary is static. Generalizations to moving solid boundaries are straightforward, requiring one to merely replace $\boldsymbol{v}$ with $\boldsymbol{v} - \boldsymbol{v}^{(b)}$ in the results of this subsection.

FIGURE 26.8: The no-slip boundary condition means that fluid has a zero tangential velocity component at the solid-fluid boundary, $\boldsymbol{v} \cdot \hat{\boldsymbol{t}} = 0$. Together, the kinematic no-normal flow boundary condition, $\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0$, plus the dynamic no-slip boundary condition, $\boldsymbol{v} \cdot \hat{\boldsymbol{t}} = 0$, mean that the fluid sticks to the solid boundary. That is, the fluid particle velocity vanishes at a solid boundary when the no-slip condition holds.

Laboratory experiments over the 19th and 20th centuries indicate that there is no relative motion of molecules at solid-fluid interfaces.[15] That is, a fluid at the solid-fluid interface has a velocity matching that of the solid so that the fluid sticks to the solid boundary as depicted in Figure 26.8. The no-slip boundary condition means that both the normal and tangential components of the fluid velocity vanish next to static solid boundaries

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v} \cdot \hat{\boldsymbol{t}} = 0 \qquad \text{no-slip condition on static solid boundaries.} \tag{26.129}$$

The no-slip boundary condition gives rise to an exchange of momentum between the solid and fluid, with this exchange mediated by viscosity. This boundary condition is the origin of the tangential stresses found in the Couette flow discussed in Section 26.8.2. In the absence of viscous friction, as per an inviscid perfect fluid, the no-slip boundary condition cannot be imposed since doing so would mathematically over-specify the flow. Consequently, for inviscid fluids the tangential component of the velocity remains unspecified at solid boundaries.

26.10.4 Lagrangian interface

Consider a Lagrangian interface within the fluid, with this interface defined so that

$$(\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{A}}) \cdot \hat{\boldsymbol{n}} = (\boldsymbol{v}^{(b)} - \boldsymbol{v}_{\mathrm{B}}) \cdot \hat{\boldsymbol{n}} = 0. \tag{26.130}$$

This condition is identical to the solid material boundary condition (26.125), so that the kinetic stress contribution to equation (26.123) vanishes. We thus have the frictional stress condition (26.126) and a Newton's third law interpretation (26.127), yet now the frictional transfer takes place between two regions of the same fluid.

26.10.5 Permeable interface

Now allow for the interface to be permeable to matter, with matter conservation meaning that

$$\rho_{\mathrm{A}} (\boldsymbol{v}_{\mathrm{A}} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} = \rho_{\mathrm{B}} (\boldsymbol{v}_{\mathrm{B}} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}}. \tag{26.131}$$

[15] As discussed in the historical essay by *Anderson* (2005), it was the work of Prandtl in 1905 that first exposed the fundamental nature of the no-slip boundary condition, and its role in establishing boundary layers around solid bodies immersed in a fluid flow.

The kinetic stress thus adds to the frictional contribution in the stress boundary condition (26.123), with the kinetic stress providing a transfer of momentum across the interface through the transfer of matter that carries a nonzero linear momentum. Rearrangement of the stress boundary condition (26.123) with use of mass conservation (26.131) leads to

$$(\mathbb{T}_{\mathrm{A}} - \mathbb{T}_{\mathrm{B}}) \cdot \hat{\boldsymbol{n}} = (\boldsymbol{v}_{\mathrm{A}} - \boldsymbol{v}_{\mathrm{B}}) \left[\rho_{\mathrm{A}} \left(\boldsymbol{v}_{\mathrm{A}} - \boldsymbol{v}^{(b)}\right) \cdot \hat{\boldsymbol{n}}\right]. \tag{26.132}$$

We unpack this boundary condition by considering two cases.

Single continuous fluid media

If the interface is within a single continuous fluid media, then $\boldsymbol{v}_{\mathrm{A}} = \boldsymbol{v}_{\mathrm{B}}$ so that the frictional stress tensor boundary condition (26.126) again holds: $(\mathbb{T}_{\mathrm{A}} - \mathbb{T}_{\mathrm{B}}) \cdot \hat{\boldsymbol{n}} = 0$.

Air-sea boundary interface

Consider now the air-sea boundary where region B is the ocean and region A the atmosphere. Introduce the dia-surface mass flux according to equation (20.63)

$$\rho_{\mathrm{A}} \left(\boldsymbol{v}_{\mathrm{A}} - \boldsymbol{v}^{(b)}\right) \cdot \hat{\boldsymbol{n}} = \rho_{\mathrm{B}} \left(\boldsymbol{v}_{\mathrm{B}} - \boldsymbol{v}^{(b)}\right) \cdot \hat{\boldsymbol{n}} = -\mathcal{Q}_{\mathrm{m}}, \tag{26.133}$$

where $\mathcal{Q}_{\mathrm{m}}$ is the mass per time per surface area crossing the boundary. The minus sign is implied by the convention that $\mathcal{Q}_{\mathrm{m}} > 0$ means that mass enters the ocean side of the interface and leaves the atmosphere side. The stress boundary condition (26.132) takes the form

$$(\mathbb{T}_{\mathrm{atm}} - \mathbb{T}_{\mathrm{ocn}}) \cdot \hat{\boldsymbol{n}} = -(\boldsymbol{v}_{\mathrm{atm}} - \boldsymbol{v}_{\mathrm{ocn}})\, \mathcal{Q}_{\mathrm{m}} \tag{26.134}$$

We might consider the velocity of the atmosphere to be unequal to that of the ocean, in which case the surface normal projection of the frictional stress tensor satisfies a jump condition in the presence of mass transport across the air-sea interface. However, following Section 1.9 of *Batchelor* (1967), available evidence suggests that when approaching the boundary interface, the velocity of the two media match, both their normal and tangential components. In this case we again return to the friction boundary condition (26.126), in which the normal projection of the frictional stress tensors match, even in the presence of mass transport across the boundary.

26.10.6 Summary comments

There are three terms in the general expression for the stress boundary condition (26.122), with contributions from pressure, friction, and kinetic stress. In the absence of surface tension (Section 26.11), pressure is continuous at the interface; i.e., its value is the same on both sides of the interface. In the absence of mass transport across the interface, then we find a continuous kinetic stress at the interface that then leads to a continuous frictional stress. However, mass transport crossing the interface leads to a jump in the friction for those cases where velocity has a jump across the interface. Even so, empirical evidence suggests that the velocity has no jump across the interface, in which case there is no jump in the normal stress.

The subject of boundary conditions for momentum are not simple, particularly in the presence of mass transport across the boundary. We have only briefly touched on the topic, with similar discussions provided by Section 1.9 of *Batchelor* (1967) and Section 4.10 of *Kundu et al.* (2016). Specialized treatments are needed when pursuing these topics in more detail.

26.10.7 Comments on boundary layers

A fundamental advance in the relevance of fluid mechanics for describing observed flows came from the 20th century work of Prandtl and others who noted the central role of viscosity, even the tiny molecular values, in forming boundary layers when fluids flow next to rigid bodies.[16] Prandtl's work focused on flows around airplane wings, thus supporting the development of aerodynamics as a scientific and engineering discipline. The key ideas transfer to geophysical flows where boundary layers form in the atmosphere and ocean as these fluids interact with the solid earth. Boundary layers also form where the atmosphere and ocean interact with one another.

A key facet of geophysical boundary layers concerns the dominance of turbulence in producing an eddy viscosity that is many orders larger than molecular viscosity. Indeed, molecular viscosity plays a role only in a very small region (the *laminar subregion*) immediately adjacent to the boundary. In contrast, the bulk of the boundary layer is dominated by turbulent flows. In Chapter 34 we study geophysical boundary layers that are affected by pressure, Coriolis, and turbulence induced friction. The role of rotation distinguishes geophysical boundary layers from engineering applications. The associated *Ekman boundary layers* are crucial for understanding circulation and transport in both the atmosphere and ocean.

26.11 Surface tension

Surface tension is present on surfaces between two immiscible liquids, between a liquid and gas, or between a fluid and a solid. It arises from the anisotropic forces acting on molecules that are within a mean free path distance from the surface, and generally leads to a resistance to forces that act to increase the surface area. Surface tension has many consequences that are part of our common experience. For example, it allows certain insects to walk on water even though their body density is greater than water. It also accounts for the predominantly spherical shape of rain drops and gas bubbles in liquids. Surface tension also gives rise to capillary waves when there is a very slight breeze on the ocean surface, or when a tiny stone is thrown into a still pond (gravity waves dominate for larger stones). We further discuss capillary waves in Section 50.10. In the present section we focus on the classical physics of surface tension.[17]

26.11.1 Capillary tube

As an introduction to surface tension, consider that atmospheric pressure at the earth's surface is roughly $p_{\text{atm}} = 10^5 \text{ N m}^{-2}$. As we saw in Section 26.8, pressure acts normal to a surface regardless the surface orientation. So fill a container of water whose weight per horizontal area is less than the atmospheric pressure, $\rho\, g\, h < p_{\text{atm}}$ and turn the container upside-down as in Figure 26.9. Does the water spill from the container? Common experience with drinking glasses indicate that water will spill. But what about containers with a very small cross-sectional area such as the pipettes used in chemistry laboratories? Pipettes, or more generally capillary tubes, hold the liquid regardless the orientation. They do so since their cross-sectional area is small enough to allow forces from surface tension to overcome gravitational instabilities acting at the liquid-gas interface. We return to this point in Section 56.3.3 when studying the *Rayleigh-Taylor* instability in the presence of

[16] For a historical treatement of boundary layer theory see *Anderson* (2005), or for a pedagogical study see *Tennekes and Lumley* (1972). The associated mathematical methods of singular perturbation theory and matched asymptotic expansions (e.g., *Dyke* (1975)) offer an example of how the study of physical systems can spawn the development of new mathematical methods.

[17] A first principles understanding of surface tension involves tools from physical chemistry that are outside of our scope. Instead, we here develop the subject phenomenologically.

surface tension. In the remainder of this section we discuss elements of surface tension with the goal to develop intuition as well as to determine the length scales where it becomes important.

FIGURE 26.9: A container of water with density ρ and height h is placed upside-down. Atmospheric pressure, $p_{\rm atm}$, will support water with thickness $h < p_{\rm atm}/(\rho\, g) \approx 10$ m if the cross-sectional area of the container is small enough to allow for surface tension to overcome the gravitationally unstable waves that otherwise allow water to spill from the container. The liquid-gas interface supports both gravity waves (Section 50.3) and capillary waves (Section 50.10). If the wavelength is small enough then surface tension suppresses the growth of unstable gravity waves so that the liquid remains within the *capillary tube*. However, for longer waves allowed by increasing the cross-sectional area, then fluctuations will allow the gravitational instability to overcome surface tension, thus breaking the interface and releasing water.

26.11.2 Force balance on an air-water interface

Consider two fluids with distinct densities. Air and water provide one example of special importance to understanding physics at the ocean-atmosphere boundary. Another example concerns two immiscible layers of water within the ocean or two layers of air within the atmosphere. For molecules well within either of the fluid regions, the intermolecular forces are statistically isotropic. In contrast, intermolecular forces are not isotropic for molecules within a mean free path distance from the interface.[18] Attractive (cohesive) intermolecular (van der Waals) forces dominate within a liquid whereas gas molecules generally feel more repulsive forces. Hence, a liquid molecule within the liquid-gas interface preferentially experiences an attractive force towards the liquid side of the interface, as depicted in Figure 26.10. Surface tension arises from the cohesive force per area acting between molecules in a direction that parallels the interface, with surface tension acting to resist perturbations to the interface shape.

Anisotropic attractive intermolecular forces cause the interface between the two fluids to behave as a stretched membrane that experiences a tensile force resisting any stretching of the interface. The magnitude of the tensile force per unit length (or energy per unit area) is the *surface tension*, γ (SI units N m^{-1} = kg s^{-2}). The surface tension is a property of the two fluids, including their temperature, as well as any impurities that might be included on the interface; e.g., oil on the surface of water effects properties of the capillary waves found on the air-sea interface (see Section 50.10). In the following we focus on the liquid-gas example to be specific and to expose issues that arise in studies of the air-sea interface. For a liquid-gas interface surrounding a liquid drop, the tensile force acts to curve the interface towards the liquid into a spherical shape.

[18] As discussed in Section 17.2, the mean free path is a statistical measure of the distance a molecule moves before hitting another molecule.

FIGURE 26.10: Surface tension at a liquid-gas interface arises from the anisotropic cohesive forces acting on liquid molecules within a mean-free-path distance, L_{mfp}, from the interface, which contrasts to the isotropic cohesive forces acting away from the interface. The net intermolecular force vanishes for interior molecules, whereas the net force acts inward on molecules at the interface. Surface tension refers to the cohesive force per area acting between molecules in a direction that is parallel to the interface.

The tensile force along a line segment is directed normal to the line and tangent to the interface

$$\boldsymbol{f}_{\mathrm{interface}} = -\gamma\, \hat{\boldsymbol{n}} \times \delta \boldsymbol{x}, \tag{26.135}$$

where $\hat{\boldsymbol{n}}$ is a normal vector pointing towards the center of the curved interface, and $\delta \boldsymbol{x}$ is a line element oriented so that the normal $\hat{\boldsymbol{n}}$ points to the left facing in the direction of the line increment. Figure 26.11 depicts the surface tensile forces acting on the surface of a spherical bubble of water. Note that it is sometimes useful to consider the product $\gamma\, \mathrm{d}\mathcal{S}$ as the work (units of N m^{-1} = Joule) required to create an area, $\mathrm{d}\mathcal{S}$, on the interface. We make use of this energetic perspective in Section 26.11.3.

To develop an expression for the pressure jump across the liquid-gas interface, consider a spherical droplet of radius R shown in Figure 26.11 and focus on the circular cross-section cut through the center of the sphere. The net tensile force acting on the circumference of the circle is

$$\boldsymbol{F}_{\mathrm{circle}} = \oint_{\mathrm{circle}} \boldsymbol{f}_{\mathrm{interface}} = -\oint_{\mathrm{circle}} \gamma\, \hat{\boldsymbol{n}} \times \delta \boldsymbol{x} = -2\pi R\, \gamma\, \hat{\boldsymbol{z}}. \tag{26.136}$$

Equilibrium of the spherical droplet is realized by a pressure jump across the circular cross-sectional area

$$\pi R^2 \left(p_{\mathrm{in}} - p_{\mathrm{out}}\right) = 2\pi R\, \gamma \Longrightarrow \left(p_{\mathrm{in}} - p_{\mathrm{out}}\right) = 2\gamma/R. \tag{26.137}$$

Hence, the pressure jump is determined by the surface tension (a property of the two fluids) and the curvature of the sphere, R, which is also the radius of curvature for the sphere. Pressure is higher inside of the sphere (i.e., on the concave side of the interface), with this pressure required to balance the pressure outside the sphere plus the surface tension. Notably, equilibrium for smaller bubbles (with $R \to 0$) requires a larger pressure difference than for larger bubbles.

The pressure jump is known as the *capillary pressure*. It arises from surface tension and curvature of the interface. The relation (26.137) is a special case of the *Young-Laplace formula*, specialized here to a sphere.

26.11.3 Young-Laplace formula

We garner added insight into the physics of surface tension by considering the energetics required to enable a virtual displacement of a surface through a pressure field along with the work required

FIGURE 26.11: Surface tension on a spherical water droplet, with water on the inside of the sphere and air on the outside. The tensile forces act parallel to the spherical interface between the water and air. When cutting a circular cross-section as shown here, the surface tensile force acts downward. In equilibrium, the net tensile forces acting downward along the circumference of the hemisphere ($2\pi R\,\gamma$) are balanced by a pressure jump across the droplet, with the interior pressure larger than the exterior pressure. Focusing on the circular cross-section, this area remains static so long as $2\pi R\,\gamma = \pi R^2\,(p_{\rm in} - p_{\rm out})$, leading to a pressure jump across the droplet interface $p_{\rm in} - p_{\rm out} = 2\,\gamma/R$. This result is general: namely, according to the Young-Laplace formula (26.147), pressure is greater on the concave side of the interface than on the convex side.

to change the area of the surface. The resulting equation for the pressure jump across the surface is referred to as the *Young-Laplace formula*, which expresses the pressure jump in terms of the surface tension and the principle radii of curvature for the surface.

Consider a horizontal surface depicted in Figure 26.12 that represents the interface seperating fluid-A from fluid-B, with $\hat{\boldsymbol{n}}$ a unit normal vector oriented from fluid-A to fluid-B. Now consider a virtual displacement of each point along the interface by an infinitesimal distance, $\delta h = \eta(x, y, t)$, with $\hat{\boldsymbol{n}}\,\delta h$ connecting points on the initial position of the interface to the displaced position, where $\delta h > 0$ if the displacement is directed towards fluid-B and $\delta h < 0$ if directed towards fluid-A. The (signed) volume swept out by an infinitesimal area $\mathrm{d}A$ is given by $\delta h\,\mathrm{d}A$. There are two forms of work required to move the surface: pressure work required to change the fluid volume and area work required to change the surface area. The pressure work is given by

$$W_{\rm volume} = -p_{\rm A}\,\delta V_{\rm A} - p_{\rm B}\,\delta V_{\rm B} = (p_{\rm B} - p_{\rm A})\,\delta V_{\rm A} = (p_{\rm B} - p_{\rm A})\,\delta h\,\mathrm{d}A, \tag{26.138}$$

where we set $\delta V_{\rm A} = -\delta V_{\rm B} = \delta h\,\mathrm{d}A$. For example, if $p_{\rm B} > p_{\rm A}$ and the displacement is into fluid-B ($\delta h > 0$), then $W_{\rm volume} > 0$. We thus find that $W_{\rm volume} > 0$ to displace the surface into the fluid region with higher pressure, whereas $W_{\rm volume} < 0$ if displacing the interface into a region with lower pressure.

In the presence of surface tension, work is needed to change to the interface area

$$W_{\rm area} = \gamma\,\delta A, \tag{26.139}$$

where δA is the change in area of an infinitesimal element on the interface

$$\delta A = \mathrm{d}\mathcal{S} - \mathrm{d}A \tag{26.140a}$$

$$= \mathrm{d}A\,\left[\sqrt{1 + (\nabla\delta h)^2} - 1\right] \tag{26.140b}$$

$$\approx \mathrm{d}A\,(\nabla\delta h)^2/2. \tag{26.140c}$$

To reach this result we made use of equation (7.33) that relates the area of an infinitesimal element on a curved surface to the area of its horizontal projection (see Section 7.3.1). We next make use of the surface curvature detailed in Section 7.3.2, where equation (7.38) shows that the vertical

FIGURE 26.12: Left panel: initial position of a material interface separating two fluid regions, fluid-A and fluid-B. Right panel: infinitesimal displacement of the interface sweeps out a volume in space, here depicted with the interface moving upward. To determine the volume, extend a unit normal vector, $\hat{\boldsymbol{n}}$, from the initial interface position and pointing towards fluid-B. For this example, $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$. Let $\delta h = \eta$ be the distance along that normal to the new position, with $\delta h > 0$ if the displacement moves towards fluid-B and $\delta h < 0$ for displacements pointing to fluid-A. We assume that displacements at each interface point can move independently of adjacent points, so that the interface area generally changes. The Young-Laplace formula (26.147) says that the pressure jumps when crossing an interface that is subject to surface tension, with pressure higher on the concave side. In this example, Young-Laplace says pressure is higher on the Fluid-A side since that it is the concave side.

displacement is given, for small displacements, by

$$-\delta h \approx \frac{1}{2}\, R_1^{-1}\, (\boldsymbol{x} \cdot \boldsymbol{e}_1)^2 + \frac{1}{2}\, R_2^{-1}\, (\boldsymbol{x} \cdot \boldsymbol{e}_2)^2. \tag{26.141}$$

R_1^{-1}, R_2^{-1} are the eigenvalues and $\boldsymbol{e}_1, \boldsymbol{e}_2$ are the corresponding eigenvectors of the matrix of second partial derivatives of $\delta h(x, y)$, whereas the inverse eigenvalues, R_1, R_2, are the radii of curvature of the displaced surface. To get signs correct, it is important to note that the radius of curvature is positive if the surface curves towards the outward normal direction, and negative otherwise (see Figure 7.5). For the example depicted in the right panel of Figure 26.12, and both radii of curvature are negative since the surface curves away from the outward normal (pointing from A to B). This convention explans the minus sign on the left side of equation (26.141).

Orienting the Cartesian axes along the eigenvector directions renders

$$(\nabla \delta h)^2 \approx (x/R_1)^2 + (y/R_2)^2 = (-\delta h)\, \left[\frac{1}{R_1} + \frac{1}{R_2}\right], \tag{26.142}$$

where we set

$$(-\delta h)/R_1 = (x/R_1)^2 \qquad \text{and} \qquad (-\delta h)/R_2 = (y/R_2)^2. \tag{26.143}$$

We are thus led to the area difference

$$\delta A \approx \mathrm{d}A\, (-\delta h)\, \left[\frac{1}{R_1} + \frac{1}{R_2}\right]. \tag{26.144}$$

Note that $\delta A > 0$ whether displacing the surface into a concave or convex direction, since the sign of δh accounts for the sign of the radii of curvature. For small displacements of the surface from its horizontal position, equation (7.41) allows us to connect the radii of curvature for a surface with the Laplacian of the displacement of the surface, in which case equation (26.144) takes on the form

$$\delta A \approx -\mathrm{d}A\, \delta h\, \nabla^2(\delta h). \tag{26.145}$$

Total work for the interface displacement is given by the sum of the area work and volume

work

$$W_{\text{area}} + W_{\text{volume}} = \mathrm{d}A\,\delta h\,\left[-\gamma\,(R_1^{-1} + R_2^{-1}) + p_{\text{B}} - p_{\text{A}}\right] = \mathrm{d}A\,\delta h\,\left[-\gamma\,\nabla^2\eta + p_{\text{B}} - p_{\text{A}}\right], \quad (26.146)$$

and equilibrium results if the net work vanishes, in which case

$$p_{\text{B}} - p_{\text{A}} = \gamma\,(R_1^{-1} + R_2^{-1}) = \gamma\nabla^2\eta, \quad (26.147)$$

where we set $\delta h = \eta$ as per Figure 26.12. This equation is the *Young-Laplace* formula, which reduces to equation (26.137) if $R_1 = R_2$ as for a sphere. It says that there is a pressure jump, known as the *capillary pressure*, across an interface as given by the surface tension times the sum of the inverse principle radii of curvature, or equivalently the surface tension times the Laplacian of the displacement. To help remember signs, note that the Young-Laplace formula (26.147) says that the pressure on the concave side of an interface is higher than on the convex side. Hence, pressure is higher on the inside of a bubble/droplet. For the example depicted in Figure 26.12, $\nabla^2\eta < 0$ since the surface is a local maximum, in which case $p_{\text{A}} > p_{\text{B}}$ since fluid A is on the concave side of the interface.

26.11.4 Soluble gas bubbles inside water

The previous considerations hold whether there is liquid or gas inside a spherical bubble or drop. As an example, consider a spherical gas bubble of radius $R = 10^{-6}$ m inside water and make use of the air-water surface tension $\gamma = 0.072$ N m^{-1} = 0.072 kg s^{-2}. We thus find the pressure jump is

$$p_{\text{in}} - p_{\text{out}} = 2\,\gamma/R \approx 144 \times 10^3 \text{ N m}^{-2} = 1.42\,p_{\text{atm}}, \quad (26.148)$$

where $p_{\text{atm}} = 1.01 \times 10^5$ N m^{-2} is standard atmospheric pressure. If the gas inside the bubble is water soluble, then the enhanced pressure inside the bubble will induce more gas to dissolve in the water, which in turn will cause the bubble to shrink and thus increase the pressure inside the bubble. Small bubbles of soluble gases can thus be squeezed towards zero radius by the effects of surface tension induced pressure.

26.11.5 When we can ignore surface tension

The sizable pressure jump (26.148) arises from the tiny radius of curvature of the bubble, with the pressure jump decreasing as the bubble radius increases. Rather than a bubble, consider an ocean surface capillary-gravity wave, such as those observed from a boat (e.g., Sections 50.3 and 50.10). Such waves may have wavelength on the order of 10^{-2} m or longer. If we set the radius of curvature to $R \sim 10^{-2}$ m, then equation (26.148) finds an entirely negligible pressure jump of $\Delta p \approx 10^{-4}\ p_{\text{a}}$.

Most geophysical fluid motion of concern in this book is associted with material interfaces having a radius of curvature on the order of meters or larger. It is for this reason that surface tension is generally ignored when studying geophysical fluid motion. That is, we can safely assume there is no pressure jump when approaching an interface between two fluid media, or between a fluid and a solid boundary. This discussion then justifies the approach considered in Section 26.10 when studying stresses at interfaces, in which we made use of Newton's third law at the interface.

Even so, the role of surface tension is central to the fundamental mechanisms of how matter, momentum, and energy are transferred across the air-sea interface. Relatedly, as we show in Section 50.10, capillary waves arise from surface tension, with capillary waves the initial response of the ocean free surface upon the imposition of a wind stress.

26.11.6 Further study

This 30-minute video from Prof. Trefethen provides a pedagogical summary of surface tension. The upside-down container of water in Figure 26.9 is based on a discussion of capillary-gravity waves in Section 3.1.3 of *Falkovich* (2011). We study capillary-gravity waves in Section 50.10. Section 1.9 of *Batchelor* (1967) discusses how surface tension acts between two fluid media, with that discussion extended into his Section 3.3 to develop boundary conditions for velocity and stress. The bubble example in Section 26.11.4 is taken from Section 1.3 of *Kundu et al.* (2016). Section 4.10 of *Kundu et al.* (2016) provides a detailed accounting of the force balance at an interface, offering more details than found in *Batchelor* (1967). The energetic arguments used to derive the Young-Laplace formula follows Section 61 of *Landau and Lifshitz* (1987). Section 46 of *Fetter and Walecka* (2003) discuss the dynamics of membranes under tension.

26.12 Exercises

EXERCISE 26.1: FORCE BALANCE FOR A NON-ACCELERATING TANGENT PLANE OCEAN

Consider an ocean basin, $\mathcal{R}$, on the rotating tangent plane as in Figure 26.2, with bottom interface separating the ocean fluid from the solid-earth, and upper interface separating the ocean fluid from the atmosphere, and where the atmosphere has a nonzero mass.[19] Assume no matter crosses the ocean boundaries; i.e., no evaporation, precipitation, nor river runoff. Hence, the ocean domain maintains a fixed mass

$$M = \int_{\mathcal{R}} \rho \, \mathrm{d}V \tag{26.149}$$

as well as fixed matter. In this case, the ocean domain is materially closed and so its center of mass position

$$\boldsymbol{X}^{\mathrm{com}} = M^{-1} \int_{\mathcal{R}} \boldsymbol{x} \, \rho \, \mathrm{d}V \tag{26.150}$$

has a velocity given by

$$\frac{\mathrm{d}\boldsymbol{X}^{\mathrm{com}}}{\mathrm{d}t} = M^{-1} \int_{\mathcal{R}} \boldsymbol{v} \, \rho \, \mathrm{d}V, \tag{26.151}$$

and corresponding acceleration

$$\frac{\mathrm{d}^2\boldsymbol{X}^{\mathrm{com}}}{\mathrm{d}t^2} = M^{-1} \int_{\mathcal{R}} \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} \, \rho \, \mathrm{d}V. \tag{26.152}$$

Apply a turbulent stress over the ocean surface with a horizontal stress vector $\boldsymbol{\tau}^{\mathrm{surf}}$, with this stress leading to motion of the ocean fluid. Allow for the ocean bottom to exchange momentum with the static solid-earth through a horizontal bottom turbulent stress, $\boldsymbol{\tau}^{\mathrm{bott}}$. Assume there are no vertical components to $\boldsymbol{\tau}^{\mathrm{surf}}$ and $\boldsymbol{\tau}^{\mathrm{bott}}$. Also use Cartesian coordinates so that Cartesian vector/tensor analysis is sufficient for this tangent plane analysis.

(a) What is the force balance for the full ocean domain if the center of mass experiences no acceleration. Express the corresponding force balance in words and in equations. Expose the contact forces arising from pressure and from turbulent stresses, as well as the body forces from Coriolis and gravity. The answer should be generally stated, with no need for specific

[19] In some applications it is suitable to assume a zero mass atmosphere. For this exercise, however, we do not make that assumption.

details. Hint: consider Figure 26.2 and include the missing forces to this diagram. Mathematically express the force balance as an integral expression as per the weak formulation of fluid mechanics (see Section 18.2).

(b) Express the vertical component of the force balance assuming the fluid is in an approximate hydrostatic balance, meaning that the pressure and gravitational forces are balanced.[20]

(c) Consider an ocean without any turbulent contact stresses at the boundaries, $\boldsymbol{\tau}^{\text{surf}} = \boldsymbol{\tau}^{\text{bott}} = 0$ and assume there is no motion anywhere in the fluid. What integral constraints are satisfied by the horizontal components of the pressure contact force? Hint: recall equations equations (26.39a) and (26.39b). Also note assume that the free surface is flat, which is consistent with the absence of motion.

(d) Assume the ocean is on an f-plane (Section 25.5) so that $\boldsymbol{\Omega} = \hat{\boldsymbol{z}}\,\Omega = \hat{\boldsymbol{z}}\,(f/2)$ is a constant vector. Also assume that the center of mass velocity vanishes, $\int_{\mathcal{R}} \rho\,\boldsymbol{v}\,\mathrm{d}V = 0$. Discuss the resulting zonal and meridional force balance. Hint: one of the forces appearing in part (a) now vanishes.

[20] In Section 28.2 we provide a discussion of when this approximation is appropriate for moving fluids. That discussion is not needed for the current exercise. Instead, we merely assume the vertical momentum balance is hydrostatic.

Chapter 27

Energy and entropy in a moving fluid

In this chapter we study the energetics of fluid flow. In particular, we are concerned with how energy is partitioned between the mechanical energy of macroscopic motion and the internal energy associated with internal degrees of freedom. To fully specify energy in fluid flows requires us to study the flow of entropy and the associated constraints arising from the second law of thermodynamics. For this purpose we extend the equilibrium thermodynamics of Chapters 23 and 24 to include time dependent moving fluid phenomena. Making this transition requires the hypothesis of *local thermodynamic equilibrium*.

READER'S GUIDE FOR THIS CHAPTER

This chapter builds from the momentum dynamics of Chapter 25 and the thermodynamics of Chapters 23 and 24. In addition to developing the budgets for mechanical energy and total energy (mechanical plus internal), we derive budgets for entropy and potential enthalpy. A particularly important practical outcome of this chapter concerns the derivation of the equation for potential enthalpy or Conservative Temperature, with this equation completing the suite of fundamental equations describing the evolution of a geophysical fluid.

- Potential energy as per Section 108 of *Landau and Lifshitz* (1980)

27.2 Gravitational potential energy

Geophysical fluids move within a gravitational field created by the mass of the planet, including the mass of the fluid itself. We typically focus on a rather simple form for the effective gravitational acceleration exemplified by the geopotential $\Phi = g\,z$, where g is the gravitational acceleration that includes effects from both central gravity plus planetary centrifugal (Section 13.10.4). However, we offer some discussion of astronomical tide producing forces in Chapter 35, whereby the geopotential is a more complicated function of space and time, $\Phi(\boldsymbol{x}, t)$. In this section we study the potential energy of a fluid element due to its presence in a gravitational field, with the geopotential providing the effective gravitational potential energy per mass of fluid elements.[1]

27.2.1 Material evolution

The gravitational potential energy per mass of a fluid element is given by the geopotential, Φ, so that the gravitational potential energy is $\Phi\,\rho\,\delta V$. Hence, the evolution of potential energy for a constant mass fluid element is given by

$$\frac{\mathrm{D}(\Phi\,\rho\,\delta V)}{\mathrm{D}t} = \rho\,\delta V\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}, \tag{27.1}$$

where $\mathrm{D}(\rho\,\delta V)/\mathrm{D}t = 0$ since the fluid element has a constant mass. The material time derivative for the geopotential

$$\frac{\mathrm{D}\Phi}{\mathrm{D}t} = \frac{\partial\Phi}{\partial t} + \boldsymbol{v}\cdot\nabla\Phi, \tag{27.2}$$

contains a local time dependence that arises from astronomical tide forcing or movement of mass on the planet (Chapter 35). As further explored in Section 27.4, the advective term represents an exchange of mechanical energy between the kinetic energy contained in fluid motion and the gravitational potential energy due to the fluid being within a gravitational field. This energy exchange arises from fluid motion across constant geopotential surfaces. For example, motion up the geopotential gradient, $\boldsymbol{v}\cdot\nabla\Phi > 0$, increases gravitational potential energy and motion down the geopotential gradient decreases potential energy. With the geopotential $\Phi = g\,z$, we have

$$\boldsymbol{v}\cdot\nabla\Phi = g\,w, \tag{27.3}$$

so that vertically upward motion ($w > 0$) increases potential energy.

27.2.2 Flux-form potential energy equation

Another way to reveal the same ideas is to make use of the kinematic identity (20.35c), so that the density weighted material time derivative of the geopotential is given by

$$\rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t} = \partial_t(\rho\,\Phi) + \nabla\cdot(\rho\,\boldsymbol{v}\,\Phi). \tag{27.4}$$

For the simple geopotential, $\Phi = g\,z$, we thus find

$$\rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t} = \rho\,g\,w \Longleftrightarrow \partial_t(\rho\,\Phi) + \nabla\cdot(\rho\,\boldsymbol{v}\,\Phi) = \rho\,g\,w. \tag{27.5}$$

[1] In this chapter we generally refer to the more concise "gravitational potential energy" or even briefer "potential energy" rather than "potential energy from the effective gravitational field."

27.2.3 Reference geopotential

There is no change to the energetics if we modify the gravitational reference state by modifying the geopotential

$$\Phi \to \Phi + \Phi_{\mathrm{r}} \tag{27.6}$$

with Φ_{r} an arbitrary constant. In particular, this offset has no effect on the evolution of gravitational potential energy of the constant mass fluid element since

$$\frac{\mathrm{D}(\Phi_{\mathrm{r}}\,\rho\,\delta V)}{\mathrm{D}t} = \Phi_{\mathrm{r}}\,\frac{\mathrm{D}(\rho\,\delta V)}{\mathrm{D}t} = 0. \tag{27.7}$$

Hence, as is well known from classical mechanics, it is not the value of the gravitational potential energy that is important, but instead it is the space and time changes that affect energetics.

27.2.4 Regionally integrated gravitational potential energy

Now consider the evolution of the gravitational potential energy integrated over a finite region $\mathcal{R}$. If the fluid region is closed to mass transport, as per a material boundary, then we can make use of the Leibniz-Reynolds transport theorem in the form of equation (21.53d) to write

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \Phi\,\rho\,\mathrm{d}V = \int_{\mathcal{R}} \frac{\mathrm{D}\Phi}{\mathrm{D}t}\,\rho\,\mathrm{d}V, \tag{27.8}$$

which is an extension of the material evolution equation (27.1). If the region is open to material mass transport, we make use Leibniz-Reynolds transport theorem in the form of equation (21.37) to find

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho\,\Phi\,\mathrm{d}V = \int_{\mathcal{R}} \frac{\partial(\rho\,\Phi)}{\partial t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \rho\,\Phi\,\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\mathrm{d}\mathcal{S} \tag{27.9a}$$

$$= \int_{\mathcal{R}} \left[\rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t} - \nabla\cdot(\rho\,\Phi\,\boldsymbol{v})\right]\mathrm{d}V + \oint_{\partial\mathcal{R}} \rho\,\Phi\,\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\mathrm{d}\mathcal{S} \tag{27.9b}$$

$$= \int_{\mathcal{R}} \rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \rho\,\Phi\,(\boldsymbol{v}^{(b)} - \boldsymbol{v})\cdot\hat{\boldsymbol{n}}\mathrm{d}\mathcal{S}, \tag{27.9c}$$

where $\boldsymbol{v}^{(b)}$ is the velocity of a point on the boundary of the domain. The evolution thus consists of the mass integrated material time evolution of the geopotential, plus a surface term that contributes to the transport of the geopotential across the regional boundaries.

If the region is a vertical column of ocean fluid with fixed horizontal cross-section, extending from the ocean surface to the ocean bottom, then there is horizontal transport across the vertical column bounds, plus vertical transport of mass across the ocean free surface. For the free surface we make use of the surface kinematic boundary condition (20.73c) to write

$$\int_{z=\eta} \rho\,\Phi\,(\boldsymbol{v}^{(b)} - \boldsymbol{v})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{z=\eta} Q_{\mathrm{m}}\,\Phi\,\mathrm{d}A. \tag{27.10}$$

In this equation, Q_{m} is the mass per time per horizontal area of matter crossing the ocean free surface at $z=\eta$ where $Q_{\mathrm{m}} > 0$ for matter entering the ocean domain, and $\mathrm{d}\mathcal{S}$ is the area element on the free surface with $\mathrm{d}A$ its horizontal projection. As noted in Section 27.2.3, we can add a constant to the geopotential without affecting the energetics, which is here seen by noting that

mass conservation means that

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \rho\,\mathrm{d}V = -\int_{\mathcal{R}} \nabla\cdot[\rho\,(\boldsymbol{v}-\boldsymbol{v}^{(b)})]\mathrm{d}V, \tag{27.11}$$

which results from setting $\Phi = 1$ in equation (27.9c). In general, we expect the transfer of mass across the surface boundary to affect the gravitational potential energy both because it adds or removes mass to the ocean domain, and because it affects the geopotential. To help interpret the sign from the boundary term, it is useful to define the reference state geopotential so that $\Phi > 0$ at the ocean surface, no matter what the value of η. We can do so by defining the reference geopotential at or below the ocean bottom. In this case, adding mass increases the gravitational potential energy and removing mass reduces it.

Consider the special case of a geopotential $\Phi = g\,z$, so returning to a $z = 0$ reference state, in which case the global ocean potential energy equation is written

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \rho\,z\,\mathrm{d}V = \int \rho\,w\,\mathrm{d}V + \int Q_{\mathrm{m}}\,\eta\,\mathrm{d}A, \tag{27.12}$$

where we cancelled the constant gravitational acceleration. Now decompose Q_{m} and η into their global area means and deviations

$$Q_{\mathrm{m}} = \overline{Q_{\mathrm{m}}} + Q'_{\mathrm{m}} \quad \text{and} \quad \eta = \overline{\eta} + \eta', \tag{27.13}$$

so that

$$g\int Q_{\mathrm{m}}\,\eta\,\mathrm{d}A = g\,\overline{Q_{\mathrm{m}}}\,\overline{\eta}\,A + g\int Q'_{\mathrm{m}}\,\eta'\,\mathrm{d}A. \tag{27.14}$$

As before, the $\overline{Q_{\mathrm{m}}}\,\overline{\eta}$ term alters potential energy relative to the arbitrary reference state, here taken as $z = 0$. The area correlation term increases potential energy in regions where $Q'_{\mathrm{m}}\,\eta' > 0$, which acts to increase the relative deviation of the free surface from its mean value. That is, $Q'_{\mathrm{m}}\,\eta' > 0$ in regions where $Q'_{\mathrm{m}} > 0$ and $\eta' > 0$ as well as in regions where $Q'_{\mathrm{m}} < 0$ and $\eta' < 0$. Conversely, the correlation term reduces potential energy where Q'_{m} and η' are anti-correlated, which acts to decrease the relative deviation of the free surface height.

27.2.5 Potential energy and vertical stratification

Consider the potential energy of a region of horizontally homogeneous fluid centered at a vertical position, $z = z_{\mathrm{c}}$, and with constant horizontal cross-sectional area, A. Assuming we do not move vertically far away from the central position, we can write the density in the linear form

$$\rho(z) = \rho(z_{\mathrm{c}}) + \frac{\mathrm{d}\rho(z_{\mathrm{c}})}{\mathrm{d}z}\,(z - z_{\mathrm{c}}) \equiv \rho_{\mathrm{c}} - K\,(z - z_{\mathrm{c}}), \tag{27.15}$$

where $K = -\mathrm{d}\rho(z_{\mathrm{c}})/\mathrm{d}z > 0$ is a shorthand for the vertical density gradient at the central point. The potential energy per volume ($\Delta V = A\,\Delta z$) for fluid in the vertical region $z \in [z_{\mathrm{c}} - \Delta z/2, z_{\mathrm{c}} + \Delta z/2]$ is given by

$$(g/\Delta z)\int z\,\rho\,\mathrm{d}z = (g/\Delta z)\int_{z_{\mathrm{c}}-\Delta z/2}^{z_{\mathrm{c}}+\Delta z/2} [\rho_{\mathrm{c}} - K\,(z - z_{\mathrm{c}})]\,z\,\mathrm{d}z \tag{27.16a}$$

$$= g\,\rho_{\mathrm{c}}\,z_{\mathrm{c}} - g\,K\,(\Delta z)^2/12. \tag{27.16b}$$

We thus see that the gravitational potential energy decreases as the vertical stratification, $K > 0$, increases, with the maximum potential energy when the stratification vanishes, $K = 0$. As seen

in Section 27.2.6, potential energy is maximized when $K = 0$ since the center of mass moves vertically upward as the stratification reduces to zero.

27.2.6 Gravitational potential energy and mixing

Consider a fluid in exact hydrostatic balance (Section 25.6) with a gravitationally stable vertical stratification where light fluid is above heavy fluid.[2] Now introduce a physical process, such as vertical mixing associated with a kinetic energy source, that reduces the vertical stratification. Reducing vertical stratification requires mixing to move heavy fluid up and light fluid down. In so doing, the kinetic energy supporting the mixing is converted into gravitational potential energy since the center of mass for the fluid column rises.

We can formulate this thought experiment by considering a column of seawater that is vertically stratified in salinity, S, and Conservative Temperature, Θ, and another column that is vertically unstratified with constant values S_{m} and Θ_{m}.[3] We assume the mass of the two columns is the same so that the bottom pressure, p_{b}, and surface pressure, p_{a}, are the same for the two columns. However, the volumes will generally differ since the density differs, so that the two free surfaces, η and η_{m}, differ. Assuming a geopotential for the homogenized column, $\Phi = g\, z_{\mathrm{m}}$, leads to the integrated potential energy

$$g \int_{\eta_{\mathrm{b}}}^{\eta_{\mathrm{m}}} \rho(S_{\mathrm{m}}, \Theta_{\mathrm{m}}, p)\, z_{\mathrm{m}}\, \mathrm{d}z_{\mathrm{m}} = - \int_{p_{\mathrm{b}}}^{p_{\mathrm{a}}} z_{\mathrm{m}}\, \mathrm{d}p, \tag{27.17}$$

where we used the hydrostatic balance to write

$$\mathrm{d}p = -g\, \rho(S_{\mathrm{m}}, \Theta_{\mathrm{m}}, p)\, \mathrm{d}z_{\mathrm{m}}. \tag{27.18}$$

Likewise, the stratified column has an integrated potential energy

$$g \int_{\eta_{\mathrm{b}}}^{\eta} \rho(S, \Theta, p)\, z\, \mathrm{d}z = - \int_{p_{\mathrm{b}}}^{p_{\mathrm{a}}} z\, \mathrm{d}p, \tag{27.19}$$

so that the difference between the gravitational potential energies per horizontal area in the two columns is given by

$$g \int_{\eta_{\mathrm{b}}}^{\eta_{\mathrm{m}}} \rho(S_{\mathrm{m}}, \Theta_{\mathrm{m}}, p)\, z\, \mathrm{d}z - g \int_{\eta_{\mathrm{b}}}^{\eta} \rho(S, \Theta, p)\, z\, \mathrm{d}z = \int_{p_{\mathrm{a}}}^{p_{\mathrm{b}}} (z_{\mathrm{m}} - z)\, \mathrm{d}p = (p_{\mathrm{b}} - p_{\mathrm{a}})\, (\overline{z_{\mathrm{m}}} - \overline{z}). \tag{27.20}$$

In this equation we introduced the center of mass positions for the vertically homogeneous column, $\overline{z_{\mathrm{m}}}$, and the stratified column, $\overline{z}$, defined by

$$\overline{z_{\mathrm{m}}} = \frac{1}{p_{\mathrm{b}} - p_{\mathrm{a}}} \int_{p_{\mathrm{a}}}^{p_{\mathrm{b}}} z_{\mathrm{m}}\, \mathrm{d}p \quad \text{and} \quad \overline{z} = \frac{1}{p_{\mathrm{b}} - p_{\mathrm{a}}} \int_{p_{\mathrm{a}}}^{p_{\mathrm{b}}} z\, \mathrm{d}p. \tag{27.21}$$

There are two contributions to the potential energy difference in equation (27.20). The first is the mass per horizontal area, as measured by the difference in bottom pressure and applied surface pressure, $(p_{\mathrm{b}} - p_{\mathrm{a}})/g > 0$. The second is the difference between the center of mass for the two

[2] See Section 31.5 for a more precise discussion of gravitational stability.

[3] See Section 31.3 for discussion of the seawater equation of state. For present purposes it is sufficient to know that seawater density is a function of the material tracer S, the thermodynamic tracer, Θ, and pressure, p. When a column is vertically homogenized that means S and Θ are constant throughout the column. However, pressure remains hydrostatic and thus is not vertically constant. Since density is a function of pressure, it too retains a vertical gradient.

columns, $\overline{z_{\rm m}} - \overline{z}$, which is a positive number since homogenizing a fluid column moves heavier water up and lighter water down so that $\overline{z_{\rm m}} > \overline{z}$. Hence, the potential energy of the homogenized column is larger than the stratified column. We develop more experience with the energetics of mixing in Exercise 27.1.

27.3 Kinetic energy of macroscopic motion

Mechanical energy is a dynamical property formed by adding the energy due to motion of fluid elements (kinetic energy) to the energy arising from the position of a fluid element within the gravitational field (gravitational potential energy). We studied the gravitational potential energy budget in Section 27.2. Here, we develop the budget for kinetic energy and then the full mechanical energy (kinetic plus gravitational potential) in Section 27.4. In Section 27.7 we then add the mechanical energy from macroscopic motion to the internal energy to develop the budget for total energy.

27.3.1 Kinetic energy budget from Cauchy's equation

We start the analysis by considering general features of the kinetic energy budget as seen from Cauchy's equation of motion (25.14)

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = \rho\, \boldsymbol{f}_{\rm body} + \nabla \cdot (-p\, \mathbb{I} + \mathbb{T}), \tag{27.22}$$

with a body force per mass, $\boldsymbol{f}_{\rm body}$, and contact stress from pressure, p, and the symmetric frictional stress tensor, $\mathbb{T}$. Taking the scalar product with $\boldsymbol{v}$ leads to

$$\rho \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = \rho\, \boldsymbol{v} \cdot \boldsymbol{f}_{\rm body} + v_n\, \partial_m(-p\, \delta_{mn} + \mathbb{T}_{mn}), \tag{27.23}$$

where

$$\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2 \tag{27.24}$$

is the kinetic energy per mass. We thus see that the kinetic energy of a fluid element is affected by work done by the body forces, $\rho\, \boldsymbol{v} \cdot \boldsymbol{f}_{\rm body}$, along with work done by stresses through both pressure and friction.

Rearranging the stress term in equation (27.23) leads to

$$\rho \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = \rho\, \boldsymbol{v} \cdot \boldsymbol{f}_{\rm body} + \nabla \cdot (-p\, \boldsymbol{v} + \boldsymbol{v} \cdot \mathbb{T}) + p\, \nabla \cdot \boldsymbol{v} - (\partial_m v_n)\, \mathbb{T}_{mn}. \tag{27.25}$$

The $\nabla \cdot (-p\, \boldsymbol{v} + \boldsymbol{v} \cdot \mathbb{T})$ contribution represents the divergence of a flux arising from pressure and viscous stress, whereas the term $p\, \nabla \cdot \boldsymbol{v}$ arises from pressure work done on a fluid element as it changes volume. For the final term in equation (27.25), as note that the frictional stress tensor is symmetric so that

$$(\partial_m v_n)\, \mathbb{T}_{mn} = \mathbb{S}_{mn}\, \mathbb{T}_{mn}, \tag{27.26}$$

where we introduced the strain rate tensor from equation (19.43a)

$$2\, \mathbb{S}_{mn} = \partial_n v_m + \partial_m v_n. \tag{27.27}$$

As shown in Section 27.3.3, the frictional stress tensors resulting from the constitutive relations in Section (26.8) mean that $\mathbb{S}_{mn}\, \mathbb{T}_{mn}$ is non-negative, in which case viscous stresses dissipate kinetic energy.

27.3.2 Kinetic energy budget for a geophysical fluid

We now develop the kinetic energy budget for a fluid in a rotating reference frame, in which case the body force is provided by the effective gravity and Coriolis. For this purpose we make use of the momentum equation (25.16), repeated here for convenience

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\,\nabla\Phi + \nabla\cdot(-p\,\mathbb{I} + \mathbb{T}) \tag{27.28a}$$

$$= -\rho\,\nabla\Phi - \nabla p + \rho\,\boldsymbol{F}, \tag{27.28b}$$

where we wrote

$$\boldsymbol{F} = \rho^{-1}\,\nabla\cdot\mathbb{T} \tag{27.29}$$

for acceleration due to viscous friction that arises from the divergence of the frictional stress tensor. Taking the scalar product the momentum equation in the form of equations (27.28a) and (27.28b) renders

$$\rho\,\frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\rho\,\boldsymbol{v}\cdot\nabla\Phi - \boldsymbol{v}\cdot\nabla p + \rho\,\boldsymbol{v}\cdot\boldsymbol{F}. \tag{27.30}$$

We thus see that the kinetic energy of a fluid element is affected by work done by the geopotential, $-\rho\,\boldsymbol{v}\cdot\nabla\Phi$, along with work done by stresses through both pressure and friction. We detail these processes in the following.

Contribution from the geopotential

Kinetic energy increases for motion directed down the geopotential gradient

$$\boldsymbol{v}\cdot\nabla\Phi < 0 \Longrightarrow \text{increases kinetic energy.} \tag{27.31}$$

For example, with a simple geopotential, $\Phi = g\,z$, kinetic energy increases where the vertical velocity is downward,

$$w < 0 \Longrightarrow -w\,g\,\rho > 0 \longleftrightarrow \text{downward motion increases } \mathcal{K} \text{ of a fluid element.} \tag{27.32}$$

As seen in Section 27.2.1, this increase in kinetic energy due to motion down the geopotential gradient is exactly balanced by a decrease in gravitational potential energy. That is, an increase in kinetic energy through motion down the geopotential comes at the cost of a decrease in the gravitational potential energy. This exact conversion between kinetic energy and potential energy is also seen in Section 14.8 for motion of the point particle.

Contribution from the pressure gradient body force

Kinetic energy increases in regions where the velocity projects down the pressure gradient,

$$\boldsymbol{v}\cdot\nabla p < 0 \Longrightarrow \text{increase kinetic energy,} \tag{27.33}$$

thus resulting in an increase in fluid speed imparted by the pressure gradient force. Conversely, kinetic energy is reduced in regions where the flow is directed up the pressure gradient. It is notable that geostrophic flows, studied in Section 32.4, have a velocity given by

$$\boldsymbol{v}_{\mathrm{g}} = (g\,\rho)^{-1}\,\hat{\boldsymbol{z}} \times \nabla p. \tag{27.34}$$

Consequently, geostrophic flows have $\boldsymbol{v}_{\mathrm{g}}\cdot\nabla p = 0$, so that the pressure gradient force has no impact on the horizontal kinetic energy of a geostrophic fluid.

Contribution from friction

Kinetic energy is reduced in regions where the velocity has a negative projection onto the direction of the friction vector, $\rho\,\boldsymbol{v}\cdot\boldsymbol{F} < 0$. As detailed in Section 27.3.3, the friction arising from a viscous stress tensor appropriate for a Newtonian fluid gives rise to two contributions to kinetic energy: the divergence of a viscous flux plus a sign-definite sink.

27.3.3 Frictional dissipation of kinetic energy

We here detail the role of friction on kinetic energy

$$\text{friction power per volume} = \rho\,\boldsymbol{v}\cdot\boldsymbol{F} = \boldsymbol{v}\cdot\mathbb{\tau}, \tag{27.35}$$

which is the frictional power per volume (energy per time per volume) that modifies the kinetic energy per volume of a fluid element, and with the frictional stress tensor, $\mathbb{\tau}$, determined by the constitutive equation (26.78). We anticipated this contribution in our general discussion of Section 27.3.1, and here provide details.

To proceed, we expose Cartesian tensor labels to have

$$\begin{aligned}
\rho\,\boldsymbol{v}\cdot\boldsymbol{F} &= v_m\,\rho\,F_m && (27.36a)\\
&= v_m\,\partial_n\mathbb{\tau}_{nm} && (27.36b)\\
&= 2\,v_m\,\partial_n(\rho\,\nu\,\mathbb{S}^{\text{dev}}_{mn}) && (27.36c)\\
&= 2\,\partial_n(\rho\,\nu\,v_m\,\mathbb{S}^{\text{dev}}_{mn}) - 2\,\rho\,\nu\,\partial_n v_m\,\mathbb{S}^{\text{dev}}_{mn} && (27.36d)\\
&= 2\,\nabla\cdot(\rho\,\nu\,\boldsymbol{v}\cdot\mathbb{S}^{\text{dev}}) - 2\,\rho\,\nu\,\mathbb{S}_{mn}\,\mathbb{S}^{\text{dev}}_{mn}, && (27.36e)
\end{aligned}$$

where we recall from Section 26.8.6 that the *deviatoric strain rate tensor* has elements given by

$$\mathbb{S}^{\text{dev}}_{mn} = \mathbb{S}_{mn} - \delta_{mn}\,\mathbb{S}_{qq}/3 \quad \text{with} \quad \mathbb{S}_{qq} = \nabla\cdot\boldsymbol{v}. \tag{27.37}$$

To reach equation (27.36e) required the identity

$$2\,\partial_n v_m\,\mathbb{S}^{\text{dev}}_{mn} = (\partial_n v_m + \partial_m v_n)\,\mathbb{S}^{\text{dev}}_{mn} + (\partial_n v_m - \partial_m v_n)\,\mathbb{S}^{\text{dev}}_{mn} = 2\,\mathbb{S}_{mn}\,\mathbb{S}^{\text{dev}}_{mn}, \tag{27.38}$$

where

$$(\partial_n v_m - \partial_m v_n)\,\mathbb{S}^{\text{dev}}_{mn} = 2\,\mathbb{R}_{mn}\,\mathbb{S}^{\text{dev}}_{mn} = 0 \tag{27.39}$$

due to symmetry of the deviatoric strain rate tensor, $\mathbb{S}^{\text{dev}}_{mn} = \mathbb{S}^{\text{dev}}_{nm}$, and anti-symmetry of the rotation tensor, $\mathbb{R}_{mn}$ (see Section 19.4 as well as Exercise 1.2). We can show that the second term in equation (27.36e) is sign-definite by noting that

$$\begin{aligned}
\mathbb{S}^{\text{dev}}_{mn}\,\mathbb{S}^{\text{dev}}_{mn} &= (\mathbb{S}_{mn} - \delta_{mn}\,\mathbb{S}_{qq}/3)^2 && (27.40a)\\
&= \mathbb{S}_{mn}\,\mathbb{S}_{mn} + \delta_{mn}\,\delta_{mn}\,\mathbb{S}_{qq}\,\mathbb{S}_{qq}/9 - 2\,\mathbb{S}_{mn}\,\delta_{mn}\,\mathbb{S}_{qq}/3 && (27.40b)\\
&= \mathbb{S}_{mn}\,\mathbb{S}_{mn} + (\mathbb{S}_{qq})^2/3 - 2\,(\mathbb{S}_{qq})^2/3 && (27.40c)\\
&= \mathbb{S}_{mn}\,(\mathbb{S}_{mn} - \delta_{mn}\,\mathbb{S}_{qq}/3) && (27.40d)\\
&= \mathbb{S}_{mn}\,\mathbb{S}^{\text{dev}}_{mn}. && (27.40e)
\end{aligned}$$

We are thus left

$$\rho\,\boldsymbol{v}\cdot\boldsymbol{F} = 2\,\nabla\cdot(\rho\,\nu\,\boldsymbol{v}\cdot\mathbb{S}^{\text{dev}}) - 2\,\rho\,\nu\,\mathbb{S}^{\text{dev}}_{mn}\,\mathbb{S}^{\text{dev}}_{mn}. \tag{27.41}$$

We interpret the two contributions to the frictional power in equation (27.41) as

$$\rho\, \boldsymbol{v} \cdot \boldsymbol{F} = \text{divergence of viscous flux} - \text{viscous dissipation}. \tag{27.42}$$

The divergence theorem means that when integrated over the full domain, the divergence of the viscous flux becomes a contribution from boundary stresses, and boundary stresses can either increase or decrease kinetic energy according to details of the boundary processes. In contrast, the sign-definite dissipation term provides a sink to the kinetic energy at each point in the fluid interior. This frictional dissipation is commonly written

$$\epsilon \equiv [\boldsymbol{v} \cdot \boldsymbol{F}]_{\text{dissipate}} = 2\, \nu\, \mathbb{S}^{\text{dev}}_{mn}\, \mathbb{S}^{\text{dev}}_{mn} \geq 0. \tag{27.43}$$

The dimensions of ϵ are $\mathrm{L}^2\ \mathrm{T}^{-3}$, which in SI units are $\mathrm{m}^2\ \mathrm{s}^{-3} = \mathrm{W\ kg}^{-1}$. We thus refer to ϵ as the kinetic energy dissipation per mass arising from viscous effects. It is also sometimes referred to as the viscous power per mass. Note that we know that $\epsilon > 0$ since $\mathbb{S}^{\text{dev}}_{mn}\, \mathbb{S}^{\text{dev}}_{mn}$ is the sum of nine perfect squares, which is seen by expanding the Einstein summation convention

$$\mathbb{S}^{\text{dev}}_{mn}\, \mathbb{S}^{\text{dev}}_{mn} = \mathbb{S}^{\text{dev}}_{1n}\, \mathbb{S}^{\text{dev}}_{1n} + \mathbb{S}^{\text{dev}}_{2n}\, \mathbb{S}^{\text{dev}}_{2n} + \mathbb{S}^{\text{dev}}_{3n}\, \mathbb{S}^{\text{dev}}_{2n}, \tag{27.44}$$

where

$$\mathbb{S}^{\text{dev}}_{1n}\, \mathbb{S}^{\text{dev}}_{1n} = \mathbb{S}^{\text{dev}}_{11}\, \mathbb{S}^{\text{dev}}_{11} + \mathbb{S}^{\text{dev}}_{12}\, \mathbb{S}^{\text{dev}}_{12} + \mathbb{S}^{\text{dev}}_{13}\, \mathbb{S}^{\text{dev}}_{13}, \tag{27.45}$$

and likewise for $\mathbb{S}^{\text{dev}}_{2n}\, \mathbb{S}^{\text{dev}}_{2n}$ and $\mathbb{S}^{\text{dev}}_{3n}\, \mathbb{S}^{\text{dev}}_{3n}$.

27.3.4 Further study

The study of physical processes contributing to kinetic energy dissipation is central to the study of ocean mixing. The review by *MacKinnon et al.* (2013) provides a pedagogical starting point for this active area of physical oceanography.

As shown in Section 17.8 of *Griffies* (2004), we can relate the global integral of the kinetic energy dissipation to the friction vector by taking the functional derivative of the dissipation with respect to the velocity field. This connection follows from the self-adjoint nature of the friction operator and it can be a useful mathematical framework for developing numerical discretizations of the viscous friction operator (e.g., *Griffies and Hallberg* (2000)). In Section 64.4.4 we consider a similar connection between the tracer diffusion operator and tracer variance.

27.4 Mechanical energy budget

Mechanical energy of the macroscopic motion is the sum of the kinetic energy plus gravitational potential energy. We here develop the budget, both differential and integral, for mechanical energy.

27.4.1 Differential mechanical energy budget

Adding the material time evolution equations for kinetic energy per mass (equation (27.30)) and gravitational potential energy per mass (equation (27.5)) leads to the material form of the

mechanical energy per mass

$$\rho\,\frac{\mathrm{D}\mathcal{M}}{\mathrm{D}t} = -\boldsymbol{v}\cdot\nabla p + 2\,\nabla\cdot(\rho\,\nu\,\boldsymbol{v}\cdot\mathbb{S}^{\mathrm{dev}}) + \rho\,(-\epsilon + \partial_t\Phi) \tag{27.46a}$$

$$= -\nabla\cdot(p\,\boldsymbol{v} - 2\,\rho\,\nu\,\boldsymbol{v}\cdot\mathbb{S}^{\mathrm{dev}}) + p\,\nabla\cdot\boldsymbol{v} + \rho\,(-\epsilon + \partial_t\Phi) \tag{27.46b}$$

$$= -\nabla\cdot\boldsymbol{J}_{\mathrm{mech}} + p\,\nabla\cdot\boldsymbol{v} + \rho\,(-\epsilon + \partial_t\Phi), \tag{27.46c}$$

where

$$\mathcal{M} = \mathcal{K} + \Phi \tag{27.47}$$

is the mechanical energy per mass of a fluid element. Equation (27.46c) introduced the *mechanical energy flux*

$$\boldsymbol{J}_{\mathrm{mech}} = p\,\boldsymbol{v} - 2\,\rho\,\nu\,\boldsymbol{v}\cdot\mathbb{S}^{\mathrm{dev}} = -\boldsymbol{v}\cdot(-p\,\mathbb{I} + \mathbb{\tau}) = -\boldsymbol{v}\cdot\mathbb{T}, \tag{27.48}$$

where $\mathbb{T}$ is the stress tensor for a Newtonian fluid given by equation (26.78) . We can write the material time evolution equation (27.49) as a flux-form conservation equation

$$\partial_t(\rho\,\mathcal{M}) + \nabla\cdot(\rho\,\mathcal{M}\,\boldsymbol{v} + \boldsymbol{J}_{\mathrm{mech}}) = p\,\nabla\cdot\boldsymbol{v} + \rho\,(-\epsilon + \partial_t\Phi). \tag{27.49}$$

Equation (27.46c) says that the material evolution of mechanical energy per mass arises from the convergence of the mechanical energy flux, $\boldsymbol{J}_{\mathrm{mech}}$, plus the work done by pressure in a fluid with non-zero flow divergence, along with frictional dissipation (more discussed in Section 27.7.3), and time changes to the geopotential. Furthermore, as shown when studying total energy in Section 27.7, mechanical energy is exchanged with internal energy through pressure work and frictional dissipation. This exchange provides the fundamental link between the mechanical energy of macroscopic motion and the internal energy of microscropic degrees of freedom. As already anticipated, there is a cancellation of the mechanical energy exchanged between kinetic and potential energy due to motion through the gravitational field. However, the time-dependent geopotential provides a source of mechanical energy arising from processes external to the fluid, such as astronomical effects that drive tidal motions.

27.4.2 Gravitational potential energy budget for a finite volume

We here develop the gravitational potential energy budget for a finite volume, $\mathcal{R}$. Using the Leibniz-Reynolds transport theorem in the form of equation (21.47) yields

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}}\rho\,\Phi\,\mathrm{d}V\right] = \int_{\mathcal{R}}\partial_t(\rho\,\Phi)\,\mathrm{d}V + \oint_{\partial\mathrm{R}}\rho\,\Phi\,\boldsymbol{v}^{(b)}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{27.50}$$

where $\boldsymbol{v}^{(b)}$ is the velocity of a point on the region boundary, $\partial\mathcal{R}$, and $\hat{\boldsymbol{n}}$ is the boundary outward normal. Next we replace the partial time derivative with

$$\partial_t(\rho\,\Phi) = \rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t} - \nabla\cdot(\rho\,\boldsymbol{v}\,\Phi), \tag{27.51}$$

in which case

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}}\rho\,\Phi\,\mathrm{d}V\right] = \int_{\mathcal{R}}\rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}\,\mathrm{d}V - \oint_{\partial\mathrm{R}}\rho\,\Phi\,(\boldsymbol{v} - \boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{27.52}$$

For the case of the full ocean domain we use the surface kinematic boundary condition (20.73a), and no-flux boundary condition on the bottom, to yield

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Phi\,\mathrm{d}V\right] = \int_{\mathcal{R}} \rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \Phi\,Q_{\mathrm{m}}\,\mathrm{d}A, \tag{27.53}$$

with Q_{m} the mass flux crossing the upper boundary at $z=\eta$, and $\mathrm{d}A$ the horizontal area element. For the simple geopotential, $\Phi = g\,z$, this equation takes the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\Phi\,\mathrm{d}V\right] = \int_{\mathcal{R}} \rho\,g\,w\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \Phi\,Q_{\mathrm{m}}\,\mathrm{d}A. \tag{27.54}$$

This budget says that the gravitational potential energy for the global ocean domain changes due to the domain integrated vertical motion, plus contributions from the transfer of mass across the free surface boundary.

27.4.3 Mechanical energy budget for a finite volume

We here consider the mechanical energy budget for a finite volume region of fluid, first deriving the budget for a real fluid and then specializing to the perfect fluid without flow divergence.

Budget for a real fluid

To derive the finite volume budget we make use of the Leibniz-Reynolds transport theorem in the form of equation (21.49), as well as the flux-form mechanical energy budget (27.49), thus leading to

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\mathcal{M}\,\mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \rho\,\mathcal{M}\,(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \oint_{\partial\mathcal{R}} \boldsymbol{J}_{\mathrm{mech}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \int_{\mathcal{R}} \left[p\,\nabla\cdot\boldsymbol{v} + \rho\,(-\epsilon + \partial_t\Phi)\right]\mathrm{d}V. \tag{27.55}$$

The first term on the right hand side arises from the advective transport of mechanical energy across the moving boundary. The second term arises from the boundary work done by pressure and viscous stresses, with equation (27.48) yielding the equivalent expression in terms of the stress tensor

$$-\oint_{\partial\mathcal{R}} \boldsymbol{J}_{\mathrm{mech}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{R}} \boldsymbol{v}\cdot\mathbb{T}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{27.56}$$

The third term in equation (27.55) is a volume source arising from pressure work applied to each fluid parcel, viscous dissipation, and time tendencies in the geopotential.

Budget for a perfect fluid with zero flow divergence

Consider the particular case of a non-divergent flow ($\nabla\cdot\boldsymbol{v}=0$), as in the Boussinesq ocean studied in Chapter 30. In this case, pressure does no work on fluid elements since each element maintains a constant volume.[4] Furthermore, assume the fluid is perfect and so do not have any viscous stresses. Finally, assume the geopotential is constant in time ($\partial_t\Phi = 0$). These assumptions bring the finite volume mechanical energy equation (27.55) to the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\,\mathcal{M}\,\mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} \rho\,\mathcal{M}\,(\boldsymbol{v}-\boldsymbol{v}^{(b)})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \oint_{\partial\mathcal{R}} p\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{27.57}$$

[4] In Section 22.2 we show that $\nabla\cdot\boldsymbol{v}=0$ means that fluid elements maintain a materially constant volume.

For this fluid, mechanical energy over a finite region changes via the advective transport of $\mathcal{M}$ across the region boundary, taking into account the distinctions between the fluid velocity and the velocity of the region boundary. Mechanical energy is also modified by pressure work acting on the region boundary. It is notable that even though the flow is non-divergent at each point, so that pressure cannot do work on fluid elements, pressure can still do work on the finite region through boundary effects. Indeed, if the region is material, then $(\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}} = 0$, in which case mechanical energy is modified only through pressure work integrated over the region boundary. It follows that a steady state mechanical energy is realized for material regions only with a vanishing steady state boundary integrated pressure work.

27.5 Hypothesis of local thermodynamic equilibrium

We make use of the hypothesis of *local thermodynamic equilibrium* in Section 27.6 to couple the equilibrium thermodynamics in Chapters 23 and 24 to fluids in macroscopic motion. This hypothesis presumes that macroscopic fluid motion is comprised of a continuum of moving fluid elements[5] that are, individually, in local thermodynamic equilibrium. For a perfect fluid, macroscopic motion does not alter the entropy for a fluid element. That is, in the absence of mixing of fluid elements, advective transport is a reversible process. In contrast, mixing of properties between real fluid elements is irreversible and thus increases entropy.

27.5.1 Elements of the local thermodynamic equilibrium hypothesis

For a real fluid, any finite sized region is generally out of thermodynamic equilibrium, as evidenced, say, by a non-uniform temperature over macroscopic length scales. Even so, the local thermodynamic equilibrium hypothesis assumes that infinitesimal fluid elements are in local thermodynamic equilibrium, thus affording the means to determine intensive thermodynamic properties (e.g., temperature, pressure, chemical potential) at each point within the fluid continuum. Furthermore, the hypothesis means that the functional dependence of state functions (e.g., internal energy, entropy, enthalpy) remains the same for the moving fluid as in thermodynamic equilibrium. This particular implication of the hypothesis provides the key operational means for extending to a moving real fluid the differential relations developed for equilibrium thermodynamics in Part IV of this book.

Theoretical foundations for the hypothesis of local thermodynamic equilibrium are rather difficult and somewhat unresolved. Indeed, many presentations postulate that the equations of equilibrium thermodynamics can be extended to moving continuous media, with justification provided *a posteriori* based on the resulting implications (e.g., Section III.2 of *DeGroot and Mazur* (1984)). We follow this approach here.[6] Fortunately, the hypothesis has proven successful for the atmosphere and ocean motions studied in this book, so that we accept it for our studies.[7] Further discussion of the hypothesis of local thermodynamic equilibrium can be found in Section 49 of *Landau and Lifshitz* (1987), chapter 5 of *Huang* (1987), and Section 19.2 of *Woods* (1975).[8]

[5] See Section 18.3.4 for a reminder of fluid elements.

[6] The hypothesis of local thermodynamic equilibrium can be motivated by noting that the microscopic motions of molecules have a much shorter equilibration time scale relative to the longer time scale of macroscopic processes of interest for fluid flow (Section 17.3.5). Even so, pursuit of that motivation has some nuances that go beyond our goals. Hence, our perspective is pragmatic, in which we assume local thermodynamic equilibrium and see what it implies.

[7] The hypothesis of local thermodynamic equilibrium is questionable for rarefied gas dynamics of the upper atmosphere, which is a subject outside the scope of this book.

[8] The extension of equilibrium thermodynamics to a moving fluid falls under the discipline of *quasi-equilibrium thermodynamics* or *linear irreversible thermodynamics*. The term "linear" in the name refers to an assumption that

27.5.2 Processes facilitating local equilibration

How does local thermodynamic equilibration come about, and how well should we expect it to be satisfied? If we assume a fluid element has length scale $L_{\text{macro}} = 10^{-4}$ m, as motivated in Section 17.2, then the question reduces to determining the time scale for a fluid element to be in have its mechanical and thermodynamical properties homogenized. We consider mechanical equilibrium to be related to the time scales for pressure to equilibrate, whereas thermodynamic equilibrium requires the additional considerations of material and thermal diffusion.

Pressure signals are transmitted by acoustic waves with speeds c_{s} (Chapter 49), so that we assume pressure equilibration times are proportional to $L_{\text{macro}}/c_{\text{s}}$. The sound speed for air at room temperature is roughly 350 m s^{-1}, so that pressure fluctuations are transmitted across an air element within roughly 3×10^{-7} s. The sound speed is about five times higher in water, thus leading to roughly 6×10^{-8} s for the pressure signal to cross an element of water. Both of these time scales are extremely tiny from a macroscopic perspective, thus supporting the assumption that pressure is rapidly equilibrated over the length scales of a fluid element.

The time scale for homogenization of temperature and matter concentrations are given by $L^2_{\text{macro}}/\kappa$, where κ is the respective molecular kinematic diffusivity for temperature or matter, which is on the order of $10^{-6}-10^{-5}$ m^2 s^{-1}. Hence, the time scale for a fluid element to homogenize its temperature and tracer concentration, through molecular diffusion, is $10^{-3}-10^{-2}$ s. This time scale is far larger than the pressure time scale, yet it is still small relative to typical macroscopic processes associated with fluid particle motion.

27.6 Thermodynamics of a moving fluid

We here extend the formalism of equilibrium thermodynamics from Chapters 23 and 24 to the case of a moving fluid. One practical outcome of this development is a framework to understand how the internal energy of microscopic degrees of freedom is exchanged with the mechanical energy of macroscopic fluid motion. For that purpose, recall the fundamental thermodynamic relation (23.56b) for a two-component fluid such as seawater or the atmosphere

$$\mathrm{d}\mathcal{I} = T\,\mathrm{d}\mathcal{S} - p\,\mathrm{d}(1/\rho) + \mu\,\mathrm{d}C. \tag{27.58}$$

This equation expresses the first law of thermodynamics for a quasi-static process (Section 23.1.5), thus relating the exact differential of specific internal energy, $\mathcal{I}$, to the specific entropy, $\mathcal{S}$, specific volume, $1/\rho$, and matter concentration, C, along with the thermodynamic temperature, T, the pressure, p, and the relative chemical potential, μ.

Now consider a finite region of fluid comprised of a continuum of fluid elements. The fluid region is generally exposed to mechanical and thermal processes that support macroscopic fluid motion. However, as discussed in Section 27.5, we assume that each fluid element is in local thermodynamic equilibrium and separately satisfies the fundamental thermodynamic relation (27.58). We furthermore assume that the thermodynamic potentials have the same functional relation across all of the fluid elements. This assumption is basic to our ability to maintain a field theoretic description of the continuum. Namely, there is no objective definition of a fluid element. Instead, they are infinitesimal regions of a continuum. So we must make use of the same functional expression for thermodynamic potentials across all of the fluid elements. This assumption allows us to take space and time derivatives of thermodynamic potentials as considered next.

the system is close to thermodynamic equilibrium throughout its motion so that thermodynamic fluxes are linear functions of the gradients of the thermodynamic state variables.

27.6.1 Concerning the transition to a continuous fluid

For a continuum fluid, each of the thermodynamic properties in the fundamental thermodynamic relation (27.58) are continuous functions of space and time. Furthermore, equation (27.58) provides a relation between exact differentials as detailed in Section 2.8. As exact differentials of continuous fields, we can make use of the space and time differentials detailed in Section 18.8.1 to write

$$\mathrm{d}\Psi = \Psi(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}, t + \mathrm{d}t) - \Psi(\boldsymbol{x}, t) = \mathrm{d}t\, \partial_t \Psi + \mathrm{d}\boldsymbol{x} \cdot \nabla \Psi, \tag{27.59}$$

where Ψ is one of the thermodynamic properties, $\mathrm{d}t$ is the time differential, and $\mathrm{d}\boldsymbol{x}$ is the vector of space differentials. Following the discussion in Section 18.8.2, we are led to the total time derivative for a property following an arbitrary trajectory $\boldsymbol{x} = \boldsymbol{X}(t)$

$$\frac{\mathrm{d}\Psi}{\mathrm{d}t} = \frac{\partial \Psi}{\partial t} + \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} \cdot \nabla \Psi. \tag{27.60}$$

Restricting the trajectory to that defined by a fluid particle, so that $\boldsymbol{v} = \mathrm{d}\boldsymbol{X}/\mathrm{d}t$, renders the material time derivative as in Section 18.8.4

$$\frac{\mathrm{D}\Psi}{\mathrm{D}t} = \frac{\partial \Psi}{\partial t} + \boldsymbol{v} \cdot \nabla \Psi. \tag{27.61}$$

We make use of this result in Section 27.6.4 to transition the quasi-static relation (27.58) to a moving fluid.

27.6.2 Space-time derivatives and thermodynamic partial derivatives

We need one more piece of formalism prior to transitioning the quasi-static relation (27.58) to a moving fluid. For this purpose, consider the particular case of specific enthalpy, in which case

$$\mathcal{H} = \mathcal{H}(\boldsymbol{x}, t) = \mathcal{H}[\mathcal{S}(\boldsymbol{x}, t), p(\boldsymbol{x}, t), C(\boldsymbol{x}, t)], \tag{27.62}$$

where the second equality exposed the natural functional dependence based on the fundamental thermodynamic relation (23.74c)

$$\mathrm{d}\mathcal{H} = T\, \mathrm{d}\mathcal{S} + (1/\rho)\, \mathrm{d}p + \mu\, \mathrm{d}C, \tag{27.63}$$

which holds for transitions between equilibrium states (Section 23.6.4). Again, this same functional dependence is assumed to hold for the case of an evolving fluid, so long as the evolution time scales are much slower than the time scales for reaching local thermodynamic equilibrium. We next make use of the chain-rule to render the spatial gradient

$$\nabla \mathcal{H} = \left[\frac{\partial \mathcal{H}}{\partial \mathcal{S}}\right]_{p,C} \nabla \mathcal{S} + \left[\frac{\partial \mathcal{H}}{\partial p}\right]_{\mathcal{S},C} \nabla p + \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{\mathcal{S},p} \nabla C. \tag{27.64}$$

This spatial gradient probes properties of the field, $\mathcal{H}(\boldsymbol{x}, t)$, which is a function of three other fields, $\mathcal{S}(\boldsymbol{x}, t), p(\boldsymbol{x}, t), C(\boldsymbol{x}, t)$. From this field theory perspective, the thermodynamic partial derivatives are computed by holding the value of the complement thermodynamic properties fixed at a point in space and time. For example, exposing space and time positions renders the awkward, yet unambiguous, expression

$$\left[\frac{\partial \mathcal{H}}{\partial \mathcal{S}}\right]_{p,C} = \left[\frac{\partial \mathcal{H}[\mathcal{S}(\boldsymbol{x}, t), p(\boldsymbol{x}, t), C(\boldsymbol{x}, t)]}{\partial \mathcal{S}(\boldsymbol{x}, t)}\right]_{p(\boldsymbol{x},t), C(\boldsymbol{x},t)}. \tag{27.65}$$

We next apply the thermodynamic partial derivative identities (23.76) to write

$$\left[\frac{\partial \mathcal{H}}{\partial \mathcal{S}}\right]_{p,C} = \left[\frac{\partial \mathcal{H}[\mathcal{S}(\boldsymbol{x},t), p(\boldsymbol{x},t), C(\boldsymbol{x},t)]}{\partial \mathcal{S}(\boldsymbol{x},t)}\right]_{p(\boldsymbol{x},t),C(\boldsymbol{x},t)} = T(\boldsymbol{x},t) \tag{27.66a}$$

$$\left[\frac{\partial \mathcal{H}}{\partial p}\right]_{\mathcal{S},C} = \left[\frac{\partial \mathcal{H}[\mathcal{S}(\boldsymbol{x},t), p(\boldsymbol{x},t), C(\boldsymbol{x},t)]}{\partial p(\boldsymbol{x},t)}\right]_{\mathcal{S}(\boldsymbol{x},t),C(\boldsymbol{x},t)} = 1/\rho(\boldsymbol{x},t) \tag{27.66b}$$

$$\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{\mathcal{S},p} = \left[\frac{\partial \mathcal{H}[\mathcal{S}(\boldsymbol{x},t), p(\boldsymbol{x},t), C(\boldsymbol{x},t)]}{\partial C(\boldsymbol{x},t)}\right]_{\mathcal{S}(\boldsymbol{x},t),p(\boldsymbol{x},t)} = \mu(\boldsymbol{x},t), \tag{27.66c}$$

thus leading to[9]

$$\nabla \mathcal{H} = T\,\nabla \mathcal{S} + \rho^{-1}\,\nabla p + \mu\,\nabla C. \tag{27.67}$$

An analogous relation also holds for time derivatives, in which case

$$\partial_t \mathcal{H} = T\,\partial_t \mathcal{S} + \rho^{-1}\,\partial_t p + \mu\,\partial_t C. \tag{27.68}$$

We thus find a direct connection between exact differentials satisfied by the fundamental thermodynamic relations in equilibrium thermodynamics (Chapters 23 and 24), and partial derivatives in both space and time. Such connections prove particularly useful in connecting between the mechanical force from pressure and gradients in thermodynamic properties. That is, the identity (27.67) offers an alternative means to express the pressure gradient acceleration appearing in the momentum equation (e.g., equation (25.15))[10]

$$-\rho^{-1}\,\nabla p = -\nabla \mathcal{H} + T\,\nabla \mathcal{S} + \mu\,\nabla C. \tag{27.69}$$

27.6.3 A caution for thermodynamic partial derivatives

One common confusion arises when not being clear on whether a mathematical expression refers to an equilibrium thermodynamic relation between thermodynamic variables, as in the fundamental thermodynamic relation (27.58), or whether it expresses a relation involving space-time field representations of thermodynamic properties. The distinction is particularly important when considering derivatives and integrals since it is necessary to know what variables are held fixed in the process of performing the operations.

For example, consider the middle relation in equation (23.86), which says that the partial derivative of the Gibbs potential with respect to pressure, holding temperature and concentration fixed, equals to the specific volume

$$\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C} = \nu_{\mathrm{s}} = \rho^{-1}. \tag{27.70}$$

However, if we encounter the Gibbs potential as a space-time function, and we use pressure as a

[9] Equation (27.67) is used on page 193 of *Landau and Lifshitz* (1987) as part of their derivation of the entropy budget for a moving fluid in the presence of heat conduction. It is also used on their page 229 to derive energetics for a fluid with both heat conduction and matter diffusion. See also their page 4 for more general discussion of how equilibrium thermodynamic relations imply relations between the space and time structure of thermodynamic functions in a moving fluid. Other treatments in the literature typically gloss over the transition of the fundamental thermodynamic relation of equilibrium thermodynamics to the quasi-equilibrium thermodynamics needed for moving fluids.

[10] We make use of the identity (27.69) for studies of circulation in Section 41.2.5 and for potential vorticity in Section 42.6.

generalized vertical coordinate, then we might find need to compute the distinct partial derivative

$$\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{x,y,t} \neq \left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C}. \tag{27.71}$$

When appropriate, we offer reminders to help avoid a cascade of misunderstandings. One point where this reminder is particularly useful is when discussing energetics for a Boussinesq fluid in Section 30.6.

27.6.4 First law for a moving fluid element

Sections 27.6.1 and 27.6.2 provide the key operational means for developing the equations of quasi-equilibrium thermodynamics, in which we apply the equilibrium thermodynamic relations to moving and evolving fluid elements. Consequently, the fundamental thermodynamic relation (27.58), which is the first law for a quasi-static process transitioning between thermodynamic equilibrium, takes the form for a moving fluid element

$$\frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} = T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \frac{p}{\rho^2}\,\frac{\mathrm{D}\rho}{\mathrm{D}t} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}. \tag{27.72}$$

Making use of the space and time derivative results from Section 27.6.2 leads to the gradient and Eulerian time derivative identities

$$\nabla\mathcal{I} = T\,\nabla\mathcal{S} + p\,\rho^{-2}\nabla\rho + \mu\,\nabla C \tag{27.73a}$$

$$\partial_t\mathcal{I} = T\,\partial_t\mathcal{S} + p\,\rho^{-2}\,\partial_t\rho + \mu\,\partial_t C. \tag{27.73b}$$

We can further massage the first law (27.72) by recalling that mass conservation as discussed in Section 20.2 means that changes in the volume of a fluid element are related to density changes via

$$\frac{1}{\delta V}\,\frac{\mathrm{D}\delta V}{\mathrm{D}t} = \frac{1}{\nu_{\mathrm{s}}}\,\frac{\mathrm{D}\nu_{\mathrm{s}}}{\mathrm{D}t} = -\frac{1}{\rho}\,\frac{\mathrm{D}\rho}{\mathrm{D}t}. \tag{27.74}$$

Hence, equation (27.72) can be written

$$\delta M\,\frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} = T\,\delta M\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} - p\,\frac{\mathrm{D}\delta V}{\mathrm{D}t} + \mu\,\delta M\,\frac{\mathrm{D}C}{\mathrm{D}t}, \tag{27.75}$$

where $\delta M = \rho\,\delta V$ is the mass of the fluid element. Since the mass of the fluid element is constant, equation (27.75) is the fluid element extension of the first law given by equation (27.58). Alternatively, we can use the further result from mass conservation (equation (20.26))

$$\frac{1}{\delta V}\,\frac{\mathrm{D}\delta V}{\mathrm{D}t} = \nabla\cdot\boldsymbol{v} \tag{27.76}$$

to write

$$\frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} = T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} - (p/\rho)\,\nabla\cdot\boldsymbol{v} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}. \tag{27.77}$$

Processes affecting internal energy that appear on the right hand side are (i) entropy production, whose form is developed in Sections 27.10 and 27.7, (ii) mechanical work from pressure modifying the volume of the fluid element, and (iii) mixing (chemical work) through the exchange of matter constituents between fluid elements. We provide further details for the first law in Section 27.7 when considering the budget for the total energy of a fluid element.

27.6.5 Enthalpy budget

It is often more convenient to consider the specific enthalpy (Section 23.6.4),

$$\mathcal{H} = \mathcal{I} + p/\rho = \mathcal{I} + p\,\nu_{\mathrm{s}}. \tag{27.78}$$

The mass continuity equation (20.20) and the internal energy equation (27.77) yield

$$\frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = \frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} + \frac{1}{\rho}\frac{\mathrm{D}p}{\mathrm{D}t} - \frac{p}{\rho^2}\frac{\mathrm{D}\rho}{\mathrm{D}t} \Longrightarrow \frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \frac{1}{\rho}\frac{\mathrm{D}p}{\mathrm{D}t} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}, \tag{27.79}$$

with the second expression consistent with equations (27.67) and (27.68) for the gradient and local time tendency of the specific enthalpy.

The specific enthalpy equation (27.79) says that for constant pressure processes, changes to specific enthalpy of a moving fluid element arise just from those processes that give rise to changes in specific entropy and changes in matter concentration

$$\frac{\mathrm{D}p}{\mathrm{D}t} = 0 \Longrightarrow \frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}. \tag{27.80}$$

Since many boundary processes occur approximately at near constant pressure (e.g., air-sea fluxes), this result motivates formulating boundary fluxes of matter and thermal energy in terms of enthalpy fluxes rather than internal energy fluxes. Also, the mixing of fluid elements occurs locally in space so that pressure of fluid elements is the same when they mix, again making enthalpy a useful thermodynamic potential for the study of mixing.

27.6.6 Thermal and chemical processes and fluxes

The internal energy of a fluid element is modified by the diabatic transfer of thermal energy. We are generally concerned with two thermal fluxes, one due to conduction and one due to radiation

$$\boldsymbol{J}_{\mathrm{therm}} = \boldsymbol{J}_{\mathrm{cond}} + \boldsymbol{J}_{\mathrm{rad}}. \tag{27.81}$$

Details of the radiant flux require topics outside our scope so we leave it unspecified. However, we consider forms for heat conduction in Section 27.10, with the simplest form being *Fourier's law* whereby $\boldsymbol{J}_{\mathrm{cond}}$ is directed down the temperature gradient.

The internal energy of a fluid element also changes through changes in the matter concentration. This change occurs when fluid elements mix at constant pressure. As mentioned in Section 27.6.5, enthalpy is the proper thermodynamic potential to consider for examining the mixing of matter concentrations. We thus assume that the transfer of chemical energy associated with a matter flux, $\boldsymbol{J}_C$, leads to a corresponding chemical energy flux given by

$$\boldsymbol{J}_{\mathrm{chem}} = \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} \boldsymbol{J}_C. \tag{27.82}$$

The enthalpy partial derivative is computed at constant pressure and temperature so to isolate the energy change associated just with mixing of matter. It is important to distinguish this partial derivative with the distinct derivative that leads to the chemical potential as in equation (23.76)

$$\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{\mathcal{S},p} = \mu. \tag{27.83}$$

As shown by Exercise 23.2, the two partial derivatives are related by

$$\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} = \mu - T\left[\frac{\partial \mu}{\partial T}\right]_{p,C}, \tag{27.84}$$

so that

$$\boldsymbol{J}_{\text{chem}} = \left[\mu - T\left[\frac{\partial \mu}{\partial T}\right]_{p,C}\right]\boldsymbol{J}_C. \tag{27.85}$$

We make use of this relation when studying the entropy budget in Section 27.10.

Details of the thermal and chemical fluxes are undetermined at this point. We garner further insights through studying the entropy budget and second law of thermodynamics in Section 27.10 and the budget for total energy in Section 27.7. It is remarkable how far the laws of thermodynamics can be used to constrain the molecular flux laws. Even so, we note that the conductive and chemical fluxes are those that arise from molecular motions rather than turbulent motions, with turbulent fluxes determined by properties of the flow whereas $\boldsymbol{J}_{\text{cond}}$ and $\boldsymbol{J}_{\text{chem}}$ are determined by properties of the fluid.

27.6.7 First law in terms of potential temperature

Equation (24.44) says that the change in entropy for a fluid element moving with constant matter concentration and at the reference pressure is given in terms of the potential temperature

$$\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = \frac{c_p}{\theta}\frac{\mathrm{D}\theta}{\mathrm{D}t} \tag{27.86}$$

For a single-component fluid, the potential temperature equals to the *in situ* temperature when $p = p_{\text{R}}$, in which case

$$c_p\frac{\mathrm{D}\theta}{\mathrm{D}t} = \theta\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} \qquad \text{at } p = p_{\text{R}} \text{ and } \mathrm{d}C = 0. \tag{27.87}$$

In general, this relation has little practical value since a fluid element generally does not maintain pressure at the reference pressure. Even so, in Exercise 27.4 we see that the relations hold for all pressures for the special case of an ideal gas, and in Exercise 27.5 we see they also hold for some liquids at all pressures.

27.6.8 Materially constant specific entropy for a perfect fluid

Each material fluid parcel within a perfect fluid maintains a constant specific entropy given that it experiences no dissipation (friction is absent), maintains a constant composition (mixing is absent), and encounters no heating (adiabatic). Consequently, specific entropy for each fluid parcel is reversibly stirred through advection

$$\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = \frac{\partial \mathcal{S}}{\partial t} + \boldsymbol{v}\cdot\nabla\mathcal{S} = 0. \tag{27.88}$$

Notably, a perfect fluid generally admits nonzero gradients of specific entropy even as each fluid element moves without altering its specific entropy.

27.6.9 Further study

DeGroot and Mazur (1984) provide an authoritative accounting of quasi-equilibrium thermodynamics as applied to continuum matter such as a fluid. *Gregg* (1984) and *Davis* (1994) apply

these methods to small-scale mixing in the ocean. Slightly different formulations can be found in *Landau and Lifshitz* (1987) and *Batchelor* (1967).

27.7 Budget for total energy

Recall from Section 14.8 that a point particle conserves its mechanical energy in the absence of friction. In contrast, the mechanical energy for a fluid element is not materially constant even when only conservative forces act on the element. The reason is that for the continuum fluid, there is (i) a conversion between mechanical energy and internal energy as pressure does work to alter the volume of fluid elements, and (ii) frictional dissipation of kinetic energy irreversibly converts some kinetic energy to internal energy through Joule heating (Section 27.7.3). In this section we combine the mechanical energy budget from Section 27.4 to the internal energy budget from Section 27.6, thus rendering the budget for total energy of a fluid element. We furthermore postulate that the domain integrated total energy changes only due to boundary effects, as well as possible changes in the geopotential such as via astronomical effects. This assumption then leads to further specifications of the processes contributing to the internal energy and enthalpy budgets.

27.7.1 Postulating the budget for total energy

In their specific (per mass) forms, the total energy of a fluid element is the sum of the internal energy, $\mathcal{I}$, of internal degress of freedom, plus the mechanical energy, $\mathcal{M}$, from macroscropic motion, with the mechanical energy the sum of the kinetic energy plus potential energy

$$\mathcal{E} = \mathcal{I} + \mathcal{M} = \mathcal{I} + \mathcal{K} + \Phi. \tag{27.89}$$

We postulate that this total energy per mass satisfies a conservation law whereby it is affected only by the convergence of a total energy flux, plus a source due to temporal changes in the geopotential

$$\rho \, \frac{\mathrm{D}\mathcal{E}}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}_{\mathcal{E}} + \rho \, \partial_t \Phi. \tag{27.90}$$

Correspondingly, the flux-form equation for total energy is

$$\frac{\partial(\rho \, \mathcal{E})}{\partial t} + \nabla \cdot (\rho \, \boldsymbol{v} \, \mathcal{E} + \boldsymbol{J}_{\mathcal{E}}) = \rho \, \partial_t \Phi. \tag{27.91}$$

The flux of total energy is given by

$$\begin{aligned} \rho \, \boldsymbol{v} \, \mathcal{E} + \boldsymbol{J}_{\mathcal{E}} &= \rho \, \boldsymbol{v} \, \mathcal{E} + \boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}} + \boldsymbol{J}_{\text{mech}} && (27.92\text{a}) \\ &= \rho \, \boldsymbol{v} \, \mathcal{E} + \boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}} - \boldsymbol{v} \cdot (-p \, \mathbb{I} + \mathbb{T}) && (27.92\text{b}) \\ &= \rho \, \boldsymbol{v} \, (\mathcal{E} + p/\rho) + \boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}} - \boldsymbol{v} \cdot \mathbb{T}, && (27.92\text{c}) \end{aligned}$$

where $\boldsymbol{J}_{\text{therm}}$ and $\boldsymbol{J}_{\text{chem}}$ were discussed in Section 27.6.6, and $\boldsymbol{J}_{\text{mech}}$ was derived in Section 27.4. We have more to say concerning the flux of total energy in Section 27.9 when studying the Bernoulli potential.

We are led to postulate the total energy equation (27.90) through assuming that $\int_{\mathcal{R}} \rho \, \mathcal{E} \, \mathrm{d}V$ remains constant in time for a region, $\mathcal{R}$, that is closed to thermal, material, and mechanical interactions, and one where the geopotential is constant in time. This assumption is based on our understanding of molecular and atomic mechanics.

27.7.2 First law of thermodynamics for a moving fluid

We now have the total energy budget as postulated in the form of equation (27.90), along with the mechanical energy budget derived in equation (27.49). Subtracting the two yields the internal energy budget

$$\rho \frac{\mathrm{D}(\mathcal{E} - \mathcal{M})}{\mathrm{D}t} = \rho \frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} = -\nabla \cdot (\boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}}) - p\, \nabla \cdot \boldsymbol{v} + \rho\, \epsilon. \tag{27.93}$$

This equation provides yet another expression for the first law of thermodynmics for a moving fluid element. It says that the internal energy of a fluid element is modified through the convergence of thermal and chemical fluxes, pressure work that alters the volume of a fluid element, and frictional dissipation through viscosity. Both the pressure work and frictional dissipation are exchanged with mechanical energy, and so they appear with opposite signs in the budget for mechanical energy. We specify the thermal and chemical fluxes in Section 27.10 when studying the entropy budget.

We can make use of the enthalpy equation (27.79) to render the enthalpy budget

$$\rho \frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} - \frac{\mathrm{D}p}{\mathrm{D}t} = -\nabla \cdot (\boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}}) + \rho\, \epsilon. \tag{27.94}$$

This equation is used in Section 27.11 when studying the evolution of temperature.

27.7.3 Joule heating from friction

Frictional dissipation, $\epsilon > 0$, measures the conversion of kinetic energy into heat, and it is thus a conversion from mechanical energy to internal energy

$$\dot{Q}_{\text{Joule}} \equiv \epsilon. \tag{27.95}$$

This term is referred to as *Joule heating* in analog to the process that occurs in electrical circuits. The Joule heating of a fluid by molecular viscosity is larger in regions where the fluid strains are larger, signalling a more efficient transfer of power to the microscales where molecular viscosity can act on the flow.

In the ocean interior, measurements indicate that $\epsilon \approx 10^{-9}$ W kg^{-1}. Dividing by $c_p = 3900$ J kg^{-1} K^{-1} leads to a heating rate of less than 10^{-3} K century^{-1}, which is a very small rate of ocean heating. Consequently, ocean Joule heating has a negligible role in the ocean heat budget and as such is generally ignored. Atmospheric flows are roughly two orders faster so that the kinetic energy per mass is four orders larger. The larger flow speeds lead to larger shears thus creating larger viscous dissipation that reaches roughly $\epsilon \approx 2$ W m^{-2} globally averaged. Hence, Joule heating is an important part of the global atmosphere enthalpy budget (*Becker*, 2003).

27.7.4 Comments on gauge symmetry

Consider again the flux-form equation for total energy (27.91). It is notable that the time tendency for the total energy remains unchanged if we shift the flux of total energy by a curl,

$$\rho\, \mathcal{E}\, \boldsymbol{v} + \boldsymbol{J}_{\mathcal{E}} \rightarrow \rho\, \mathcal{E}\, \boldsymbol{v} + \boldsymbol{J}_{\mathcal{E}} + \nabla \times \boldsymbol{G}, \tag{27.96}$$

with $\boldsymbol{G}$ referred to as a *gauge function*. This arbitrariness in the definition of total energy flux is ubiquitous in physics; e.g., see the discussion of the electromagnetic field energy flux in Section 27-4 in Volume II of *Feynman et al.* (1963).[11] We conclude that the energy flux has no unique local

[11] The Feynman lectures are available online through the California Institute of Technology.

physical meaning. Instead, it is only the convergence of the energy flux that has an unambiguous meaning given by its roel in affecting a time change to the energy at a point in space.

We also encounter such *gauge symmetry* in the potential vorticity flux discussed in Chapter 43, as well as the vector streamfunction for an incompressible fluid in Section 22.5.1. In some cases we can exploit the symmetry to our subjective desires, such as discussed in Section 43.5.6 for potential vorticity. However, we know of no strategic use of gauge symmetry for the study of energy budgets.

27.7.5 Further study

The postulate of globally integrated total energy conservation in Section 27.7.1, and the associated discussion of energy budgets, follow that from Section 33 of *Serrin* (1959), Section II.4 of *DeGroot and Mazur* (1984), Chapter 14 of *Callen* (1985), Sections 49 and 58 of *Landau and Lifshitz* (1987), Chapters 3 and 4 of *Müller* (2006), Appendix B of *IOC et al.* (2010), Section 2.4 of *Olbers et al.* (2012), Chapter 1 of *Vallis* (2017), and Section 13.5.5 of *Thorne and Blandford* (2017).

27.8 Thermodynamic equilibrium with macroscopic motion

We derived the properties of thermodynamic equilibria in Section 23.2.8 for a single component fluid, and in Section 24.1 for a binary fluid in the presence of a geopotential. We here extend those discussions to the case of a finite region of a fluid undergoing macroscopic motion in the absence of gravity. We assume no external forces or torques, so that the total linear momentum and total angular momentum remain constant. As in our earlier discussions, we derive the properties of thermodynamic equilibrium by assuming entropy is an extremum at equilibrium. Furthermore, the extremum must be consistent with the variety of conserved quantities, thus motivating the use of Lagrange multipliers as part of the formalism needed to determine the extremum.

27.8.1 Deriving the equilibrium conditions

To focus on the allowed macroscopic motion, we ignore external fields such as from gravity, in which case the total energy is the sum of the internal energy plus kinetic energy

$$\mathcal{E}^{\mathrm{e}} = \mathcal{I}^{\mathrm{e}} + P^2/(2\,M), \tag{27.97}$$

where $\boldsymbol{P} = M\,\boldsymbol{v}$ is the linear momentum of the system with velocity $\boldsymbol{v}$ and mass M, and $P^2 = \boldsymbol{P}\cdot\boldsymbol{P}$ is the squared momentum. If the macroscopic system is materially and mechanically closed then total energy remains constant, as does the linear momentum and angular momentum. Thermodynamic equilibrium is realized by maximizing the function

$$\Psi = \mathcal{S}^{\mathrm{e}} + \boldsymbol{A}\cdot\boldsymbol{P} + \boldsymbol{B}\cdot(\boldsymbol{x}\times\boldsymbol{P}), \tag{27.98}$$

where $\boldsymbol{x}$ is the position of the macroscopic system, and the vectors $\boldsymbol{A}$ and $\boldsymbol{B}$ are constant Lagrange multipliers. Note that for convenience we assume the system to be macroscopically small but microscopically large (e.g., a fluid element) so that we can assign a single position vector to the system.

Should entropy be a function of the total energy (which is a constant of the motion) or remain a function of just the internal energy? To answer this question we appeal to the statistical interpretation of entropy whereby the number of microstates corresponding to a particular macrostate is Galilean invariant.[12] The local rest state, where total energy equals to internal energy, is thus

[12] Recall our discussion of Galilean invariance in Section 18.9.

sufficient for defining the functional dependence[13]

$$\mathcal{S}^{\mathrm{e}} = \mathcal{S}^{\mathrm{e}}(V, \mathcal{I}^{\mathrm{e}}) = \mathcal{S}^{\mathrm{e}}[V, \mathcal{E}^{\mathrm{e}} - P^2/(2M)]. \tag{27.99}$$

Hence, maximizing Ψ with respect to the linear momentum component, P_m, requires the derivative

$$\left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial P_m}\right]_V = \left[\frac{\partial \mathcal{S}^{\mathrm{e}}}{\partial \mathcal{I}^{\mathrm{e}}}\right]_V \frac{\partial \mathcal{I}^{\mathrm{e}}}{\partial P_m} = -\frac{1}{T}\frac{P_m}{M} = -\frac{v_m}{T}, \tag{27.100}$$

so that the macroscopic velocity at equilibrium is

$$\frac{\partial \Psi}{\partial P_m} = 0 \Longrightarrow \boldsymbol{v} = T\,(\boldsymbol{A} + \boldsymbol{B} \times \boldsymbol{x}). \tag{27.101}$$

With temperature uniform throughout the macroscopic system at thermodynamic equilibrium, we find a velocity decomposed into a uniform translation plus a rigid-body rotation. That is, a closed macroscopic system in thermodynamic equilibrium can, at most, exhibit uniform translation plus rigid-body rotation. More general macroscopic motion is not possible when the system is in thermodynamic equilibrium. Furthermore, note that each component of the strain rate tensor vanishes for uniform translation plus a rigid-body rotation (see Exercise 19.2). For the Newtonian fluids considered in this book, a zero strain rate tensor means there are no frictional stresses (Section 26.8.6), thus ensuring no frictionally generated entropy.

The Cauchy-Stokes decomposition from Section 19.4.6 shows that at each time instance, motion of a fluid element can be kinematically decomposed into translation, rotation, and dilation. Dilation occurs through mechanical work. In its absence, and without heating or mixing, the fluid element moves through sequences of translations and rotations that maintain thermodynamic equilibrium. With dilation, heating, and/or matter mixing, we conceive of a moving fluid as a continuum of fluid elements that, on a time scale that is tiny relative to macroscopic processes, adjusts to thermodynamic equilibrium in response to interactions with the surrounding fluid environment.

27.8.2 Further study

We here followed the dicussion of §10 in *Landau and Lifshitz* (1980). See also a complementary discussion in Section 1.8 of *Kamenkovich* (1977), who considers a two-component fluid in the presence of gravity. *Kamenkovich* (1977) finds that although *in situ* temperature is a uniform constant in thermodynamic equilibrium, the salinity is not constant.

27.9 Bernoulli's theorem

The total energy equation (27.90) reveals that the material time change for the total energy of a fluid element is affected by the convergence of pressure times velocity. Hence, even in the absence of irreversible processes (i.e., a perfect fluid) and with a time-independent geopotential, the total energy of a fluid element is not materially invariant. The pressure flux, $p\,\boldsymbol{v}$, is a fundamental contribution to energy within the continuum. As shown in this section, it is the pressure work required for the fluid element to mechanically exist within the continuum. We thus refer to $p\,\boldsymbol{v}$ as the mechanical *injection work*. This conceptualization of $p\,\boldsymbol{v}$ arises in the context of exploring the remarkably versatile Bernoulli theorem, which is particularly useful in diagnosing energetic properties of steady flows.

[13] See footnote on page 36 of *Landau and Lifshitz* (1980) for more discussion.

27.9.1 Bernoulli potential

Consider the flux-form equation for the total energy, (27.91), written here as

$$\frac{\partial(\rho\,\mathcal{E})}{\partial t} + \nabla\cdot\left[\rho\,\boldsymbol{v}\,(\mathcal{E}+p/\rho) + \boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}} - \boldsymbol{v}\cdot\mathbb{T}\right] = \rho\,\partial_t\Phi. \tag{27.102}$$

The left hand side indicates that total energy of a fluid element is locally modified by the advective transport of the quantity

$$\mathcal{E} + p/\rho = (\mathcal{K}+\Phi) + (\mathcal{I}+p/\rho) = \mathcal{M} + \mathcal{H} \equiv \mathcal{B}, \tag{27.103}$$

where we introduced the *Bernoulli potential*, which is the sum of the mechanical energy per mass plus the enthalpy per mass

$$\mathcal{B} = \mathcal{M} + \mathcal{H} = \mathcal{K} + \Phi + \mathcal{I} + p/\rho. \tag{27.104}$$

For a perfect fluid there is no irreversible transfer of heat, matter, or momentum so that

$$\text{perfect fluid} \Longrightarrow \boldsymbol{J}_{\text{therm}} = 0 \quad \text{and} \quad \boldsymbol{J}_{\text{chem}} = 0 \quad \text{and} \quad \mathbb{T} = 0. \tag{27.105}$$

Hence, we see that integration over a region with zero boundary transfer of $\boldsymbol{v}\,\mathcal{B}$ leads to the conservation of total energy for a perfect fluid with a time independent geopotential. Note that for some purposes it can be useful to write the total energy equation (27.102) as an equation for the Bernoulli function, which takes the form

$$\frac{\partial(\rho\,\mathcal{B})}{\partial t} + \nabla\cdot\left[\rho\,\boldsymbol{v}\,\mathcal{B} + \boldsymbol{J}_{\text{therm}} + \boldsymbol{J}_{\text{chem}} - \boldsymbol{v}\cdot\mathbb{T}\right] = \partial_t p + \rho\,\partial_t\Phi. \tag{27.106}$$

27.9.2 Mechanical injection work

Why is $\rho\,\mathcal{E}$ affected by the convergence of $\rho\,\boldsymbol{v}\,\mathcal{B}$ rather than the convergence of $\rho\,\boldsymbol{v}\,\mathcal{E}$? To answer this question,[14] again note that the Bernoulli potential is the sum of the total energy per mass of a fluid element, $\mathcal{E}$, plus the term p/ρ. So what is p/ρ? Imagine carving out a tiny region from within a continuous fluid with pressure p and specific volume $1/\rho$, leaving behind a "hole". The mechanical work required to carve out this hole is precisely equal to p/ρ. Correspondingly, we interpret p/ρ as the mechanical work required to inject a unit mass of fluid with specific volume $1/\rho$ into a region with pressure p. We thus refer to p/ρ as the *injection work*, and we in turn see that specific enthalpy, $\mathcal{H} = \mathcal{I} + p/\rho$ (equation (27.78)), measures the internal energy plus the mechanial work required for a fluid element to exist within a continuum.

We can support the above interpretation by considering the flux, $\rho\,\boldsymbol{v}\,\mathcal{B}$, in a perfect fluid that penetrates a static closed fluid region

$$\oint_{\partial\mathcal{R}} \rho\,\boldsymbol{v}\,\mathcal{B}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{R}} \rho\,\boldsymbol{v}\,\mathcal{E}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \oint_{\partial\mathcal{R}} p\,\boldsymbol{v}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{27.107}$$

The first term on the right hand side is the flux of total energy (mechanical plus internal) that penetrates the region boundary, $\partial\mathcal{R}$. The second term is the mechanical work done by pressure acting on the boundary. The example in Section 27.9.3 further supports this perspective, whereby we develop the energetics of a control volume of fluid moving through a pipe.

[14] This argument follows Section 13.5.4 of *Thorne and Blandford* (2017) as well as Section 6 of *Landau and Lifshitz* (1987).

27.9.3 Bernoulli's theorem for a steady perfect fluid

Consider a perfect fluid flow in steady state (vanishing Eulerian time derivatives). Steady state mass conservation means that

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \, \boldsymbol{v}) = 0. \tag{27.108}$$

This relation, along with a steady state energy in equation (27.102) (absent friction, heating, mixing, and with a time-independent geopotential), means that the steady state velocity field is locally tangent to isosurfaces of the Bernoulli potential

$$\boldsymbol{v} \cdot \nabla \mathcal{B} = 0. \tag{27.109}$$

We thus see that for the perfect fluid to be in a steady state, the Bernoulli potential is constant along streamlines, which is a result known as *Bernoulli's theorem*. Hence, as the fluid moves along a streamline, there is an exchange between the total energy per mass, $\mathcal{E}$, and the injection work, p/ρ, such that their sum remains constant.

A constant Bernoulli potential for steady flow is used frequently in engineering fluid dynamics to interpret flow around objects, such as for flow around a wing, in which case the sum $p + \rho \, \boldsymbol{v}^2/2$ is sometimes referred to as the *total pressure* or *stagnation pressure*. It leads to a realization of *Bernoulli's principle*, whereby in regions of low pressure the energy per mass is relatively large, whereas the converse holds in regions of high pressure. The change in energy is largely due to a change in the kinetic energy, so that flow is fast in regions of low pressure (e.g., top of the wing, flow around a train moving through a tunnel) and slow in regions of high pressure (e.g., bottom of the wing).[15] That is, the Bernoulli principle provides an energetic expression for why a fluid slows down when moving into a region of relatively high pressure, and speeds up when moving to a region of low pressure.

27.9.4 Traditional derivation of Bernoulli's theorem

For completeness we offer a second derivation of Bernoulli's theorem that follows a more traditional route and reveals some useful manipulations. For this purpose, convert the advective-form momentum equation (25.16) into its vector-invariant form by making use of the vector identity (see Section 2.3.4)

$$\boldsymbol{\omega} \times \boldsymbol{v} = -\mathcal{K} + (\boldsymbol{v} \cdot \nabla) \, \boldsymbol{v}. \tag{27.110}$$

This identity allows us to eliminate velocity self-advection in favor of the vorticity and kinetic energy per mass

$$\frac{\partial \boldsymbol{v}}{\partial t} + \boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v} = -\frac{1}{\rho} \nabla p - \nabla \mathcal{M}, \tag{27.111}$$

where

$$\boldsymbol{\omega}_{\mathrm{a}} = \boldsymbol{\omega} + 2 \, \boldsymbol{\Omega} \tag{27.112}$$

is the absolute vorticity (see Chapter 41) and we set the irreversible terms to zero since we are assuming a perfect fluid. The Eulerian time evolution for the kinetic energy per mass is therefore given by

$$\frac{\partial \mathcal{K}}{\partial t} = -\frac{1}{\rho} \, \boldsymbol{v} \cdot \nabla p - \boldsymbol{v} \cdot \nabla \mathcal{M}, \tag{27.113}$$

where we set $\boldsymbol{v} \cdot (\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v}) = 0$.

[15] See this discussion and video for why it is incorrect to use Bernoulli's theorem for explaining the lift on an airplane wing.

For Bernoulli's theorem we are interested in the steady state, with a steady kinetic energy per mass realized by the balance

$$\rho^{-1}\, \boldsymbol{v} \cdot \nabla p = -\boldsymbol{v} \cdot \nabla \mathcal{M}. \tag{27.114}$$

We can connect this steady state balance to the Bernoulli potential by noting that for a steady perfect and single-component fluid, equation (27.69) allows us to write

$$\rho^{-1}\, \boldsymbol{v} \cdot \nabla p = \boldsymbol{v} \cdot (\nabla \mathcal{H} - T\, \nabla \mathcal{S}). \tag{27.115}$$

Combining with equation (27.114) renders

$$\boldsymbol{v} \cdot (\nabla \mathcal{H} + \nabla \mathcal{M} - T\, \nabla \mathcal{S}) = \boldsymbol{v} \cdot (\nabla \mathcal{B} - T\, \nabla \mathcal{S}) = 0. \tag{27.116}$$

A perfect fluid maintains materially constant specific entropy (Section 27.6.8), which in a steady state means that

$$\boldsymbol{v} \cdot \nabla \mathcal{S} = 0 \qquad \text{and} \qquad \boldsymbol{v} \cdot \nabla \mathcal{B} = 0 \qquad \Longleftarrow \text{steady state perfect fluid.} \tag{27.117}$$

That is, for a steady perfect fluid the velocity is aligned with isosurfaces of specific entropy and Bernoulli potential.

27.9.5 Steady flow in a pipe

To help further understand Bernoulli's theorem and the contribution from the mechanical work provided by pressure forces, consider the steady flow of a constant density perfect fluid in a frictionless pipe as depicted in Figure 27.1. For this system, Bernoulli's theorem says that the following simplified form of the Bernoulli potential is constant for flow along a streamline

$$\mathcal{B} = \boldsymbol{v}^2/2 + p/\rho + g\, z = \text{constant}. \tag{27.118}$$

Note that internal energy dropped out since for a constant density fluid the internal energy is a constant and so plays no role in the energetics. Equation (27.118) means that there is a precise balance between the kinetic energy per mass, injection work, and geopotential for a steady and constant density fluid. For example, for flow following a constant geopotential, pressure is relatively low in regions of large kinetic energy whereas pressure is relatively high in regions of small kinetic energy. We further pursue this understanding by showing that the statement (27.118) of Bernoulli's theorem can be derived through traditional energetic arguments, whereby the mechanical work done on the fluid system equals to the system's change in kinetic energy (see Section 11.1.4 for the particle mechanics version of this *work-energy theorem*).

For this purpose, let the system under examination be a control volume of fluid as described in the caption to Figure 27.1, and examine the work done on the control volume over an arbitrary time increment, Δt. During this time, a mass of fluid given by

$$M = \rho\, A_1\, u_1\, \Delta t = \rho\, A_2\, u_2\, \Delta t \tag{27.119}$$

moves through the pipe, with $A_1\, u_1 = A_2\, u_2$ following from volume conservation, and we assumed that the $u_{1,2} = \Delta x_{1,2}/\Delta t$ measures the average velocity across the pipe cross-section. Mechanical work is applied to the fluid in the control volume by pressure acting on the end caps (contact force) and by gravity acting throughout the fluid (body force).

- PRESSURE WORK: At the left end cap, pressure from fluid to the left of the control volume does work on the control volume by the amount $p_1\, A_1\, \Delta x_1 = p_1\, M/\rho$. On the right end,

FIGURE 27.1: An example to illustrate the basic physics of Bernoulli's theorem and pressure work, whereby we depict the flow of a perfect and constant density fluid from left to right in a pipe of variable cross-section and variable height. We study the energetics of a control volume (dark blue region) moving with the fluid. The top panel shows the control volume at one time and the lower panel shows the control volume at a time Δt later, after which a mass of fluid, M, has moved through the system. Volume conservation means that $(u_1\,\Delta t)\,A_1 = (u_2\,\Delta t)\,A_2$, where $\Delta x_{1,2}$ is the horizontal displacement of the fluid plug over time Δt, $u_{1,2}$ is the cross-sectional area average velocity, $A_{1,2}$ is the pipe cross-sectional area, and $M = \rho\,\Delta x_1\,A_1 = \rho\,\Delta x_2\,A_2$ is the mass of fluid moving over the Δt time increment. Pressure forces, $p_{1,2}$, at the end caps point inward (compressive), with pressure on the left larger than that on the right to support the fluid moving to the right. As the fluid moves upward it increases its gravitational potential energy and in so doing the fluid does work against gravity.

the control volume does work on the fluid to its right, which means that a negative work is applied to the control volume in the amount $-p_2\,A_2\,\Delta x_2 = -p_2\,M/\rho$.

- GRAVITATIONAL WORK: Fluid downstream at the right end is higher than fluid upstream on the left end. The control volume must do work against gravity to achieve this altitude increase and this work is given by $-g\,M\,(z_2 - z_1)$.

As the fluid moves from left to right, the control volume changes its kinetic energy by the amount $(M/2)\,(u_2^2 - u_1^2)$. Equating this kinetic energy change to the work applied to the control volume renders

$$(1/2)\,(u_2^2 - u_1^2) = (1/\rho)\,(p_1 - p_2) - g\,(z_2 - z_1), \tag{27.120}$$

where the mass, M, dropped out. Rearrangement then leads to

$$u^2/2 + p/\rho + g\,z = \text{constant}, \tag{27.121}$$

which is a statement of Bernoulli's theorem (27.118).

Making use of volume conservation allows us to rearrange equation (27.120) to determine the pressure difference between the left and right end of the pipe

$$p_1 - p_2 = \rho\,g\,(z_2 - z_1) - (\rho/2)\,u_1^2\,[1 - (A_1/A_2)^2]. \tag{27.122}$$

To help understand this result, consider two special cases starting with $A_1 = A_2$. We see that for equal cross-sectional areas, the pressure drop equals to the increase in gravitational potential energy,

$$p_1 - p_2 = \rho\, g\, (z_2 - z_1) > 0 \quad \text{with } A_2 = A_1, \tag{27.123}$$

so that the pressure work equals to the gravitational work required to lift the fluid. Next consider $z_2 = z_1$ so that there is no change in gravitational potential energy but there is a change in cross-sectional area, in which case

$$p_1 - p_2 = -(\rho/2)\, u_1^2\, [1 - (A_1/A_2)^2] < 0 \quad \text{with } z_2 = z_1. \tag{27.124}$$

In this case there is a pressure increase as the fluid moves into a region with larger cross-sectional area ($A_2 > A_1$). This pressure increase slows the fluid speed, which accords with volume conservation.

These examples support our understanding of how pressure provides mechanical work on fluid control volume boundaries, with that work required to maintain conservation of mechanical energy (seen in the above case with $A_2 = A_1$) and conservation of volume (see in the above case with $z_2 = z_1$). Indeed, taking the control volume to be a tiny fluid element furthers our understanding of the p/ρ injection work contribution to the Bernoulli potential (27.103).

27.9.6 Steady flow over a topographic bump

We build from the discussion of steady pipe flow in Section 27.9.5 by describing a more geophysically relevant case of steady single-component perfect fluid flowing over a topographic bump. In Figure 27.2 we illustrate this flow in the absence of rotation. As the fluid moves over the bump, it speeds up in order to maintain volume continuity. In regions of faster flow, Bernoulli's theorem (27.118) says that the pressure is lower, which is realized here by a lowering of the sea surface height over the bump. For a small bump, we can imagine that the flow remains symmetric with respect to the bump, so that the flow downstream of the bump is a reflection of the upstream flow. To maintain steady flow in the presence of a larger bump requires a larger pressure drop, which will eventually break the symmetry between downstream and upstream. For an even larger topographic bump, we find there is no way to satisfy Bernoulli's theorem, in which case the flow transitions into at time dependent *hydraulic jump*.

As for the pipe flow, the steady flow maintains two flow constants: the volume flow rate and the simplified form of the Bernoulli potential in equation (27.118)

$$\mathcal{T} = v\, h\, \Delta \quad \text{and} \quad \mathcal{B} = \boldsymbol{v}^2/2 + p/\rho + g\, z, \tag{27.125}$$

where h is the thickness of the layer and Δ the width in the direction perpendicular to the flow. Also, recall that the Bernoulli potential is a constant along a particular streamline. However, for a constant density layer the Bernoulli potential is independent of depth, as we illustrate below. For simplicity we assume the flow is only a function of the along-stream coordinate, y, and furthermore assume the pressure on the upper interface is a uniform constant p_{a}. We also assume the top and botton interfaces of the layer are material, which then means they are each streamlines.

It is more convenient to work with the flow rate, $\mathcal{T} = v\, h\, \Delta$, than the velocity, v, in which case the Bernouilli potential is given by

$$\mathcal{B} = \mathcal{T}^2/(2\, h^2\, \Delta^2) + p/\rho + g\, z. \tag{27.126}$$

Far upstream of the bump the layer thickness takes on its unperturbed value, H, so that the

FIGURE 27.2: Depicting steady flow of a single-component fluid with constant density, ρ, flowing over a topographic bump and viewed from a non-rotating reference frame so there is no Coriolis acceleration. We assume all properties are a function only of the along-stream position, y, and $z = 0$ is taken at the position of a flat topography. For steady flow of a constant density fluid, the volume transport, $\mathcal{T}$, is constant and given by $\mathcal{T} = v\,h\,\Delta$, where Δ is the width of the flow in the direction perpendicular to the page, and $h = \eta - \eta_b$ is the layer thickness. The simplified form of the Bernouilli potential given by equation (27.118) is also constant along any streamline, $\mathcal{B} = \boldsymbol{v}^2/2 + p/\rho + g\,z =$ constant. The top panel shows the flow for a very small topographic bump, so that the flow is symmetric around the bump. The lower panel show flow for a larger bump that requires more fluid upstream of the bump to support enough pressure drop for steady flow to make it over the bump.

Bernoulli potential along the surface streamline at $z = H$ is given by

$$\mathcal{B} = \mathcal{T}^2/(2\,H^2\,\Delta^2) + p_a/\rho + g\,H. \tag{27.127}$$

Notice how every term on the right hand side is positive, so that $\mathcal{B} > 0$. Also notice that the Bernoulli potential along the bottom streamline takes the same value

$$\mathcal{B} = \mathcal{T}^2/(2\,H^2\,\Delta^2) + p_b/\rho = \mathcal{T}^2/(2\,H^2\,\Delta^2) + (p_a + \rho\,h\,H)/\rho, \tag{27.128}$$

which results since the layer has constant density. Now express the Bernoulli potential in a region affected by the bump, in which case

$$\mathcal{B} = \mathcal{T}^2/(2\,h^2\,\Delta^2) + p_a/\rho + g\,\eta = \mathcal{T}^2/(2\,h^2\,\Delta^2) + p_a/\rho + g\,(h + \eta_b). \tag{27.129}$$

We observe that

$$\mathcal{B} - g\,\eta_b = T^2/(2\,h^2\,\Delta^2) + p_a/\rho + g\,h \geq 0, \tag{27.130}$$

with this quantity referred to as the *Bernoulli head*. The condition $\mathcal{B} - g\,\eta_b \geq 0$ holds so long as the flow maintains the assumptions of Bernouili's theorem. However, if the topography is too tall, then $\mathcal{B} - g\,\eta_b \leq 0$, in which case the flow can no longer satisfy the Bernoulli theorem. This result leads us to define a critical topography height

$$\eta_b^{\text{crit}} = \mathcal{B}/g = \mathcal{T}^2/(2\,H^2\,\Delta^2\,g) + p_a/(\rho\,g) + H. \tag{27.131}$$

When topography is larger than this height, the flow cannot reach a steady state and/or the flow develops a dependence on the direction perpendicular to the page. In either case, the assumptions of Bernoulli's theorem breakdown.

27.9.7 Further study

For an examination of Bernoulli's theorem for flows in a non-rotating reference frame, such as flow in laminar boundary layers, see this video from Prof. Shapiro. Chapter 3 of *Acheson* (1990) and the text from *Pratt and Whitehead* (2008) make use of Bernoulli's theorem for understanding flows over obstacles with and without the Coriolis acceleration. Their Section 1.4 forms the basis for the discussion in Section 27.9.6. See also Exercise 8.6 of *Klinger and Haine* (2019).

27.10 Entropy budget for the ocean

In this section we consider the entropy budget for the ocean and make use of the second law of thermodynamics to infer specific forms for the thermal and chemical fluxes introduced in Section 27.6.6. The discussion also holds for the atmosphere in the absence of phase transitions, though we focus on the ocean application to be specific. Hence, the matter concentration in this section is the salt concentration for seawater.

The entropy budget follows by rearranging the enthalpy equation (27.79)

$$T\,\rho\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = \rho\,\frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} - \frac{\mathrm{D}p}{\mathrm{D}t} - \mu\,\rho\,\frac{\mathrm{D}C}{\mathrm{D}t}, \tag{27.132}$$

with the enthalpy budget in the form (27.94) yielding

$$T\,\rho\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = -\nabla\cdot(\boldsymbol{J}_{\mathrm{therm}} + \boldsymbol{J}_{\mathrm{chem}}) + \rho\,\epsilon + \mu\,\nabla\cdot\boldsymbol{J}_C, \tag{27.133}$$

where we wrote the tracer equation as

$$\rho\,\frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_{\mathrm{C}}, \tag{27.134}$$

following Section 21.1.3. Through manipulations pursued in Section 27.10.1, we identify a non-advective entropy flux and a corresponding entropy source. This form of the entropy budget is useful since we can then invoke the second law to insist that the entropy source is non-negative, and that statement renders some constraints on the thermal and chemical fluxes.

27.10.1 Non-advective entropy flux and entropy source

To start the manipulations, divide equation (27.133) by T and rewrite in terms of a flux convergence plus a source

$$\rho\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = -\nabla\cdot\left[\frac{\boldsymbol{J}_{\mathrm{therm}} + \boldsymbol{J}_{\mathrm{chem}} - \mu\,\boldsymbol{J}_C}{T}\right] + \nabla(1/T)\cdot(\boldsymbol{J}_{\mathrm{therm}} + \boldsymbol{J}_{\mathrm{chem}} - \mu\,\boldsymbol{J}_C) - (\boldsymbol{J}_C/T)\cdot\nabla\mu + \frac{\rho\,\epsilon}{T}. \tag{27.135}$$

Recall from the identity (27.84) that we can write the chemical energy flux as

$$\boldsymbol{J}_{\mathrm{chem}} = \left[\frac{\partial\mathcal{H}}{\partial C}\right]_{T,p}\boldsymbol{J}_C = \left[\mu - T\left[\frac{\partial\mu}{\partial T}\right]_{C,p}\right]\boldsymbol{J}_C = (\mu - T\,\mu_T)\,\boldsymbol{J}_C, \tag{27.136}$$

where we introduced a shorthand for the third equality. This identity then leads to

$$\boldsymbol{J}_{\mathrm{chem}} - \mu\,\boldsymbol{J}_C = -T\,\mu_T\,\boldsymbol{J}_C, \tag{27.137}$$

in which case the entropy equation (27.135) becomes

$$\rho \frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = -\nabla \cdot \left[\frac{\boldsymbol{J}_{\text{therm}} - T\,\mu_T\,\boldsymbol{J}_C}{T} \right] + \nabla(1/T) \cdot (\boldsymbol{J}_{\text{therm}} - T\,\mu_T\,\boldsymbol{J}_C) - (\boldsymbol{J}_C/T) \cdot \nabla\mu + \frac{\rho\,\epsilon}{T}. \quad (27.138)$$

We thus identify the non-advective entropy flux

$$\boldsymbol{J}_{\mathcal{S}} = \frac{\boldsymbol{J}_{\text{therm}}}{T} - \left[\frac{\partial\mu}{\partial T}\right]_{p,C} \boldsymbol{J}_C = \frac{\boldsymbol{J}_{\text{therm}}}{T} + \left[\frac{\partial\mathcal{S}}{\partial C}\right]_{T,p} \boldsymbol{J}_C, \quad (27.139)$$

where the second equality made use of the Maxwell relation

$$-\left[\frac{\partial\mathcal{S}}{\partial C}\right]_{T,p} = \left[\frac{\partial\mu}{\partial T}\right]_{p,C}, \quad (27.140)$$

which is derived as part of the solution to Exercise 23.2. The additional terms comprise the entropy source

$$\begin{aligned}
\Sigma_{\mathcal{S}} &= \frac{\rho\,\epsilon}{T} + \nabla(1/T) \cdot (\boldsymbol{J}_{\text{therm}} - T\,\mu_T\,\boldsymbol{J}_C) - (\boldsymbol{J}_C \cdot \nabla\mu)/T && (27.141\text{a})\\
&= \frac{\rho\,\epsilon}{T} + \frac{\nabla T}{T^2} \cdot (T\,\mu_T\,\boldsymbol{J}_C - \boldsymbol{J}_{\text{therm}}) - (\boldsymbol{J}_C \cdot \nabla\mu)/T && (27.141\text{b})\\
&= \frac{\rho\,\epsilon}{T} - \frac{\nabla T \cdot \boldsymbol{J}_{\text{therm}}}{T^2} + \frac{\boldsymbol{J}_C \cdot (\mu_T\,\nabla T - \nabla\mu)}{T} && (27.141\text{c})\\
&= \frac{\rho\,\epsilon}{T} - \frac{\nabla T \cdot \boldsymbol{J}_{\text{therm}}}{T^2} - \frac{\boldsymbol{J}_C \cdot (\mu_C\,\nabla C + \mu_p\,\nabla p)}{T} && (27.141\text{d})\\
&= \frac{\rho\,\epsilon}{T} - \frac{\nabla T \cdot \boldsymbol{J}_{\text{therm}}}{T^2} - \frac{\boldsymbol{J}_C}{T} \cdot \left[\left[\frac{\partial\mu}{\partial C}\right]_{T,p} \nabla C + \left[\frac{\partial\mu}{\partial p}\right]_{T,C} \nabla p \right], && (27.141\text{e})
\end{aligned}$$

where we wrote the gradient of the chemical potential, $\mu(T, p, C)$, as

$$\nabla\mu = \left[\frac{\partial\mu}{\partial T}\right]_{p,C} \nabla T + \left[\frac{\partial\mu}{\partial p}\right]_{T,C} \nabla p + \left[\frac{\partial\mu}{\partial C}\right]_{T,p} \nabla C = \mu_T\,\nabla T + \mu_p\,\nabla p + \mu_C\,\nabla C. \quad (27.142)$$

The non-advective entropy flux (27.139) arises from the thermal and chemical fluxes, and the entropy source (27.141e) includes contributions from those fluxes as well as the frictional dissipation of mechanical energy.

27.10.2 Constraints from the second law of thermodynamics

The second law of thermodynamics states that the entropy source is non-negative

$$\Sigma_{\mathcal{S}} \geq 0 \Longleftarrow \text{second law of thermodynamics.} \quad (27.143)$$

This condition imposes constraints on the frictional dissipation, thermal flux, and tracer flux. Since frictional dissipation in Newtonian fluids (equation (27.43)) is non-negative, $\epsilon \geq 0$, we make use of the second law to constrain just the thermal flux and tracer flux. Furthermore, recall from equation (27.81) that the thernal flux is comprised of a radiant flux and conductive flux. We assume that radiant flux is determined by processes external to the fluid. We thus use the second law to constrain just the conductive portion of the thermal flux along with the tracer flux. That

is, from the entropy source (27.141e) we have the second law constraint

$$-\nabla T \cdot \boldsymbol{J}_{\text{cond}} - T\,\mu_C\,\boldsymbol{J}_C \cdot \left[\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right] \geq 0. \tag{27.144}$$

This constraint can be satisfied by assuming the conductive and tracer fluxes are of the form

$$\rho^{-1}\,\boldsymbol{J}_{\text{cond}} = -c_{\text{p}}\,\kappa_T\,\nabla T - \kappa_{TC}\left[\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right] \tag{27.145a}$$

$$\rho^{-1}\,\boldsymbol{J}_C = -\kappa_C\left[\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right] - \kappa_{CT}\,\nabla T. \tag{27.145b}$$

The variety of molecular fluxes

The first term in the conductive thermal flux (27.145a) is known as *Fourier's law of conduction*

$$\boldsymbol{J}_{\text{cond}}^{\text{Fourier}} = -\rho\,c_{\text{p}}\,\kappa_T\,\nabla T, \tag{27.146}$$

in which case the conductive thermal flux is directed down the gradient of the *in situ* temperature. The second term leads to a conductive thermal flux in the presence of matter concentration gradients and pressure gradients, and this process is known as the *Dufour effect*

$$\boldsymbol{J}_{\text{cond}}^{\text{Dufour}} = -\rho\,\kappa_{TC}\left[\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right]. \tag{27.147}$$

The first term in the matter flux (27.145b) is known as *Fick's law of diffusion*

$$\boldsymbol{J}_C^{\text{Fick}} = -\rho\,\kappa_C\,\nabla C. \tag{27.148}$$

The second term in in the matter flux (27.145b) is known as *barodiffusion*

$$\boldsymbol{J}_C^{\text{barodiff}} = -(\rho\,\kappa_{CT}\,\mu_p/\mu_C)\,\nabla p, \tag{27.149}$$

which is a matter flux arising from a pressure gradient. Finally, the matter flux arising from temperature gradients is known as the *Soret effect*

$$\boldsymbol{J}_C^{\text{Soret}} = -\rho\,\kappa_{CT}\,\nabla T. \tag{27.150}$$

Thermodynamic equilibrium and the vertical gradient of salinity

In Section 24.1, we learned that thermodynamic equilibrium for a fluid in a gravity field leads to a uniform temperature, T, and a pressure in exact hydrostatic balance. The salt flux must vanish in thermodynamic equilibrium, but in the presence of a pressure gradient we have a nonzero vertical salinity gradient from equation (27.145b) given by

$$\frac{\mathrm{d}C}{\mathrm{d}z} = -\frac{\mu_p}{\mu_C}\,\frac{\mathrm{d}p}{\mathrm{d}z} = \frac{\mu_p\,\rho\,g}{\mu_C}. \tag{27.151}$$

This relation is identical to equation (24.20) resulting from our study of conditions for thermodynamic equilibrium of a binary fluid in a gravity field. It is satisfying to see the same thermodynamic equilibrium condition arise from the rather different path taken here.

Invoking Onsager reciprocity condition

The Onsager reciprocity conditions[16] are now invoked to relate the two off-diagonal coefficients according to

$$T\,\mu_C\,\kappa_{CT} = \kappa_{TC}, \tag{27.152}$$

which brings the entropy condition to the form

$$c_{\mathrm{p}}\,\kappa_T\,|\nabla T|^2 + \kappa_C\,\mu_C\,T\left|\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right|^2 + 2\,\kappa_{TC}\,\nabla T\cdot\left[\nabla C + \frac{\mu_p}{\mu_C}\,\nabla p\right] \geq 0. \tag{27.153}$$

This condition then constrains the phenomenological constants κ_C, κ_T and κ_{TC} so that

$$|\kappa_{TC}|^2 \leq \kappa_T\,\kappa_C\,c_{\mathrm{p}}\,T\,\mu_S. \tag{27.154}$$

Comments on measurements

The cross-diffusion coefficients, κ_{TC} and κ_{CT}, are both measured to be very small for seawater, so that the Dufour effect and Soret effect are commonly ignored. Furthermore, in an ocean in thermodynamic equilibrium, the vertical salinity gradient implied by equation (27.151) is roughly 3 g kg^{-1} per 1000 m. This vertical salinity gradient is far larger than measured in the ocean, thus providing evidence that turbulent fluxes, even in the ocean interior, dominate over molecular fluxes. That is, the observed ocean has sufficient turbulence to keep it well away from thermodynamic equilibrium.

27.10.3 A summary presentation

We here summarize the previous material by skipping details for the entropy flux, thermal flux, and matter flux. For this purpose, write the budget for the total energy in the form

$$\rho\,\frac{\mathrm{D}\mathcal{E}}{\mathrm{D}t} = -\nabla\cdot(p\,\boldsymbol{v} - \boldsymbol{v}\cdot\mathbb{T}) + \rho\left[-\epsilon + T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}\right] + \rho\,\partial_t\Phi. \tag{27.155}$$

Now assume that the specific entropy and matter concentration satisfy the evolution equations

$$\rho\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_{\mathcal{S}} + \Sigma_{\mathcal{S}} \quad\text{and}\quad \rho\,\frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_C, \tag{27.156}$$

thus rendering

$$\rho\left[T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \mu\,\frac{\mathrm{D}C}{\mathrm{D}t}\right] = -T\,\nabla\cdot\boldsymbol{J}_{\mathcal{S}} + T\,\Sigma_{\mathcal{S}} - \mu\,\nabla\cdot\boldsymbol{J}_{\mathrm{C}} \tag{27.157a}$$

$$= -\nabla\cdot(T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + \nabla T\cdot\boldsymbol{J}_{\mathcal{S}} + \nabla\mu\cdot\boldsymbol{J}_{\mathrm{C}} + T\,\Sigma_{\mathcal{S}}, \tag{27.157b}$$

which then brings the total energy equation (27.155) into the form

$$\rho\,\frac{\mathrm{D}\mathcal{E}}{\mathrm{D}t} = -\nabla\cdot(p\,\boldsymbol{v} - \boldsymbol{v}\cdot\mathbb{T} + T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + [-\rho\,\epsilon + \nabla T\cdot\boldsymbol{J}_{\mathcal{S}} + \nabla\mu\cdot\boldsymbol{J}_{\mathrm{C}} + T\,\Sigma_{\mathcal{S}}] + \rho\,\partial_t\Phi. \tag{27.158}$$

We now postulate that the globally integrated total energy is constant in the absence of boundary processes and with a time independent geopotential. In the presence of mechanical dissipation and matter constituent mixing, a necessary condition for such global energy conservation is for

[16] See Chapter 14 of *Callen* (1985) for these conditions and their underlying dynamical connections.

the specific entropy source to take the form

$$T\,\Sigma_{\mathcal{S}} = \rho\,\epsilon - \nabla T\cdot \boldsymbol{J}_{\mathcal{S}} - \nabla\mu\cdot\boldsymbol{J}_{\mathrm{C}}. \tag{27.159}$$

That is, the entropy source arises from frictional dissipation, entropy mixing, and matter mixing. With this form for the entropy source, the total energy budget (27.158) is given by the material form and the equivalent flux-form expressions

$$\rho\,\frac{\mathrm{D}\mathcal{E}}{\mathrm{D}t} = -\nabla\cdot(p\,\boldsymbol{v} - \boldsymbol{v}\cdot\mathbb{T} + T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + \rho\,\partial_t\Phi \tag{27.160a}$$

$$\frac{\partial(\rho\,\mathcal{E})}{\partial t} = -\nabla\cdot(\mathcal{E}\,\boldsymbol{v} + p\,\boldsymbol{v} - \boldsymbol{v}\cdot\mathbb{T} + T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + \rho\,\partial_t\Phi. \tag{27.160b}$$

The modified form of the internal energy budget (27.77) is found by subtracting the mechanical energy budget (27.49) from the total energy budget (27.160a)

$$\rho\,\frac{\mathrm{D}\mathcal{I}}{\mathrm{D}t} = \rho\,\frac{\mathrm{D}(\mathcal{E}-\mathcal{M})}{\mathrm{D}t} = -p\,\nabla\cdot\boldsymbol{v} - \nabla\cdot(T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + \rho\,\epsilon. \tag{27.161}$$

The corresponding enthalpy budget (27.79) is given by

$$\rho\,\frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} - \frac{\mathrm{D}p}{\mathrm{D}t} = -\nabla\cdot(T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}}) + \rho\,\epsilon = -\nabla\cdot\boldsymbol{J}_{\mathcal{H}} + \rho\,\epsilon. \tag{27.162}$$

In the second equatlity we defined the enthalpy flux

$$\boldsymbol{J}_{\mathcal{H}} = T\,\boldsymbol{J}_{\mathcal{S}} + \mu\,\boldsymbol{J}_{\mathrm{C}} \tag{27.163a}$$

$$= \boldsymbol{J}_{\mathrm{therm}} - T\left[\frac{\partial\mu}{\partial T}\right]_{p,C}\boldsymbol{J}_C + \mu\,\boldsymbol{J}_C \tag{27.163b}$$

$$= \boldsymbol{J}_{\mathrm{therm}} + \left[\frac{\partial\mathcal{H}}{\partial C}\right]_{T,p}\boldsymbol{J}_C \tag{27.163c}$$

$$= \boldsymbol{J}_{\mathrm{therm}} + \boldsymbol{J}_{\mathrm{chem}}, \tag{27.163d}$$

where we used equation (27.139) for the entropy flux, $\boldsymbol{J}_{\mathcal{S}}$, equation (27.136) for the chemical flux, $\boldsymbol{J}_{\mathrm{chem}}$, and the thermodynamic identity (27.84) for the third equality. Furthermore, recall that the thermal flux, $\boldsymbol{J}_{\mathrm{therm}}$, is the sum of a conductive plus radiative contribution as per equation (27.81).

27.10.4 Comments

It is remarkable how the second law of thermodynamics is able to predict new physical processes through considering the various forms that the thermal and matter fluxes can take to ensure a positive entropy source. *Caldwell* (1973) and *Caldwell and Eide* (1981) estimate the Soret effect for seawater, where they propose some relevance of this effect in quiescent ocean regions with strong gradients. In contrast, for liquids the Dufour effect is about 1000 times smaller than Fickian heat conduction and so it is safely ignored throughout the ocean. *McDougall and Turner* (1982) and *McDougall* (1983) studied double-diffusive convection in the presence of cross-diffusion, extending the oceanographic applications to arbitrary solutions with a pair of solutes. None of these studies consider the role of pressure gradients in generating fluxes.

For most purposes of oceanography, the fluxes considered in this section are far smaller than those induced by turbulent flow processes. In this case, the flux relations reduce to the Fickian and

Fourier expressions yet with turbulent exchange coefficients rather than their molecular values. Turbulence thus makes molecular diffusive processes generally negligible for the ocean. Indeed, we already made this conclusion when noting that thermodynamic equilibrium implies a sizable vertical salinity gradient as given by equation (27.151). Whereas turbulence acts to produce a homogenous salinity (as well as potential temperature and potential enthalpy), molecular diffusion leads to a rather large vertical salinity gradient. Since the vertical salinity gradient implied by thermodynamic equilibrium is much larger than that measured in the ocean, we conclude that the ocean is far from a thermodynamic equilibrium state.

27.10.5 Further study

Much of our presentation in this section followed that from Sections 2.4 and 2.5 from *Olbers et al.* (2012) and Appendix B of *IOC et al.* (2010). *Graham and McDougall* (2013) extend these ideas to a turbulent ocean. The physical ideas underlying the Onsager reciprocity conditions are lucidly discussed in Chapter 14 of *Callen* (1985).

27.11 Temperature evolution

In specifying the state of a fluid element it is sensible to make use of the temperature, pressure, and tracer concentration given that these state properties are readily measured in the laboratory and environment. Furthermore, these properties are the natural variables for the Gibbs potential (Section 23.6.6). Hence, given values for (T, p, C) we can determine the Gibbs potential and then determine all other thermodynamic properties by taking partial derivatives.

How do we specify the evolution of (T, p, C) for a fluid element? Evolution of the matter concentration follows from the tracer equation (an advection-diffusion equation) as developed in Section 21.1. Pressure measures the compressive stress acting on each fluid element (Section 26.8), with its specification depending on the dominant dynamical balances (see Section 27.13). Temperature reflects the energy of the internal microscopic degrees of freedom within a fluid element, with its evolution the subject of this section. We show how Conservative Temperature, Θ, rather than *in situ* temperature, T, or potential temperature, θ, offers the simplest prognostic equation of the three temperature variables. The key reason is that Θ evolves almost precisely like a material tracer, driven by the convergence of fluxes, whereas the equations for T and θ contain extra source terms in additon to flux convergences.

27.11.1 Evolution of *in situ* temperature

In developing the temperature equation it is useful to start from the prognostic equation for enthalpy as developed in Sections 27.6.5. For that purpose we write the enthalpy equation (27.162) as

$$\rho \frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = \frac{\mathrm{D}p}{\mathrm{D}t} - \nabla \cdot \boldsymbol{J}_{\mathcal{H}} + \rho\, \epsilon, \tag{27.164}$$

with the enthalpy flux, $\boldsymbol{J}_{\mathcal{H}}$, written in terms of the entropy and tracer fluxes as per equation (27.163d).

To reveal a prognostic equation for temperature, we write enthalpy as a function of (T, p, C) so that

$$\frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = \left[\frac{\partial \mathcal{H}}{\partial T}\right]_{p,C} \frac{\mathrm{D}T}{\mathrm{D}t} + \left[\frac{\partial \mathcal{H}}{\partial p}\right]_{T,C} \frac{\mathrm{D}p}{\mathrm{D}t} + \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} \frac{\mathrm{D}C}{\mathrm{D}t}. \tag{27.165}$$

The partial derivatives can be related to response functions via the following. First, the specific

heat capacity at constant pressure is given by equation (23.101)

$$\left[\frac{\partial \mathcal{H}}{\partial T}\right]_{p,C} = c_{\mathrm{p}}. \tag{27.166}$$

Next, we make use of the Gibbs potential identities in Section 23.6.6 to write

$$\left[\frac{\partial \mathcal{H}}{\partial p}\right]_{T,C} = \left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C} - T\left[\frac{\partial}{\partial p}\right]_{T,C}\left[\frac{\partial \mathcal{G}}{\partial T}\right]_{p,C} \tag{27.167a}$$

$$= \nu_{\mathrm{s}} - T\left[\frac{\partial}{\partial T}\right]_{p,C}\left[\frac{\partial \mathcal{G}}{\partial p}\right]_{T,C} \tag{27.167b}$$

$$= \nu_{\mathrm{s}} - T\left[\frac{\partial \nu_{\mathrm{s}}}{\partial T}\right]_{p,C} \tag{27.167c}$$

$$= \nu_{\mathrm{s}}\,(1 - T\,\alpha_{\mathrm{T}}), \tag{27.167d}$$

where α_{T} is the thermal expansion coefficient given by equation (23.102). Use of these identities in the enthalpy equation (27.165) and rearrangement leads to the *in situ* temperature equation

$$c_{\mathrm{p}}\,\rho\,\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_{\mathcal{H}} + \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p}\nabla\cdot\boldsymbol{J}_{\mathrm{C}} + \alpha_{\mathrm{T}}\,T\,\frac{\mathrm{D}p}{\mathrm{D}t} + \rho\,\epsilon. \tag{27.168}$$

The *in situ* temperature of a fluid element thus evolves according to convergence of the enthalpy fluxes, divergence of matter concentration fluxes, material time changes to pressure, and frictional dissipation. We can massage this expression a bit more by introducing the enthalpy flux (27.163c) so that

$$c_{\mathrm{p}}\,\rho\,\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_{\mathrm{therm}} - \boldsymbol{J}_{C}\cdot\nabla\left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p} + \alpha_{\mathrm{T}}\,T\,\frac{\mathrm{D}p}{\mathrm{D}t} + \rho\,\epsilon, \tag{27.169}$$

where constraints on the conductive portion of the thermal flux were discussed in Section 27.10.2.

27.11.2 Evolution of potential temperature

We can convert the *in situ* temperature equation (27.168) into a version of the potential temperature equation by recalling the expression (24.26) for the lapse rate

$$\hat{\Gamma} = \left[\frac{\partial T}{\partial p}\right]_{C,\mathcal{S}} = \frac{T\,\alpha_{\mathrm{T}}}{\rho\,c_{\mathrm{p}}} \tag{27.170}$$

so that equation (27.168) takes the form

$$c_{\mathrm{p}}\,\rho\left[\frac{\mathrm{D}T}{\mathrm{D}t} - \hat{\Gamma}\,\frac{\mathrm{D}p}{\mathrm{D}t}\right] = -\nabla\cdot\boldsymbol{J}_{\mathcal{H}} + \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p}\nabla\cdot\boldsymbol{J}_{\mathrm{C}} + \rho\,\epsilon. \tag{27.171}$$

Making use of the definition (24.31) for potential temperature renders

$$c_{\mathrm{p}}\,\rho\,\frac{\mathrm{D}\theta}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{J}_{\mathcal{H}} + \left[\frac{\partial \mathcal{H}}{\partial C}\right]_{T,p}\nabla\cdot\boldsymbol{J}_{\mathrm{C}} + \rho\,\epsilon. \tag{27.172}$$

As expected, pressure changes are removed from the evolution equation for potential temperature.

27.11.3 Conservative Temperature for the ocean

Rather than expressing enthalpy as a function $\mathcal{H}(T, p, C)$, we make use of its natural coordinate dependence $\mathcal{H}(\mathcal{S}, p, C)$ from Section 23.6.4, which leads to the enthalpy equation in the form (27.162)

$$\rho \frac{\mathrm{D}\mathcal{H}}{\mathrm{D}t} = \frac{\mathrm{D}p}{\mathrm{D}t} - \nabla \cdot \boldsymbol{J}_{\mathcal{H}} + \rho\, \epsilon. \tag{27.173}$$

The pressure term arises just like for *in situ* temperature. Its presence suggests we introduce the *potential enthalpy*.

Potential enthalpy and Conservative Temperature

The potential enthalpy is defined to be the enthalpy of a fluid element moved to a reference pressure, p_{R}, while maintaining fixed specific entropy and fixed tracer concentration

$$\mathcal{H}^{\mathrm{pot}}(\mathcal{S}, C) = \mathcal{H}(\mathcal{S}, p_{\mathrm{R}}, C). \tag{27.174}$$

As for potential temperature (Section 24.3.3), it is most convenient to take p_{R} as the standard atmospheric pressure, thus corresponding to the standard pressure at the air-sea interface. This definition parallels that for potential temperature given by equation (24.36). It is also motivated by the exchange of enthalpy (heat) across the air-sea boundary, thus providing a natural means to study coupled air-sea processes.

By construction, the material time derivative of potential enthalpy is given by

$$\rho \frac{\mathrm{D}\mathcal{H}^{\mathrm{pot}}}{\mathrm{D}t} = \rho \left[\frac{\partial \mathcal{H}^{\mathrm{pot}}}{\partial \mathcal{S}}\right]_C \frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} + \rho \left[\frac{\partial \mathcal{H}^{\mathrm{pot}}}{\partial C}\right]_{\mathcal{S}} \frac{\mathrm{D}C}{\mathrm{D}t} \tag{27.175a}$$

$$= \theta\left(-\nabla \cdot \boldsymbol{J}_{\mathcal{S}} + \Sigma_{\mathcal{S}}\right) - \mu_{\mathrm{R}}\, \nabla \cdot \boldsymbol{J}_{\mathrm{C}} \tag{27.175b}$$

$$= (\theta/T)\left[\rho\, \epsilon - \nabla \cdot \boldsymbol{J}_{\mathrm{H}}\right] - \left[\mu_{\mathrm{R}} - (\theta/T)\, \mu\right] \nabla \cdot \boldsymbol{J}_{\mathrm{C}}, \tag{27.175c}$$

where we set

$$\theta = \left[\frac{\partial \mathcal{H}^{\mathrm{pot}}}{\partial \mathcal{S}}\right]_C \qquad \text{and} \qquad \mu_{\mathrm{R}} = \left[\frac{\partial \mathcal{H}^{\mathrm{pot}}}{\partial C}\right]_{\mathcal{S}} \tag{27.176}$$

and used equation (27.159) for the entropy source, $\Sigma_{\mathcal{S}}$. Now define the Conservative Temperature, Θ, via

$$c_{\mathrm{p}}^{\mathrm{ref}}\, \Theta \equiv \mathcal{H}^{\mathrm{pot}}(\mathcal{S}, C) = \mathcal{H}(\mathcal{S}, p_{\mathrm{R}}, C), \tag{27.177}$$

where $c_{\mathrm{p}}^{\mathrm{ref}}$ is an arbitrary reference specific heat capacity. For the ocean, *McDougall* (2003) suggested that $c_{\mathrm{p}}^{\mathrm{ref}}$ be chosen so that $\Theta = \theta$ at a salinity of 35 parts per thousand. *McDougall* (2003) furthermore argued that the terms appearing in the potential enthalpy equation (27.175c) are well approximated for the ocean by just the convergence of the enthalpy flux. Hence, the Conservative Temperature satisfies, to a very good approximation, the source-free tracer equation

$$\rho\, c_{\mathrm{p}}^{\mathrm{ref}} \frac{\mathrm{D}\Theta}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}_{\mathrm{H}}. \tag{27.178}$$

Key points regarding the Conservative Temperature equation

The Conservative Temperature equation (27.178) is mathematically identical to the material tracer equation, and as such it offers an elegant means to prognose thermodynamic properties of the fluid and to perform budget analyses. We further emphasize two points in regards to this equation relative to the potential temperature equation (27.172).

- The source terms (those not associated with flux convergences) on the right hand side of the potential temperature equation are much larger than those in the Conservative Temperature equation. In particular, *McDougall* (2003) and *Graham and McDougall* (2013) showed that the potential temperature sources are roughly 100 times larger in certain regions of the ocean than the Conservative Temperature sources.

- The heat capacity appearing in the Conservative Temperature equation is a fixed constant, by construction. This feature contrasts to the space-time variable heat capacity, c_{p}, appearing in both the *in situ* temperature equation (27.168) and potential temperature equation (27.172). The space-time variations of c_{p} are not negligible (e.g., order 5% for the global ocean), thus making the non-constant heat capacity required for the T and θ equations very inconvenient for purposes of budget analyses (see *McDougall et al.* (2021) for more on this point).

We close by noting that the enthalpy flux, $\boldsymbol{J}_{\mathrm{H}}$, is related to the entropy flux and concentration flux as per equation (27.163d). As discussed in Section 2.6 of *Olbers et al.* (2012), the dominant terms appearing in this flux arise from entropy, which itself is largely due to fluxes of temperature. Consequently, the flux $\boldsymbol{J}_{\mathrm{H}}$ is well approximated as a flux just of Θ.

27.11.4 Alternative functional dependencies for specific enthalpy

Thus far in this section, we have considered specific enthalpy to be a function of (T, p, C) as well as its natural functional dependence, $(\mathcal{S}, p, C)$. The introduction of potential temperature and Conservative Temperature allow us to consider two more functional depenencies

$$\mathcal{H} = \mathcal{H}^{\mathrm{natural}}(\mathcal{S}, p, C) = \mathcal{H}^{\mathrm{T}}(T, p, C) = \mathcal{H}^{\theta}(\theta, p, C) = \mathcal{H}^{\Theta}(\Theta, p, C). \tag{27.179}$$

We use distinct notations for the functions since they each return specific enthalpy yet when fed distinct input. Given the more common use of either potential temperature or Conservative Temperature in atmosphere and ocean sciences, the final two functional dependencies are most commonly used in practice. Note that for brevity, we often drop the extra notation adorning the specific enthalpy symbol, except where confusion may arise. As an example of the above functional dependence, consider the exact differential of specific enthalpy when written using the (Θ, p, C) dependence, in which

$$\mathrm{d}\mathcal{H} = \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial \Theta}\right]_{p,C} \mathrm{d}\Theta + \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial p}\right]_{\Theta,C} \mathrm{d}p + \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial C}\right]_{\Theta,p} \mathrm{d}C \tag{27.180a}$$

$$= \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial \Theta}\right]_{p,C} \mathrm{d}\Theta + \rho^{-1}\,\mathrm{d}p + \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial C}\right]_{\Theta,p} \mathrm{d}C, \tag{27.180b}$$

where we set

$$\rho^{-1} = \left[\frac{\partial \mathcal{H}^{\Theta}}{\partial p}\right]_{\Theta,C}, \tag{27.181}$$

which is a generalization of the partial derivative (23.76) holding for the natural functional dependence. Further discussion of the other partial derivatives are provided in *Graham and McDougall* (2013) as well as Appendices A.10 and A.11 of *IOC et al.* (2010).

27.11.5 Further study

The discussion in this section largely followed the more complete ocean discussion given in Section 2.6 of *Olbers et al.* (2012), which is itself based on *McDougall* (2003) and *Graham and McDougall*

(2013).

Considerations for a realistic atmosphere involve phase changes (liquid-vapor and liquid-solid), with the associated latent heat exchanges are leading order contributions to the enthalpy budget (see *Lauritzen et al.* (2022) for a comprehensive review). Additionally, the role of frictional dissipation is not negligible in the atmosphere whereas it is negligible in the ocean (see Section 27.7.3).

27.12 Conservation laws and potential properties

A central facet of theoretical physics concerns the development of concepts and tools to expose conservation laws and their underlying symmetries.[17] We routinely make use of such laws in geophysical fluid mechanics to provide constraints on the fluid motion and to study budgets of corresponding properties to help understand fundamental processes. As such, conservation laws offer great physical insight and predictive utility. We close this chapter by summarizing some conceptual points concerning conservation laws. In particular, we identify the need to distinguish laws that involve just the convergence of a flux from those that also include non-conservative "source" terms. We also distinguish between material and non-material conservation laws, in which properties satisfying material conservation laws are materially invariant in the absence of local mixing processes.

27.12.1 Flux-form conservation laws

Certain scalar properties studied in fluid mechanics satisfy conservation laws that are written as

$$\rho \, \frac{\mathrm{D}\psi}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J} \Longleftrightarrow \frac{\partial(\rho \, \psi)}{\partial t} = -\nabla \cdot (\rho \, \boldsymbol{v} \, \psi + \boldsymbol{J}). \tag{27.182}$$

The right hand side of the flux-form expression (second equation) involves a flux that is comprised of an advective term, $\rho \, \boldsymbol{v} \, \psi$, plus a non-advective term, $\boldsymbol{J}$. Examples of conservation laws of this type include the material tracer concentration, $\psi = C$, as in equation (27.188); the Conservative Temperature, $\psi = \Theta$, as in equation (27.189); the total energy, $\psi = \mathcal{E}$, in the absence of astronomical forces, as in equation (27.160b); and the potential vorticity, $\psi = Q$, as in equation (42.49). In Chapter 21, we saw how this differential equation leads to finite volume conservation properties for the integral of ψ-stuff within a region, $\int_{\mathcal{R}} \psi \, \rho \, \mathrm{d}V$, with the evolution of this integral only affected by area integrated fluxes, $\rho \, \boldsymbol{v} \, \psi + \boldsymbol{J}$, penetrating the region boundary (mathematically seen by applying the divergence theorem).

Conservation laws of the form (27.182) are a direct consequence of the *local* conservation of ψ-stuff within the fluid. That is, the amount of ψ-stuff changes at a point only through the local convergence of fluxes onto that point, and likewise for a finite region. Such conservation laws are consistent with basic notions of causality and locality that appear throughout physics, with a discussion of such conservation laws offered in Section 27-1 of *Feynman et al.* (1963).

27.12.2 Conservation laws that are not flux-form

The presence of source/sinks are relevant for chemical or biogeochemical reactions, whereby matter is converted from one form to another. Such processes are not mathematically represented as the convergence of a flux. As such, they are not contained in the conservation law (27.182) and they are correspondingly referred to as *non-conservative processes*. Even without chemical reactions,

[17] See Chapter 14 for the connection between conservation laws and symmetries, as embodied by Noether's theorem.

not all fluid properties satisfy flux-form conservation laws of the form (27.182). For example, linear momentum of a fluid element is affected by pressure, Coriolis, and effective gravity, and these processes are not represented as the convergence of a flux.

As discussed in Chapter 14, conservation laws are associated with symmetries of the physical system. Correspondingly, non-conservative terms appearing in an evolution equation often reflect the breaking of a symmetry. For example, motion around a sphere does not conserve linear momentum even in the absence of forces, whereas linear momentum is conserved for free motion in a planar geometry.

27.12.3 Non-material or wave-like transport of properties

Pressure is of particular note since pressure perturbations travel through a compressible fluid via acoustic waves (Chapter 49), or, in the case of an incompressible flow, a pressure perturbation is felt globally and instantaneously as reflected in the elliptic Poisson equation satisfied by pressure (Section 30.3). More generally, the wave mediated transfer of forces, or other fluid properties such as momentum or mechanical energy, is an example of a non-material transfer; i.e., a transfer of information not arising from the transfer of matter. Non-material wave mediated transfer often occurs much faster than material transfer, with matter transport only mediated through advection and diffusion. Correspondingly, material substances (and potential enthalpy) are not directly affected by wave transport. Rather, waves affect material substances only so far as they affect advection and diffusion.

27.12.4 Material and non-material conservation laws

Mass invariance for a fluid element reflects matter conservation in classical physics, which in turn motivates the kinematic perspective pursued throughout this book that follows fluid elements whose mass remains constant. Relatedly, in the absence of irreversible mixing, the matter content of the fluid element remains invariant so that its tracer concentration is materially constant

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} = 0. \tag{27.183}$$

For example, in the absence of mixing, the salt content of seawater and the water content of moist air are materially invariant, so that the salt concentration and water concentration in a fluid element remains invariant. Correspondingly, in the presence of mixing between two fluid elements, the net material tracer in the combined fluid element equals to the sum of the tracer content in the contributing elements. We refer to fluid properties satisfying such conservation laws as *materially conservative properties*.

What about fluid properties that satisfy a local flux-form conservation law of the form (27.182), and yet do not remain materially invariant in the absence of mixing? For example, consider the total energy, $\mathcal{E}$, from Section 27.7. Even in the absence of entropy sources (i.e., no mixing) and astronomical forces (i.e., constant gravity), mechanical work from pressure modifies the internal energy of the fluid element via the energy equation (27.160a)

$$\rho \frac{\mathrm{D}\mathcal{E}}{\mathrm{D}t} = -\nabla \cdot (p\,\boldsymbol{v}). \tag{27.184}$$

Pressure work means that when two fluid elements are combined, the total energy of the combined fluid, $\mathcal{E}_{12}$, is not generally equal to the sum of their separate total energies,

$$\mathcal{E}_{12} \neq \mathcal{E}_1 + \mathcal{E}_2. \tag{27.185}$$

So although total energy is locally conserved in the sense that it is affected by a local flux convergence, it does not satisfy a material-like conservation law. We say that total energy is a *non-materially conservative* fluid property. Notably, when integrated globally over a domain closed to energy fluxes, including mechanical energy fluxes (meaning there is no pressure work applied to the domain boundaries), and when there are no time dependent astronomical forces, then the domain integrated total energy, $\int \rho \, \mathcal{E} \, \mathrm{d}V$, remains constant. This *global* conservation law means that the total energy is conserved globally. Conservation laws for non-materially conserved properties, such as total energy, offer a less powerful constraint on fluid motion than the material conservation laws. Even so, global conservation can be of great use when studying energy transformations within a closed domain.

We summarize the above discussion by noting that for a fluid property to be locally conservative, it is necessary that the density weighted material derivative of that property be given by the convergence of a flux as in equation (27.182). To be materially conservative, a property must have its flux convergence vanish in the absence of mixing processes that are local in space and time. A diffusive flux satisfies this property (see Chapter 64 for more on diffusion). In contrast, the pressure flux convergence acting to modify total energy, $-\nabla \cdot (p \, \boldsymbol{v})$, can be nonzero even in regions where there is no mixing of matter since pressure is transported by waves (Section 27.12.3). So although total energy is locally conserved, its flux is dependent on non-local processes as mediated by waves, so that total energy satisfies a non-material conservation law.

27.12.5 Concerning potential properties

As introduced in Sections 24.3 and 27.11.3, to study fluid mixing it is useful to work with scalar fields that are not affected by adiabatic and isentropic pressure work. For this reason, rather than *in situ* temperature, we prefer to work with potential temperature, θ, or Conservative Temperature, Θ, both of which are potential properties as discussed in Section 24.3.1. Some potential properties are also endowed with the local conservation property discussed above, which makes local budgets available just like for a material tracer. For example, Conservative Temperature is very well approximated as a conservative property, with its non-flux form sources far smaller than potential temperature (Section 27.11.3). In contrast, neither *in situ* temperature nor total energy are potential properties since an adiabatic and isentropic change in pressure alters the *in situ* temperature and total energy of a fluid element.

27.12.6 Further study

Much from this section is motivated by the more extensive discussion in Sections A.8 and A.9 of *IOC et al.* (2010).

27.13 Summary equations for rotating and stratified fluids

We close this chapter by summarizing the physical content of the suite of partial differential equations describing rotating and stratified fluids.

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\rho\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho\,\nabla\Phi - \nabla p + \nabla \cdot \mathbb{T} \qquad \text{momentum} \tag{27.186}$$

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho\,\nabla \cdot \boldsymbol{v} \qquad \text{mass continuity} \tag{27.187}$$

$$\rho \frac{\mathrm{D}C}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}(C) \qquad \text{matter conservation} \tag{27.188}$$

$$\rho \frac{\mathrm{D}\Theta}{\mathrm{D}t} = -\nabla \cdot \boldsymbol{J}(\Theta) \qquad \text{potential enthalpy conservation} \tag{27.189}$$

$$\rho = \rho(C, \Theta, p) \qquad \text{equation of state.} \tag{27.190}$$

It is a testament to the success of classical continuum mechanics that these equations are of use for describing fluid phenomena from the millimetre scale to the astrophysical scale. We summarize the following terms in these equations.

- LINEAR MOMENTUM AND VELOCITY: Newton's second law of motion, as developed for a fluid in Chapter 25, provides the prognostic equation for the velocity field, $\boldsymbol{v}$. Each of the three velocity components evolves according to its respective dynamical equation (27.186). As noted at the end of Section 25.2.3, we write the momentum equation in the form (27.186) by separating the time dependence of the basis vectors into a term arising from rigid-body rotation (which leads to planetary Coriolis and planetary centrifugal accelerations) and a term arising from the motion of the fluid relative to the rotating sphere (which leads to the metric acceleration when using non-Cartesian coordinates).

- MASS CONSERVATION: Kinematics provides a constraint on the velocity field according to the needs of mass conservation for a fluid element (Section 20.2). This constraint leads to the continuity equation (27.187).

- MATERIAL TRACER CONSERVATION: Kinematic constraints from the conservation of matter (Section 21.1) leads to the material tracer equation (27.188). Evolution is determined by the convergence of tracer fluxes, $\boldsymbol{J}$, with this flux specified by molecular diffusion as discussed in Section 64.3, or through other parameterized processes when sampling flow on scales larger than millimetres (see Chapter 66).

- THERMODYNAMIC TRACER: The Conservative Temperature, Θ, (Section 27.11.3), evolves according to the convergence of fluxes, just like a material tracer.

- DENSITY: The *in situ* density can be updated in time via mass continuity (equation (27.187)) or via knowledge of (C, Θ, p). We discussed the many forms of density for the ocean and atmosphere in Section 31.3.

- PRESSURE: There is no prognostic equation for pressure. Rather, pressure is diagnosed based on knowledge of other fields. Here are sketches of how that diagnostic calculation is performed.

  - For an ideal gas, pressure is diagnosed from the ideal gas relation (24.48) using the density and temperature.

- For fluid flow maintaining an approximate hydrostatic balance (Section 28.2), pressure is diagnosed at a point through knowledge of the weight per area above the point.
- For a non-divergent fluid flow as per the oceanic Boussinesq fluid (Chapter 30), pressure is no longer connected thermodynamically to partial derivatives of the thermodynamic potentials (Section 23.6). Instead, pressure is determined kinematically by the non-divergence constraint. In particular, for a non-hydrostatic Boussinesq fluid, pressure is diagnosed by solving a Poisson equation derived from taking the divergence of the momentum equation (see Section 30.3).

- GEOPOTENTIAL: The geopotential, Φ, is specified once the height above an arbitrary reference level is known, as well as the effective gravitational acceleration (Section 13.10.4). For geophysical fluid studies, the reference level is generally taken at the level of a resting sea surface. We thus often write the radial coordinate as

$$r = R_{\mathrm{e}} + z \tag{27.191}$$

where $R_{\mathrm{e}} = 6.371 \times 10^6$ m is the radius of a sphere whose volume approximates that of the earth (equation (13.118)), and z is the geopotential coordinate measuring the height above sea level.

- EARTH'S SPIN: The earth's angular velocity, $\boldsymbol{\Omega}$, is time constant for geophysical fluid studies of concern here. Its value is discussed in Section 13.1.

- FRICTION: The friction vector,

$$\rho \boldsymbol{F} = \nabla \cdot \mathbb{T}, \tag{27.192}$$

is the divergence of a symmetric and trace-free deviatoric stress tensor, $\mathbb{T}$ (Section 26.8). The stress tensor is determined through a constitutive relation as a function of the strain and viscous properties.

- KINEMATIC AND DYNAMIC BOUNDARY CONDITIONS: Kinematic and dynamic boundary conditions consist of the exchange of matter, momentum, and enthalpy with the surrounding media, such as the solid earth or another fluid component (e.g., atmosphere-ocean exchange). We discuss the boundary conditions for matter in a homogeneous fluid in Section 20.4; matter in a multi-constituent fluid in Section 21.5; for momentum in Section 26.10; and for ocean buoyancy in Section 67.6.

27.14 Exercises

EXERCISE 27.1: ENERGETICS OF OCEAN MIXING

In this exercise we develop some basics for the energetics of mixing, thus providing more experience with the ideas developed in Section 27.2.6. We do so by examining a vertical column of seawater with uniform horizontal cross-sectional area, A. Let the initial conditions consist of two homogeneous regions stacked vertically, with thickness h_n, mass M_n, density ρ_n, Conservative Temperature Θ_n, and salinity S_n, where $n = 1$ is the lower region and $n = 2$ the upper region. Assume this column to be stably stratified so that $\Delta\rho = \rho_1 - \rho_2 > 0$. We then completely mix the two regions to produce a homogeneous column of fluid of mass M, salinity S, and Conservative Temperature Θ. We ignore pressure effects on density, so that the density is uniform in the two

regions prior to mixing, and uniform in the full column after mixing. The conservation of mass, conservation of salt, and conservation of potential enthalpy (heat), mean that these scalar properties remain the same before and after the mixing, thus allowing us to compute the properties of the homogenized column

$$M = M_1 + M_2 \quad \text{and} \quad M\,\Theta = M_1\,\Theta_1 + M_2\,\Theta_2 \quad \text{and} \quad M\,S = M_1\,S_1 + M_2\,S_2. \tag{27.193}$$

(a) Compute the gravitational potential energy of the initial seawater column, taking the bottom of the column as the zero reference level.

(b) Compute the gravitational potential energy of the fluid column after homogenization. Verify that the gravitational potential energy of the homogenized column is greater than the initial column. For this question, assume the final thickness of the column equals to the sum of the initial thicknesses. This assumption is not exact but is very accurate for our purposes. For an exact calculation see equation (67.112) in our study of sea level in Section 67.7.7.

(c) If the same amount of energy used to increase in gravitational potential energy was instead used to increase kinetic energy of the homogenized fluid, what is the expression for the change in squared velocity? Write your expression in terms of the thicknesses, h_n, and densities, ρ_n.

(d) If the change in gravitational potential energy were converted to potential enthalpy of the homogenized fluid, what is the expression for the increase in Conservative Temperature, Θ? Again, write your expression in terms of the thicknesses, h_n, and densities, ρ_n.

(e) Compute the change in speed and change in Conservative Temperature for the previous parts of this exercise using the following values for a region of seawater: $c_{\mathrm{p}} = 3992.1$ J kg^{-1} K^{-1}, $\rho_1 = 1020$ kg m^{-3}, $\Delta\rho = 1$ kg m^{-3}, $h_1 = 1$ m, and $h_2 = 1$ m.

EXERCISE 27.2: A MODIFIED FRICTIONAL STRESS TENSOR

Following the methods from Section 27.3.3, assume viscous friction in the momentum equation takes the form

$$\rho\,\boldsymbol{F} = \partial_n(\rho\,\nu\,\partial_n \boldsymbol{v}), \tag{27.194}$$

with $\nu > 0$ a scalar kinematic viscosity (generally non-constant). This friction operator corressponds to the frictional stress tensor

$$\mathbb{T}_{nm} = \rho\,\nu\,\partial_n v_m. \tag{27.195}$$

(a) Show that when integrated over the full domain

$$\int \boldsymbol{F}\cdot\boldsymbol{v}\,\rho\,\mathrm{d}V < 0, \tag{27.196}$$

where boundary terms are ignored. Hence, the global integrated kinetic energy is dissipated (reduced) through the impacts of viscosity in the interior of the domain. Note that for this exercise, it is sufficient to assume Cartesian tensors so that

$$\rho\,\boldsymbol{F}\cdot\boldsymbol{v} = \rho\,F_m\,v_m = \partial_n(\rho\,\nu\,\partial_n v_m)\,v_m. \tag{27.197}$$

(b) What property does the assumed $\mathbb{T}_{nm}$ in equation (27.195) *not* satisfy, thus making it unsuitable as a frictional stress tensor? Discuss according to what we studied in Section 26.4.

EXERCISE 27.3: INTEGRATED FRICTIONAL DISSIPATION FOR AN INCOMPRESSIBLE FLUID
Consider an incompressible fluid ($\nabla \cdot \boldsymbol{v} = 0$ along with ρ is constant). Assume the fluid is contained in a region, $\mathcal{R}$, whose boundary, $\partial\mathcal{R}$, is static. Also assume the velocity satisfies the no-slip condition on $\partial\mathcal{R}$, as relevant for a viscous fluid. Show that the frictional dissipation of kinetic energy (Section 27.3.3) has a global integral

$$\int_{\mathcal{R}} \boldsymbol{v} \cdot \boldsymbol{F}\, \rho \, \mathrm{d}V = -\rho\, \nu \int_{\mathcal{R}} |\boldsymbol{\omega}|^2 \, \mathrm{d}V, \tag{27.198}$$

where $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$ is the vorticity. Hint: derive equation (19.100) from exercise 19.1, and specialize that equation to the case of an incompressible fluid.

EXERCISE 27.4: THERMODYNAMIC MANIPULATIONS FOR IDEAL GASES
This question develops some manipulations with the potential temperature.

(a) Beginning with the expression (24.92) for potential temperature of an ideal gas, show that

$$\mathrm{d}\theta = \frac{\theta}{T}\left[\mathrm{d}T - \frac{\nu_{\mathrm{s}}}{c_{\mathrm{p}}}\mathrm{d}p\right]. \tag{27.199}$$

(b) Given the result (27.199), show that an ideal gas satisfies the following relation

$$T\,\mathrm{d}\mathcal{S} = \frac{c_p\, T}{\theta}\,\mathrm{d}\theta. \tag{27.200}$$

Whereas the relation (24.44) holds for a general fluid only at the reference pressure, this exercise shows that it holds for an ideal gas at all pressures. As a result, a moving fluid of ideal gas satisfies the material time relation

$$T\,\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = \frac{c_p\, T}{\theta}\frac{\mathrm{D}\theta}{\mathrm{D}t} \Rightarrow \frac{c_p\, T}{\theta}\frac{\mathrm{D}\theta}{\mathrm{D}t} = \dot{Q}. \tag{27.201}$$

EXERCISE 27.5: THERMODYNAMIC MANIPULATIONS FOR A LIQUID
Consider seawater with specific entropy given by (see Section 1.7.2 of *Vallis* (2017))

$$\mathcal{S}(S,T,p) = \mathcal{S}_0 + c_{\mathrm{p0}} \ln(T/T_o)\left[1 + \beta^*_{\mathrm{S}}\,(S - S_o)\right] - \alpha_o\, p\left[\beta_{\mathrm{T}} + \beta_{\mathrm{T}}\,\gamma^* \frac{p}{2} + \beta^*_{\mathrm{T}}\,(T - T_o)\right], \tag{27.202}$$

and corresponding specific heat capacity at constant pressure

$$c_{\mathrm{p}}(S,T,p) = c_{\mathrm{p0}}\left[1 + \beta^*_{\mathrm{S}}\,(S - S_o)\right] - \alpha_o\, p\, \beta^*_{\mathrm{T}}\, T. \tag{27.203}$$

In these equations, T is the *in situ* temperature, S is the salinity, and p is the *in situ* pressure. All other terms on the right hand side to these expressions are empirical constants. Verify that the specific entropy differential for a fluid element with constant composition is given by

$$\theta\,\mathrm{d}\mathcal{S} = c_{\mathrm{p}}(S,\theta,p_{\mathrm{R}})\,\mathrm{d}\theta, \tag{27.204}$$

where θ is the potential temperature and p_{R} is the corresponding reference pressure. Consequently, we can write for a moving fluid element

$$\dot{Q} = \frac{c_{\mathrm{p}}\, T}{\theta}\,\frac{\mathrm{D}\theta}{\mathrm{D}t}, \tag{27.205}$$

where we evaluate the non-constant heat capacity at $c_{\mathrm{p}}(S,\theta,p_{\mathrm{R}})$. We see that certain liquids

have an expression for heating that is analogous to that for an ideal gas, with the ideal gas case discussed in Exercise 27.4. Hint: Make use of the identity (24.36).

EXERCISE 27.6: BERNOULLI THEOREM AND TWO SHEETS OF PAPER (EXERCISE 1.22 OF *Sutherland* (2010))
Hold two sheets of paper from their top edge so they are two fingers-widths apart. Blow between the two sheets. Do they separate or come together. Explain in terms of the physics discussed in this chapter. Hint: make use of the simplest form of Bernoulli's theorm from Section 27.9.

EXERCISE 27.7: DYNAMICALLY INCONSISTENT VELOCITY
Consider the two dimensional non-divergent vector field

$$\boldsymbol{u} = \Gamma\,(y^2\,\hat{\boldsymbol{x}} + x^2\,\hat{\boldsymbol{y}}), \tag{27.206}$$

with Γ a constant of dimensions $\mathrm{L}^{-1}\,\mathrm{T}^{-1}$. In this exercise we will show that it *cannot* be a physically realizable velocity field.

(a) Assuming $\boldsymbol{u}$ is a velocity field for fluid flow, then determine the pressure field giving rise to this velocity. Assume a constant density, non-rotating reference frame, zero friction, and no boundary effects. Do so by making use of the Bernoulli theorem in equation (27.118) for horizontal (constant z) flow, and thus provide the expression for pressure, and express that pressure along a streamline. Hint: compute the streamfunction corresponding to the velocity, and choose a convenient streamline upon which to evaluate the pressure.

(b) Now make use of the momentum equation to find the pressure gradient. Attempt to integrate this equation to then find the pressure field. You should reach an inconsistency. Given this inconsistency, what can you conclude about the physical realizability of the given $\boldsymbol{u}$ as a velocity vector? Discuss. Hint: recall the discussion of exact differentials in Section 2.8.

EXERCISE 27.8: CROCCO'S THEOREM
Prove that the spatial gradient of the Bernoulli potential for a single-component steady state perfect fluid can be written

$$\mathcal{B} = T\,\nabla\mathcal{S} + \boldsymbol{v}\times\boldsymbol{\omega}_{\mathrm{a}}. \tag{27.207}$$

This result is known as Crocco's Theorem (*Crocco*, 1937). We derive two conclusions from this theorem. First, in a steady state, there is a nonzero vorticity non-parallel to the velocity whenever $\mathcal{B} - T\,\nabla\mathcal{S}$; i.e.,

$$\boldsymbol{v}\times\boldsymbol{\omega}_{\mathrm{a}} = \mathcal{B} - T\,\nabla\mathcal{S}. \tag{27.208}$$

Second, it means that the velocity for a single-component perfect fluid in steady state is aligned parallel to isosurfaces of both the Bernoulli potential and the specific entropy

$$\boldsymbol{v}\cdot\nabla\mathcal{B} = T\,\boldsymbol{v}\cdot\nabla\mathcal{S}. \tag{27.209}$$

We encounter another form of this theorem for the steady state shallow water equations in Exercise 40.6.

Hint: to help formulate the proof, study the discussion in Section 27.9.3 where we showed that the Bernoulli potential is constant along a steady flow streamline in a perfect fluid. Also recall equation (27.115), which is valid for a steady state and applied here to a single-component fluid.

Chapter 28

Approximate hydrostatic flow

For a moving fluid with scales of motion that maintain a small vertical to horizontal aspect ratio, we show in this chapter that the vertical pressure gradient and gravitational acceleration individually remain far larger than other accelerations acting on a fluid element. In this case, the vertical momentum equation, even for the moving fluid, remains approximately in hydrostatic balance column-by-column. We thus have a flow whereby each vertical column is in hydrostatic balance, and yet there are horizontal pressure gradients that drive horizontal motion. Correspondingly, there is also vertical motion. In this chapter, we study the many facets of this *approximately hydrostatic flow*.

More generally, we observe that the ocean and atmosphere thermo-hydrodynamical equations (27.186)-(27.190) explain a huge range of phenomena. Yet by encapsulating so many physical scales of motion and associated dynamical processes, the equations are difficult to manage when studying a focused dynamical regime. Therefore, it is common to approximate or filter the equations to remove scales that are not of direct interest to the problem at hand, thus enabling a more telescopic view of the dynamics. The *hydrostatic primitive equations* provide an important example of this approach.

READER'S GUIDE TO THIS CHAPTER

The column-by-column hydrostatic balance found in the approximate hydrostatic flow is ubiquitous in large-scale fluid flows in the atmosphere and ocean. We thus make extensive use in this book of the corresponding expressions for the pressure gradients holding for such flows. Relatedly, the hydrostatic primitive equations have been very useful in the study of ocean and atmosphere circulation since their introduction in the 1950s, and we make use of them in various forms throughout the remainder of this book.

28.1 The hydrostatic primitive equations

The hydrostatic *primitive equations* provide a set of approximate equations for use in studying large-scale atmospheric and oceanic phenomena. Indeed, nearly all numerical models of the large-scale atmospheric and oceanic circulation are based on the primitive equations. They make use of the following three approximations.

28.1.1 Hydrostatic approximation

As discussed in Section 25.6, a static fluid in a gravity field maintains an exact hydrostatic balance, whereby the pressure at a point equals to the weight per area of fluid above that point. As shown in Section 28.2, the hydrostatic balance is very closely maintained column-by-column for the large scales in a moving geophysical fluid. Hence, it is appropriate for many purposes to take the *hydrostatic approximation* for the vertical momentum equation, with this approximation central to the study of large-scale geophysical fluid dynamics.

The hydrostatic approximation results in a balance within the vertical momentum equation (25.21) between the vertical pressure gradient and the effective gravitational force

$$\frac{\partial p}{\partial r} = -\rho\, g, \tag{28.1}$$

with this balance holding separately for each vertical column. Notably, there are no viscous or turbulent terms appearing in the hydrostatic balance.

Vertical integration of this equation, while assuming g is constant, renders a diagnostic expression for the hydrostatic pressure at a point as a function of the weight per horizontal area above the point

$$p(r, \lambda, \phi, t) = p(r_0, \lambda, \phi, t) + g \int_r^{r_0} \rho(r', \lambda, \phi, t)\, \mathrm{d}r'. \tag{28.2}$$

Note that we exposed the horizontal space dependence along with the time dependence for the density and hence the hydrostatic pressure. That is, an approximate hydrostatic fluid flow has horizontal pressure gradients as well as time dependence.

We emphasize that in making the hydrostatic approximation, we are *not* assuming that vertical motion vanishes. In fact, there is vertical motion. But with the hydrostatic approximation,

the vertical motion is not prognosed by the vertical momentum equation. Instead, it must be diagnosed via the constraints imposed on the motion. We have more comment on this point in Section 28.2.7. Furthermore, there are no other terms appearing in the vertical momentum equation, so that we retain just the vertical pressure gradient and the gravity term. Friction or boundary turbulent stresses do not appear in the hydrostatic balance, whereas they generally do appear in the non-hydrostatic vertical momentum equation.

28.1.2 Shallow fluid approximation

The ocean and atmosphere each form a fluid shell that envelopes the outer portion of the planet. The thickness of the these fluids is small relative to the earth's radius. The shallow fluid approximation[1] builds this scale separation into the equations of motion by setting the radial coordinate equal to the earth's radius

$$r = R_{\mathrm{e}} + z \approx R_{\mathrm{e}}. \tag{28.3}$$

This approximation is made where r appears as a multiplier, but not as a derivative operator. For example, the spherical coordinate gradient operator (25.23) takes the approximate form

$$\nabla = \frac{\hat{\boldsymbol{\lambda}}}{r\cos\phi}\frac{\partial}{\partial\lambda} + \frac{\hat{\boldsymbol{\phi}}}{r}\frac{\partial}{\partial\phi} + \hat{\boldsymbol{r}}\frac{\partial}{\partial r} \approx \frac{\hat{\boldsymbol{\lambda}}}{R_{\mathrm{e}}\cos\phi}\frac{\partial}{\partial\lambda} + \frac{\hat{\boldsymbol{\phi}}}{R_{\mathrm{e}}}\frac{\partial}{\partial\phi} + \hat{\boldsymbol{r}}\frac{\partial}{\partial r}. \tag{28.4}$$

This approximation proves useful when computing the depth integrated fluid mechanical equations for studies where we wish to remove the vertical degress of freedom. Examples include the depth integrated mechanical energy in Section 28.1.6, the depth integrated momentum equation in Section 29.4, the depth integrated angular momentum equation in Section 29.5, and the depth integrated vorticity equations in Sections 45.4, 45.6, and 45.7.

28.1.3 Traditional approximation

The *traditional approximation* comprises three approximations that come as a package in order to maintain physical consistency.

Coriolis acceleration

The traditional approximation sets to zero the Coriolis terms in the horizontal momentum equations involving the vertical velocity. We are thus concerned only with the local vertical component of the earth's angular rotation vector (see discussion in Section 13.9.8)

$$\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{Z}} = \Omega\,(\hat{\boldsymbol{\phi}}\,\cos\phi + \hat{\boldsymbol{r}}\,\sin\phi) \to \Omega\,\sin\phi\,\hat{\boldsymbol{r}} = \boldsymbol{f}/2, \tag{28.5}$$

where

$$\boldsymbol{f} = (2\,\Omega\sin\phi)\,\hat{\boldsymbol{r}} \tag{28.6}$$

is the Coriolis parameter and $\hat{\boldsymbol{Z}}$ is the spherical earth unit vector pointing out of the north pole (Figure 10.1).[2]

[1] The shallow fluid approximation is distinct from the *shallow water approximation* treated in Part VI of this book.

[2] We use the capital $\hat{\boldsymbol{Z}}$ to distinguish this north pole unit vector from the local $\hat{\boldsymbol{z}} = \hat{\boldsymbol{r}}$ unit vector pointing vertical relative to a tangent plane discussed in Section 25.5.

Metric terms

The traditional approximation also drops the metric terms, uw/r and vw/r, associated with the vertical velocity as they appear in the horizontal momentum equations (25.19) and (25.20). These terms are generally smaller than the other terms since w is much smaller than the horizontal velocity for large-scale geophysical fluid flow.

Physical consistency

The shallow fluid approximation and both parts of the traditional approximation must be taken together in order to maintain a consistent energy and angular momentum conservation principle for the resulting equations. As shown in Exercise 28.1, taking one but not the other leads to a physically inconsistent set of equations

28.1.4 Summary of the hydrostatic primitive equations

The above approximations lead to the primitive equations written in spherical coordinates

$$\frac{\mathrm{D}u}{\mathrm{D}t} - \frac{u\,v\tan\phi}{R_\mathrm{e}} - f\,v = -\frac{1}{\rho\,R_\mathrm{e}\cos\phi}\,\frac{\partial p}{\partial\lambda} + F^\lambda \tag{28.7}$$

$$\frac{\mathrm{D}v}{\mathrm{D}t} + \frac{u^2\tan\phi}{R_\mathrm{e}} + f\,u = -\frac{1}{\rho\,R_\mathrm{e}}\,\frac{\partial p}{\partial\phi} + F^\phi \tag{28.8}$$

$$\frac{\partial p}{\partial z} = -g\,\rho, \tag{28.9}$$

where the gradient operator is given by equation (28.4). We can write these equations in the vector form

$$\rho\,\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + (f + u\tan\phi/R_\mathrm{e})\,\hat{\boldsymbol{z}}\times\rho\,\boldsymbol{u} = -\rho\,\nabla\Phi - \nabla p + \rho\,\boldsymbol{F}, \tag{28.10}$$

where

$$\boldsymbol{F} = \hat{\boldsymbol{\lambda}}\,F^\lambda + \hat{\boldsymbol{\phi}}\,F^\phi \tag{28.11}$$

is the horizontal friction acceleration, and the vertical component of equation (28.10) is the hydrostatic balance. Furthermore, the material time derivative in this equation signifies the relative acceleration

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \hat{\boldsymbol{\lambda}}\,\frac{\mathrm{D}u}{\mathrm{D}t} + \hat{\boldsymbol{\phi}}\,\frac{\mathrm{D}v}{\mathrm{D}t}. \tag{28.12}$$

28.1.5 Flux-form mechanical energy budget

For fluid flow maintaining the approximate hydrostatic approximation, the kinetic energy is dominated by the horizontal motions. Indeed, as we now show, the proper form of the kinetic energy is precisely that contained just in the horizontal motions. We do so by taking the scalar product of the horizontal velocity with the momentum equation (28.10) to render

$$\rho\,\frac{\mathrm{D}\mathcal{K}^\mathrm{hyd}}{\mathrm{D}t} = -\rho\,\boldsymbol{u}\cdot\nabla\Phi - \boldsymbol{u}\cdot\nabla p + \rho\,\boldsymbol{u}\cdot\boldsymbol{F}, \tag{28.13}$$

where we introduced the hydrostatic kinetic energy per mass

$$\mathcal{K}^\mathrm{hyd} = \boldsymbol{u}\cdot\boldsymbol{u}/2. \tag{28.14}$$

Making use of the hydrostatic balance in the presence of a simple geopotential, $\Phi = g\,z$ (so that $\boldsymbol{u}\cdot\nabla\Phi = 0$), leads to

$$\rho\,\frac{\mathrm{D}\mathcal{K}^{\mathrm{hyd}}}{\mathrm{D}t} = -(\boldsymbol{v}\cdot\nabla p - w\,\partial_z p) + \rho\,\boldsymbol{u}\cdot\boldsymbol{F} \tag{28.15a}$$

$$= -\nabla\cdot(\boldsymbol{v}\,p) + p\,\nabla\cdot\boldsymbol{v} - w\,g\,\rho + \rho\,\boldsymbol{u}\cdot\boldsymbol{F}, \tag{28.15b}$$

which leads to the flux-form conservation equation for kinetic energy

$$\partial_t(\rho\,\mathcal{K}^{\mathrm{hyd}}) + \nabla\cdot[\boldsymbol{v}\,(\rho\mathcal{K}^{\mathrm{hyd}} + p)] = p\,\nabla\cdot\boldsymbol{v} - \rho\,g\,w + \rho\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{28.16}$$

Furthermore, $\Phi = g\,z$ means that

$$\rho\,\mathrm{D}\Phi/\mathrm{D}t = \partial_t(\rho\,\Phi) + \nabla\cdot(\rho\,\boldsymbol{v}\,\Phi) = \rho\,g\,w, \tag{28.17}$$

in which case the flux-form equation for the mechanical energy per mass, $\mathcal{M}^{\mathrm{hyd}}$, is given by

$$\partial_t(\rho\,\mathcal{M}^{\mathrm{hyd}}) + \nabla\cdot[\rho\,\boldsymbol{v}\,(\mathcal{M}^{\mathrm{hyd}} + p/\rho)] = p\,\nabla\cdot\boldsymbol{v} + \rho\,\boldsymbol{u}\cdot\boldsymbol{F}, \tag{28.18}$$

where

$$\mathcal{M}^{\mathrm{hyd}} = \mathcal{K}^{\mathrm{hyd}} + \Phi = \boldsymbol{u}\cdot\boldsymbol{u}/2 + g\,z. \tag{28.19}$$

Equation (28.18) compares to the non-hydrostatic mechanical energy equation (27.49). The key difference is that the kinetic energy per mass is here just given by the horizontal flow (28.14). Additionally, the friction vector for the hydrostatic flow is horizontal. Otherwise, the physical interpretation of the mechanical energy budget accords with that for the non-hydrostatic flow given in Section 27.4.

28.1.6 Depth integrated mechanical energy budget

We here extend the analysis from Section 28.1.5 to derive the depth integrated mechanical energy budget for the hydrostatic primitive equations. The kinetic energy per area contained in the horizontal flow as integrated over a column is given by

$$\int_{\eta_{\mathrm{b}}}^{\eta} \rho\,\mathcal{K}^{\mathrm{hyd}}\,\mathrm{d}z = \frac{1}{2}\int_{\eta_{\mathrm{b}}}^{\eta} \rho\,\boldsymbol{u}\cdot\boldsymbol{u}\,\mathrm{d}z. \tag{28.20}$$

Leibniz's rule leads to the time tendency

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\eta_{\mathrm{b}}}^{\eta} \rho\,\mathcal{K}^{\mathrm{hyd}}\,\mathrm{d}z = \partial_t\eta\,[\rho\,\mathcal{K}^{\mathrm{hyd}}]_{z=\eta} + \int_{\eta_{\mathrm{b}}}^{\eta} \partial_t(\rho\,\mathcal{K}^{\mathrm{hyd}})\,\mathrm{d}z. \tag{28.21}$$

Making use of the kinetic energy equation (28.16) as well as Leibniz's rule gives the budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\eta_{\mathrm{b}}}^{\eta} \rho\,\mathcal{K}^{\mathrm{hyd}}\,\mathrm{d}z = [\rho\,\mathcal{K}^{\mathrm{hyd}} + p_{\mathrm{a}}]_{z=\eta}\,(\partial_t\eta - w + \boldsymbol{u}\cdot\nabla\eta)_{z=\eta} + [\rho\,\mathcal{K}^{\mathrm{hyd}} + p_{\mathrm{b}}]_{z=\eta_{\mathrm{b}}}\,(w - \boldsymbol{u}\cdot\nabla\eta_{\mathrm{b}})_{z=\eta_{\mathrm{b}}}$$
$$- \nabla_z\cdot\int_{\eta_{\mathrm{b}}}^{\eta}(\rho\,\boldsymbol{u}\,\mathcal{K}^{\mathrm{hyd}} + \boldsymbol{u}\,p)\,\mathrm{d}z + \int_{\eta_{\mathrm{b}}}^{\eta}(p\,\nabla\cdot\boldsymbol{v} - \rho\,g\,w + \rho\,\boldsymbol{u}\cdot\boldsymbol{F})\,\mathrm{d}z. \tag{28.22}$$

Note that when bringing ∇_z outside the vertical integral, besides making use of Leibniz's rule, we also assumed ∇_z is itself independent of z, which is trivially the case with Cartesian coordinates. However, for spherical coordinates the assumption requires the shallow fluid approximation so

that the r^{-1} appearing in the gradient operator is replaced by R_{e}^{-1} as per equation (28.4). It is here that we see that the depth integrated equations are most usefully posed when working with the hydrostatic primitive equations.

The bottom kinematic boundary condition (20.41) and surface boundary condition (20.79) then give the depth-integrated kinetic energy budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\eta_{\mathrm{b}}}^{\eta}\rho\,\mathcal{K}^{\mathrm{hyd}}\,\mathrm{d}z = Q_{\mathrm{m}}\,[\mathcal{K}^{\mathrm{hyd}}+p_{\mathrm{a}}/\rho]_{z=\eta} - \nabla_z\cdot\int_{\eta_{\mathrm{b}}}^{\eta}(\rho\,\boldsymbol{u}\,\mathcal{K}^{\mathrm{hyd}}+\boldsymbol{u}\,p)\,\mathrm{d}z + \int_{\eta_{\mathrm{b}}}^{\eta}(p\,\nabla\cdot\boldsymbol{v}-\rho\,g\,w+\rho\,\boldsymbol{u}\cdot\boldsymbol{F})\,\mathrm{d}z. \quad (28.23)$$

The first term on the right hand side arises from the mass transport across the ocean surface, along with the applied surface pressure. The second term is the convergence of the depth integrated flux of kinetic energy plus pressure. The final term is the depth integral of the buoyancy conversion term plus frictional work. Similar manipulations starting from the flux-form mechanical energy budget (28.18) lead to the depth integrated budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\eta_{\mathrm{b}}}^{\eta}\rho\,\mathcal{M}^{\mathrm{hyd}}\,\mathrm{d}z = Q_{\mathrm{m}}\,[\mathcal{M}^{\mathrm{hyd}}+p_{\mathrm{a}}/\rho]_{z=\eta} - \nabla_z\cdot\int_{\eta_{\mathrm{b}}}^{\eta}(\rho\,\boldsymbol{u}\,\mathcal{M}^{\mathrm{hyd}}+\boldsymbol{u}\,p)\,\mathrm{d}z + \int_{\eta_{\mathrm{b}}}^{\eta}(p\,\nabla\cdot\boldsymbol{v}+\rho\,\boldsymbol{u}\cdot\boldsymbol{F})\,\mathrm{d}z. \quad (28.24)$$

28.1.7 Comments and further study

The primitive equations make use of the momentum equations, which contrasts to *non-primitive* equation methods that develop evolution equations for the vorticity and divergence. *Smagorinsky* (1963) was an early proponent of the hydrostatic primitive equations for use in studying the large-scale ocean and atmospheric circulation. These equations form the basis for many general circulation models of the atmosphere and ocean. However, it is notable that finer resolution simulations, that admit strong vertical motions, must make use of the non-hydrostatic equations. Non-hydrostatic simulations are particularly relevant when studying clouds in the atmosphere and fine-scale mixing in the ocean, with both of these processes involving nontrivial vertical accelerations that break the hydrostatic approximation. These models sometimes also time step the momentum equations, and as such are referred to as *non-hydrostatic primitive equation* models.

28.2 Elements of approximate hydrostatic pressure

For a static fluid with identically zero net acceleration, the vertical pressure gradient precisely balances the weight of fluid to thus realize exact hydrostatic balance. We discussed this static solution to the equations of motion in Sections 25.6 and 26.5. For a moving fluid with scales of motion that maintain a small vertical to horizontal aspect ratio, the presentation in this section reveals that the vertical pressure gradient and gravitational acceleration individually remain far larger than other accelerations acting on a fluid element. In this case, the vertical momentum equation, even for the moving fluid, remains approximately in hydrostatic balance column-by-column. We thus have a fluid flow whereby each vertical fluid column is in hydrostatic balance, and yet there are horizontal pressure gradients that drive motion. In this section we study aspects of such approximately hydrostatic fluid flows.

For simplicity in this section we make use of Cartesian coordinates rather than the spherical coordinates used in Section 28.1.

28.2.1 Expressions for the hydrostatic pressure

Making the hydrostatic approximation in the vertical momentum equation leads to the local balance

$$\frac{\partial p}{\partial z} = -\rho\, g. \tag{28.25}$$

Vertically integrating upward from a point within the ocean to the ocean surface leads to the hydrostatic pressure

$$p(x, y, z, t) = p_{\mathrm{a}}(x, y, t) + g \int_z^{\eta} \rho(x, y, z', t)\, \mathrm{d}z'. \tag{28.26}$$

In this equation we wrote $p(\eta) = p_{\mathrm{a}}$ for the pressure at the ocean free surface, $z = \eta(x, y, t)$, arising from the weight of the overlying atmosphere or sea ice; i.e., this is the applied pressure acting on the top of the ocean fluid. A similar integration applies to the atmosphere

$$p(x, y, z, t) = g \int_z^{z_{\mathrm{top}}} \rho(x, y, z', t)\, \mathrm{d}z', \tag{28.27}$$

where $z = z_{\mathrm{top}}$ is the top of the atmosphere, sometimes approximated by $z_{\mathrm{top}} = \infty$. For both the ocean and the atmosphere, we assume g remains a constant over the vertical extent of the fluid, which is a sensible approximation even for the top of the atmosphere.

In both the ocean and atmosphere, the hydrostatic pressure at a vertical position, z, equals to the weight per horizontal area of matter above that position, with equations (28.26) and (28.27) providing explicit expressions in terms of *in situ* density and boundary contributions. These expressions offer a huge simplification for how we determine pressure, with the remainder of this section providing example implications.

28.2.2 Evolution of hydrostatic pressure

We expect that hydrostatic pressure evolves according to the convergence of mass onto the column of fluid above that point. The ocean hydrostatic pressure also changes due to time changes in the applied upper boundary pressure. Here we derive mathematical expressions that support these expectations, with Figure 28.1 providing a schematic.

FIGURE 28.1: Evolution of hydrostatic pressure for a vertical position in the atmosphere (left panel) and ocean (right panel) according to equations (28.30) and (28.33a). Hydrostatic pressure at a vertical position, z, which here is the bottom of the fluid column, arises from the convergence of mass onto the column over the region above z. The ocean column also has a contribution from the time tendency of applied surface pressure plus the mass of coming across the top boundary. For the atmosphere as assume the top boundary is at $z_{\mathrm{top}} = \infty$ and so there is no mass coming across that boundary.

Hydrostatic pressure in the atmosphere

A time derivative of the atmospheric hydrostatic pressure (28.27) renders

$$\partial_t p = g \int_z^{z_{\text{top}}} \partial_t \rho(x, y, z', t)\, \mathrm{d}z'. \tag{28.28}$$

Note the absence of a time derivative on z_{top}. We ensure this time derivative is not relevant by setting z_{top} to a constant value well above anything of physical relevance; e.g., $z_{\text{top}} \approx \infty$. Now insert the mass continuity equation (20.6) and make further use of Leibniz's rule to write

$$\partial_t p = -g \int_z^{z_{\text{top}}} \nabla \cdot (\boldsymbol{v}\, \rho)\, \mathrm{d}z' \tag{28.29a}$$

$$= g\, \rho(z)\, w(z) - g \int_z^{z_{\text{top}}} \nabla_z \cdot (\boldsymbol{u}\, \rho)\, \mathrm{d}z', \tag{28.29b}$$

where we set $w(z_{\text{top}})\, \rho(z_{\text{top}}) = 0$. The first term on the right hand side arises from the vertical mass flux into the fluid column from below. The second term arises from the horizontal convergence of mass as integrated over the column above the position, z. If the vertical position of the bottom limit on the integral is independent of horizontal position, then we can pull the horizontal divergence operator outside of the integral to render

$$\partial_t p = g\, \rho(z)\, w(z) - g\, \nabla_z \cdot \int_z^{z_{\text{top}}} \boldsymbol{u}\, \rho\, \mathrm{d}z'. \tag{28.30}$$

In Exercise 28.3 we derive an expression for the bottom pressure, $p(x, y, z = \eta_{\text{b}}(x, y), t)$, where we must use Leibnitz's rule to pull the horizontal derivative outside of the integral.

Hydrostatic pressure in the ocean

The derivation for the ocean requires some more work since the ocean free surface is a permeable space and time dependent function. A time derivative of the ocean pressure expression (28.26) renders

$$\partial_t p = \partial_t p_{\text{a}} + g\, \rho(\eta)\, \partial_t \eta + g \int_z^{\eta} \partial_t \rho(x, y, z', t)\, \mathrm{d}z', \tag{28.31}$$

where we made use of Leibniz's rule to take the time derivative of the upper limit at $z = \eta(x, y, t)$, and with the shorthand $\rho(\eta) = \rho(x, y, z = \eta, t)$. Now insert the mass continuity equation (20.6) and make further use of Leibniz's rule to write

$$\partial_t (p - p_{\text{a}}) - g\, \rho(\eta)\, \partial_t \eta = g \int_z^{\eta} \partial_t \rho(x, y, z', t)\, \mathrm{d}z' \tag{28.32a}$$

$$= -g \int_z^{\eta} \nabla \cdot (\boldsymbol{v}\, \rho)\, \mathrm{d}z' \tag{28.32b}$$

$$= -g\, [\rho(\eta)\, w(\eta) - \rho(z)\, w(z)] - g \int_z^{\eta} \nabla_z \cdot (\boldsymbol{u}\, \rho)\, \mathrm{d}z' \tag{28.32c}$$

$$= g\, \rho(z)\, w(z) + g\, [(-w + \boldsymbol{u} \cdot \nabla \eta)\, \rho]_{z=\eta} - g \nabla_z \cdot \int_z^{\eta} \boldsymbol{u}\, \rho\, \mathrm{d}z' \tag{28.32d}$$

$$= g\, \rho(z)\, w(z) + g\, (Q_{\text{m}} - \rho(\eta)\, \partial_t \eta) - g \nabla_z \cdot \int_z^{\eta} \boldsymbol{u}\, \rho\, \mathrm{d}z', \tag{28.32e}$$

where the last step made use of the kinematic boundary condition (20.79) for the ocean free surface, with Q_{m} the mass flux entering the ocean across the free surface. Rearrangement, and

cancellation of the $\rho(\eta)\,\partial_t\eta$ term appearing on both sides, leads to

$$\partial_t p = \partial_t p_{\mathrm{a}} + g\,\rho(z)\,w(z) + g\,Q_{\mathrm{m}} - g\nabla_z \cdot \int_z^\eta \boldsymbol{u}\,\rho\,\mathrm{d}z'. \tag{28.33a}$$

The first term on the right hand side arises from time fluctuations of the applied pressure at $z = \eta$. The second and third terms measure the vertical convergence of mass onto the column of fluid sitting above the vertical position, with $\rho(z)\,w(z)$ the mass flux entering the column from below and Q_{m} the mass flux entering from across the free surface. The final term arises from the vertically integrated horizontal mass transport converging onto the column above the position of interest.

28.2.3 Heuristic scaling

We here present a scale analysis to justify the hydrostatic approximation. This analysis serves to introduce a common method used in fluid mechanics to identify those processes that may be dominant for a particular flow regime. In particular, the flow regime of interest here occurs with a small vertical to horizontal aspect ratio

$$\alpha_{\mathrm{aspect}} \equiv \frac{H}{L} \ll 1, \tag{28.34}$$

with H a typical length scale for vertical motion and L the horizontal length scale. This regime is fundamental to the large-scale circulation of the ocean and atmosphere. As the hydrostatic approximation is concered with the force balances in a fluid column, it is sufficient to ignore rotation when performing a scale analysis.

Consider the vertical momentum equation (25.43c) from the tangent plane and traditional approximations (Section 25.5), along with the associated scales for the various terms

$$\frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial z} - g \tag{28.35a}$$

$$\frac{W}{T} + \frac{U\,W}{L} + \frac{W\,W}{H} = -\frac{1}{\rho}\,\frac{\partial p}{\partial z} - g. \tag{28.35b}$$

In the second equation we introduced the following scales for the terms appearing on the left hand side of the first equation.

- L is the horizontal scale of the motion.
- H is the vertical scale of the motion.
- W is the vertical velocity scale.
- U is the horizontal velocity scale. For this analysis we do not distinguish between the zonal and meridional velocity scales, writing U for both. This assumption is not always valid, such as when scaling for jet stream or equatorial flows, both of which have larger zonal speeds than meridional.
- T is the time scale of the motion. We assume that the time scale is determined by horizontal advection[3] so that $T \sim L/U$.

[3]This assumption for time scale is not always appropriate, such as for studies of waves where we may instead consider time scales according to a wave speed and wave length.

To get a sense for the numbers, consider large-scale atmospheric flows with $W = 10^{-2}$ m s^{-1}, $L = 10^5$ m, $H = 10^3$ m, $U = 10$ m s^{-1}. These numbers lead to $T = L/U = 10^4$ s and to the values for the vertical momentum equation

$$10^{-6} \text{ m s}^{-2} \sim -\frac{1}{\rho}\frac{\partial p}{\partial z} - g. \tag{28.36}$$

With $g \sim 10$ m s^{-2}, the only term that can balance the gravitational acceleration is the vertical pressure gradient. A similar analysis holds for large-scale ocean flows where we set $W = 10^{-3}$ m s^{-1}, $L = 10^3$ m, $H = 10^1$ m, $U = 10^{-1}$ m s^{-1}. These numbers lead to $T = L/U = 10^4$ s and to

$$10^{-7} \text{ m s}^{-2} \sim -\frac{1}{\rho}\frac{\partial p}{\partial z} - g. \tag{28.37}$$

In either case, large scale motion maintains an approximate hydrostatic balance whereby $\partial p/\partial z = -\rho\, g$.

We offer a more formal scale analysis in Section 30.2, making use of the oceanic Boussinesq equations derived in Chapter 30. For the remainder of this section we explore certain properties of a fluid flow maintaining an approximate hydrostatic balance.

28.2.4 Removal of a dynamically irrelevant background state

The previous analysis pointed to the dominance of the hydrostatic balance in the vertical momentum equation for large scale motions. However, is that analysis sufficient to understand what causes motion? To help answer that question, consider a density field that is decomposed into a constant, ρ_0, plus a deviation

$$\rho(\boldsymbol{x}, t) = \rho_0 + \rho'(\boldsymbol{x}, t), \tag{28.38}$$

with a corresponding decomposition of the pressure field

$$p(\boldsymbol{x}, t) = p_0(z) + p'(\boldsymbol{x}, t) \qquad \text{with} \qquad \frac{\mathrm{d}p_0}{\mathrm{d}z} = -\rho_0\, g. \tag{28.39}$$

That is, the pressure is decomposed into a background *static pressure* field that is just a function of z, plus a deviation from the background pressure. In this case, the non-rotating vertical momentum equation takes the form

$$\rho\,\frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{\partial p'}{\partial z} - \left[\frac{\mathrm{d}p_0}{\mathrm{d}z} + \rho_0\, g\right] = -\frac{\partial p'}{\partial z}. \tag{28.40}$$

We thus see that the exact hydrostatically balanced background pressure, $p_0(z)$, has no dynamical implications. Correspondingly, to garner a more relevant scaling for the hydrostatic balance it is appropriate to ask whether the dynamically active pressure, p', is approximately hydrostatic.

For flows with small aspect ratios, the vertical momentum equation remains approximately hydrostatic even when removing the dynamically inactive background pressure field. So our intuition about hydrostatic dominance holds unchanged even for the dynamical pressure. The formal justification of this approximation is nicely framed within the Boussinesq equations of Chapter 30 since the pressure force in these equations exposes just the dynamically active pressure. We thus postpone further discussion of hydrostatic scaling until Section 30.2.

28.2.5 Ocean dynamic topography

There are occasions in oceanography where it is useful to study the thickness of a layer bounded by isobars. For example, it is often assumed in dynamical oceanography that there is a pressure at which currents vanish (*level of no motion*), with the reduced gravity model of Section 36.3 studying the associated dynamical implications. We also consider this situation in Section 28.3.5, in which the level of no motion is realized by a vanishing horizontal pressure gradient. Here we consider the thickness of fluid extending from the ocean free surface to a chosen pressure level in the ocean interior as given by (see Figure 28.2)

$$D(p) = \eta - z(p). \tag{28.41}$$

Assuming a hydrostatic balance for each fluid column allows us to relate this expression to the vertical integral between two pressure surfaces of the specific volume, ρ^{-1}

$$D(p) = \int_{z(p)}^{\eta} \mathrm{d}z = g^{-1} \int_{p_\mathrm{a}}^{p} \frac{\mathrm{d}p'}{\rho}, \tag{28.42}$$

where the second step used the hydrostatic balance and absorbed a minus sign by swapping integral limits. We refer to the thickness $D(p)$ as the *dynamic topography* with respect to a reference pressure, p. Note that $D(p)$ is sometimes also called the *steric sea level*.

FIGURE 28.2: The ocean dynamic topography, $D(p) = \eta - z(p)$, is the thickness of a layer from the sea surface at $z = \eta(x, y, t)$ to the vertical position of a constant pressure surface, $z = z(x, y, p, t)$.

Evolution of the dynamic topography arises from changes in the pressure applied to the free surface as well as changes in the specific volume

$$g \frac{\partial D(p)}{\partial t} = -\frac{1}{\rho(\eta)} \frac{\partial p_\mathrm{a}}{\partial t} + \int_{p_\mathrm{a}}^{p} \frac{\partial \rho^{-1}}{\partial t} \, \mathrm{d}p. \tag{28.43}$$

Importantly, the time derivative here acts on the specific volume when computed on surfaces of constant pressure. If the depth, $z(p)$, of the constant pressure surface is static, then the evolution of layer thickness, $D(p)$, is identical to the sea surface, η. In general, there is no such static pressure level, thus making the time tendencies differ, though certain situations warrant this approximation.

28.2.6 Surfaces of atmospheric geopotential height and pressure

In Section 24.4.10 we computed the geopotential height within an exact hydrostatic and ideal gas atmosphere. We here apply those results to the case of approximate hydrostatic and ideal gas columns, making use of equation (24.82) for the difference in geopotential height between two constant pressure surfaces (isobars)

$$Z_2 - Z_1 = -(R^{\text{atm}} \langle T \rangle / g) \ln(p_2/p_1). \tag{28.44}$$

In this equation, $\langle T \rangle$ is the mean temperature within the column as computed according equation (24.80), and R^{atm} is the specific gas constant for air given by equation (24.51). The geopotential thickness is positive when the isobars have $p_2 < p_1$. This situation holds when level-2 sits at a higher altitude in the atmosphere than level-1, whereby the hydrostatic pressure decreases moving upward. Furthermore, the geopotential thickness is directly proportional to the column mean temperature so that a warmer column is thicker. This result is expected since for a given mass of air, a warmer column is less dense and so isobars are higher over warmer hydrostatic air columns than cooler columns. Correspondingly, when moving horizontally along a constant geopotential surface, we encounter higher pressure when moving into a region of warmer air. This situation is entirely analogous to that in Figure 28.6 when studying the horizontal pressure difference between two hydrostatic and equal mass columns of seawater.

FIGURE 28.3: Thickness of the layer of an ideal gas atmosphere located between two constant pressure surfaces as given by equation (28.44): $Z_2 - Z_1 = -(R^{\text{atm}} \langle T \rangle / g) \ln(p_2/p_1)$. Evidently, when the flow is approximately hydrostatic, then $p_2 < p_1$ so that the thickness of the layer is positive. Also notice that the layer thickness increases when the column averaged temperature, $\langle T \rangle$, increases. Correspondingly, when moving horizontally along a constant geopotential surface (fixed z), we encounter higher pressure when moving into a region of warmer air and lower pressure when moving into a region of colder air.

28.2.7 Concerning vertical motion

Unbalanced vertical accelerations still exist in an approximate hydrostatic flow. Yet these vertical accelerations are not seen in the prognostic equations, since the vertical momentum equation reduces to a local hydrostatic balance. Hence, rather than compute vertical motion prognostically, vertical motion in an approximate hydrostatic flow must be diagnosed through constraints on the motion.

For example, an important constraint on the large-scale ocean circulation arises from vorticity and potential vorticity conservation, which are topics considered in Part VII of this book. Mass continuity discussed in Section 30.1.4 provides another constraint. In particular, horizontal velocity divergence in a non-divergent flow is balanced by vertical velocity convergence as per equation

(30.17). The vertical pressure forces required to produce the vertical motion are those precisely needed to maintain volume continuity. In a hydrostatic flow, we do not directly compute these forces for the purpose of prognosing vertical accelerations. Rather, the vertical acceleration is inferred through kinematic constraints. The associated forces can be diagnosed given the velocity and the accelerations.

28.2.8 Further study

Section 2.7.4 in *Vallis* (2017) provides examples of scales over which the hydrostatic relation remains a useful approximation in geophysical fluid flows. Further discussions of dynamic topography are given in Appendix B.4 of *Griffies et al.* (2014) as well as in *Tomczak and Godfrey* (1994). This 8-minute video from Prof. Hogg offers an introduction to hydrostatic pressure.

28.3 Horizontal pressure gradients

In contrast to an exact hydrostatic fluid, where there is no motion, there are generally horizontal pressure gradients in an approximate hydrostatic fluid flow, and these horizontal gradients drive horizontal motion. Such horizontal pressure gradients can arise from horizontal differences in the mass density. We refer to such pressure gradients as *internal pressure gradients* since they arise from density gradients internal to the fluid. Horizontal pressure gradients can also arise from horizontal gradients in the total mass of a fluid column, with such pressure gradients referred to as *external pressure gradients*.[4]

In developing an understanding of the horizontal pressure accelerations in an approximate hydrostatic flow, it is useful to examine the variety of expressions for the pressure gradient, which is the purpose of this section. In so doing, we reveal insights into how pressure drives horizontal fluid motion.

28.3.1 Top down horizontal pressure gradient

In this section we examine the horizontal pressure gradient in an approximate hydrostatic flow, and do so by integrating from the top down. This approach complements that in Section 28.3.2, which starts from the bottom and integrates up.

External and internal contributions to the horizontal pressure gradient

Recall equation (28.26), which expresses the hydrostatic pressure at a point within the ocean

$$p(x, y, z, t) = p_{\mathrm{a}}(x, y, t) + g \int_z^{\eta} \rho(x, y, z', t)\, \mathrm{d}z'. \tag{28.45}$$

In this equation, $p_{\mathrm{a}} = p[x, y, z = \eta(x, y, t), t]$ is the pressure applied to the ocean free surface at $z = \eta(x, y, t)$ from any mass above the ocean, such as the atmosphere or cryosphere. In many idealized cases we assume the media above the ocean is massless, in which case $p_{\mathrm{a}} = 0$. Now introduce the globally referenced Archimedean buoyancy (see Chapter 31) as defined by

$$b = -g\,(\rho - \rho_0)/\rho_0, \tag{28.46}$$

[4]Note that some authors refer to *baroclinic* and *barotropic* pressure gradients rather than the *internal* and *external* used here.

in which case the hydrostatic pressure is

$$p = -g\,\rho_0\,z + g\,\rho_0\,[\eta + p_{\rm a}/(g\,\rho_0)] - \rho_0 \int_z^\eta b\,{\rm d}z'. \tag{28.47}$$

The first term is a background pressure that increases moving downward. However, this background pressure has no horizontal dependence and so it does not contribute to the horizontal pressure gradient. In contrast, the second and third terms have horizontal gradients and are thus sometimes referred to as the *dynamical pressure*. The second term arises from the free surface height plus the applied surface pressure. This term is uniformly felt throughtout the fluid column since it has no vertical dependence. The free surface term is the product of the large number, $g\,\rho_0$, times a small free surface undulation, η. The third term arises from buoyancy within the fluid computed relative to the constant background density, ρ_0, and this term is a function of vertical position. Furthermore, it is the vertical integral over a generally large depth range of the buoyancy. In this manner, the second and third terms can be of comparable magnitude.

The horizontal gradient of the hydrostatic pressure (28.47) is given by

$$\nabla_z p = \underbrace{\nabla_z p_{\rm a} + g\,\rho(\eta)\,\nabla_z \eta}_{\text{external contribution}} - \underbrace{\rho_0 \int_z^\eta \nabla_z b\,{\rm d}z'}_{\text{internal contribution}} = \underbrace{\nabla_z p_{\rm a} + g\,\rho(\eta)\,\nabla_z \eta}_{\text{external contribution}} + \underbrace{g \int_z^\eta \nabla_z \rho\,{\rm d}z'}_{\text{internal contribution}}. \tag{28.48}$$

The internal contribution to the pressure gradient arises from horizontal gradients in Archimedean buoyancy that are integrated vertically over the region above the point of interest. The external contribution acts throughout the vertical fluid column since it is only a function of horizontal position and time. Every point within the fluid column instantly feels this term whenever there is a gradient in the applied surface pressure, the surface height, or the surface buoyancy, with $\rho_0[g - b(\eta)] = g\,\rho(\eta)$.

Mathematical comments regarding the external contribution

Observe that the external contributions to the horizontal pressure gradient in equation (28.48) are all functions of horizontal position and time, so there is no z dependence to hold fixed when computing ∇_z on these terms. Even so, we sometimes retain the ∇_z notation to align with that required to denote a horizontal gradient operator acting on three dimensional fields, such as buoyancy, $b(x, y, z, t)$, and density, $\rho(x, y, z, t)$).

Also observe that the external contribution can be written as the horizontal pressure gradient evaluated at the ocean surface[5]

$$(\nabla_z p)_{z=\eta} = \nabla_z p_{\rm a} + g\,\rho(\eta)\,\nabla_z \eta, \tag{28.49}$$

so that the pressure gradient in equation (28.48) can be written in the succinct form

$$\nabla_z p = (\nabla_z p)_{z=\eta} - \rho_0 \int_z^\eta \nabla_z b\,{\rm d}z' = (\nabla_z p)_{z=\eta} + g \int_z^\eta \nabla_z \rho\,{\rm d}z'. \tag{28.50}$$

Observe that the component of the horizontal pressure gradient in a direction tangent to the free surface arises just from the $\nabla_z p_{\rm a}$ term.

Mathematically, equation (28.49) decomposes the horizontal pressure gradient into the hori-

[5] On the right hand side of equation (28.49), all terms are a function just of the horizontal position computed along the $z = \eta$ ocean surface, so that we could write ∇ rather than ∇_z. Yet on the left hand side it is important to write ∇_z, since we are evaluating the horizontal pressure gradient at the surface.

zontal gradient of pressure along the curved free surface (the $\nabla_z p_\mathrm{a}$ term), plus a term that accounts for curvature of the free surface (the $g\,\rho(\eta)\,\nabla_z \eta$ term). As seen in Section 61.2, this decompostion of the horizontal pressure gradient, made throughout the fluid column, is a key step needed to formulate the equations of motion using generalized vertical coordinates.

28.3.2 Bottom up horizontal pressure gradient

It is sometimes useful to work with the bottom pressure and bottom topography, rather than the free surface height. For this purpose we invert the formulation from Section 28.3.1 by introducing the bottom pressure

$$p_\mathrm{b} = p_\mathrm{a} + g \int_{\eta_\mathrm{b}}^{\eta} \rho \, \mathrm{d}z, \tag{28.51}$$

in which case

$$\begin{aligned} p &= p_\mathrm{a} + g \int_{z}^{\eta} \rho \, \mathrm{d}z && (28.52\mathrm{a}) \\ &= p_\mathrm{a} + g \int_{\eta_\mathrm{b}}^{\eta} \rho \, \mathrm{d}z - g \int_{\eta_\mathrm{b}}^{z} \rho \, \mathrm{d}z && (28.52\mathrm{b}) \\ &= p_\mathrm{b} - g \int_{\eta_\mathrm{b}}^{z} (\rho - \rho_0 + \rho_0) \, \mathrm{d}z && (28.52\mathrm{c}) \\ &= p_\mathrm{b} - g\,\rho_0\,(z - \eta_\mathrm{b}) + \rho_0 \int_{\eta_\mathrm{b}}^{z} b \, \mathrm{d}z', && (28.52\mathrm{d}) \end{aligned}$$

so that the corresponding expression for the horizontal hydrostatic pressure gradient is

$$\nabla_z p = \underbrace{\nabla_z p_\mathrm{b} + g\,\rho(\eta_\mathrm{b})\,\nabla_z \eta_\mathrm{b}}_{\text{external contribution}} + \underbrace{\rho_0 \int_{\eta_\mathrm{b}}^{z} \nabla_z b \, \mathrm{d}z'}_{\text{internal contribution}} = \underbrace{\nabla_z p_\mathrm{b} + g\,\rho(\eta_\mathrm{b})\,\nabla_z \eta_\mathrm{b}}_{\text{external contribution}} - \underbrace{g \int_{\eta_\mathrm{b}}^{z} \nabla_z \rho \, \mathrm{d}z'}_{\text{internal contribution}}. \tag{28.53}$$

The horizontal pressure gradient at the bottom

Just as for the pressure gradient expression (28.48), observe that equation (28.53) decomposes the horizontal pressure gradient into an external and internal contribution. The internal contribution arises from gradients in the buoyancy as integrated below the depth of interest. The external contributions arise from gradients in the bottom pressure, which measures the mass per area of fluid within the column, plus gradients in the bottom topography as weighted by the bottom buoyancy (28.59). The external contribution can be written as the horizontal pressure gradient evaluated at the ocean bottom

$$(\nabla_z p)_{z=\eta_\mathrm{b}} = \nabla_z p_\mathrm{b} + g\,\rho(\eta_\mathrm{b})\,\nabla_z \eta_\mathrm{b}, \tag{28.54}$$

which accords with equation (28.49) for the horizontal pressure gradient evaluated at the ocean surface. Evidently, the horizontal pressure gradient at the ocean bottom equals to the gradient of the bottom pressure, plus a term that accounts for the bottom slope. Furthermore, the component of the horizontal pressure gradient in a direction tangent to the ocean bottom arises just from the $\nabla_z p_\mathrm{b}$ term. Finally, we make use of expression (28.54) to produce a more succinct form of the horizontal pressure gradient (28.53)

$$\nabla_z p = (\nabla_z p)_{z=\eta_\mathrm{b}} + \rho_0 \int_{\eta_\mathrm{b}}^{z} \nabla_z b \, \mathrm{d}z' = (\nabla_z p)_{z=\eta_\mathrm{b}} - g \int_{\eta_\mathrm{b}}^{z} \nabla_z \rho \, \mathrm{d}z'. \tag{28.55}$$

Further decomposing the bottom pressure contribution

The bottom pressure contribution to equations (28.53) and (28.55) is generally dominated by gradients in the bottom topography. These gradients are static and so it can be useful to isolate the bottom topography by taking the horizontal gradient of equation (28.51) to find

$$\nabla_z p_\mathrm{b} = \nabla p_\mathrm{a} + g\,\rho(\eta)\,\nabla\eta - g\,\rho(\eta_\mathrm{b})\,\nabla\eta_\mathrm{b} + g\int_{\eta_\mathrm{b}}^{\eta} \nabla_z\rho\,\mathrm{d}z \tag{28.56a}$$

$$= \left[\nabla p_\mathrm{a} + g\,\rho(\eta)\,\nabla\eta - b(\eta_\mathrm{b})\,\nabla\eta_\mathrm{b} + g\int_{\eta_\mathrm{b}}^{\eta} \nabla_z\rho\,\mathrm{d}z\right] - g\,\rho_0\,\nabla\eta_\mathrm{b}, \tag{28.56b}$$

in which case we write the bottom pressure gradient as

$$\nabla_z p_\mathrm{b} = \nabla_z p'_\mathrm{b} - g\,\rho_0\,\nabla_z\eta_\mathrm{b}, \tag{28.57}$$

so that the horizontal pressure gradient takes the form

$$\nabla_z p = \underbrace{\nabla_z p'_\mathrm{b} - \rho_0\,b(\eta_\mathrm{b})\,\nabla_z\eta_\mathrm{b}}_{\text{external contribution}} \;+\; \underbrace{\rho_0\int_{\eta_\mathrm{b}}^{z} \nabla_z b\,\mathrm{d}z'}_{\text{internal contribution}}, \tag{28.58}$$

where we introduced the bottom buoyancy via

$$\rho_0\,[g - b(\eta_\mathrm{b})]\,\nabla\eta_\mathrm{b} = g\,\rho(\eta_\mathrm{b})\,\nabla\eta_\mathrm{b}. \tag{28.59}$$

28.3.3 Horizontal pressure gradient at the ocean surface and bottom

We have already given expressions for the horizontal pressure gradient along the ocean surface (equation (28.49)) and ocean bottom (equation (28.54)). Here we list these equalities again, along with two more expressions that follow from evaluating equation (28.50) at the ocean bottom and equation (28.55) at the ocean surface

$$(\nabla_z p)_{z=\eta} = \nabla_z p_\mathrm{a} + g\,\rho(\eta)\,\nabla_z\eta = (\nabla_z p)_{z=\eta_\mathrm{b}} - g\int_{\eta_\mathrm{b}}^{\eta} \nabla_z\rho\,\mathrm{d}z \tag{28.60a}$$

$$(\nabla_z p)_{z=\eta_\mathrm{b}} = \nabla_z p_\mathrm{b} + g\,\rho(\eta_\mathrm{b})\,\nabla_z\eta_\mathrm{b} = (\nabla_z p)_{z=\eta} + g\int_{\eta_\mathrm{b}}^{\eta} \nabla_z\rho\,\mathrm{d}z. \tag{28.60b}$$

28.3.4 Inverse barometer sea level

A zero horizontal pressure gradient at the ocean surface, in the presence of an applied surface pressure, is known as an *inverse barometer sea level*, whereby

$$(\nabla_z p)_{z=\eta} = \nabla_z p_\mathrm{a} + g\,\rho(\eta)\,\nabla_z\eta = 0, \tag{28.61}$$

which leads to

$$\nabla_z\cdot[g\,\rho(\eta)\,\nabla_z\eta] = -\nabla_z^2 p_\mathrm{a}. \tag{28.62}$$

Assuming $\rho(\eta)$ is roughly constant, then the inverse barometer sea level is depressed under an atmospheric high pressure (where $\nabla_z^2 p_\mathrm{a} < 0$) and it rises under an atmospheric low (where $\nabla_z^2 p_\mathrm{a} > 0$), with Figure 28.4 providing a schematic. We again encounter the inverse barometer when studying shallow water theory in Section 36.2.2.

FIGURE 28.4: Illustrating the inverse barometer response of sea level under an atmospheric high pressure where $\nabla^2 p_\mathrm{a} < 0$. The inverse barometer sea level is depressed according to equation (28.62).

28.3.5 Compensation of internal and external pressure gradients

Following from our considerations of the level of no motion in Section 28.2.5, we here consider the case in which there is zero horizontal pressure gradient along a constant geopotential surface (i.e., a level of no motion)

$$z = \eta_\mathrm{nm}. \tag{28.63}$$

We might find this case to be relevant in the deep ocean where flow can be much smaller than the upper ocean. What is required from the hydrostatic pressure field to realize this level of no motion? Based on the expressions (28.50) and (28.55), the pressure field must satisfy

$$0 = (\nabla_z p)_{z=\eta_\mathrm{nm}} = (\nabla_z p)_{z=\eta} + g \int_{\eta_\mathrm{nm}}^{\eta} \nabla_z \rho \,\mathrm{d}z = (\nabla_z p)_{z=\eta_\mathrm{b}} - g \int_{\eta_\mathrm{b}}^{\eta_\mathrm{nm}} \nabla_z \rho \,\mathrm{d}z. \tag{28.64}$$

Each of these equations expresses a compensation between external and internal contributions to the pressure gradient so that

$$(\nabla_z p)_{z=\eta} = -g \int_{\eta_\mathrm{nm}}^{\eta} \nabla_z \rho \,\mathrm{d}z \tag{28.65a}$$

$$(\nabla_z p)_{z=\eta_\mathrm{b}} = g \int_{\eta_\mathrm{b}}^{\eta_\mathrm{nm}} \nabla_z \rho \,\mathrm{d}z. \tag{28.65b}$$

In Figure 28.5 we illustrate the compensation (28.65a) that results if an external pressure gradient from a sloping sea level exactly balances the internal pressure gradient from horizontal density gradients (assuming $\nabla p_\mathrm{a} = 0$), so that

$$\rho(\eta)\,\nabla_z \eta = -\int_{\eta_\mathrm{nm}}^{\eta} \nabla_z \rho \,\mathrm{d}z. \tag{28.66}$$

This equation allows us to estimate the scale for the free surface slope by writing

$$\rho_0\,|\nabla_z \eta| \sim H\,|\nabla_z \rho| = (H\,\rho_0/g)\,|S\,N^2|, \tag{28.67}$$

where S is the slope of the density surfaces, $H = \eta - \eta_\mathrm{nm}$ is the depth of the fluid, and N^2 is the squared buoyancy frequency. Assuming $|S| \approx 10^{-3}$, $H \approx 3 \times 10^3$ m, and $N^2 \approx 10^{-6}$ s^{-2} leads to the free surface slope

$$|\nabla_z \eta| \approx 10^{-7}. \tag{28.68}$$

Evidently, the free surface slope is much smaller than that of the interior density surfaces. We see this property again when studying the reduced gravity model in Section 36.3.

FIGURE 28.5: Illustrating the compensation of internal and external horizontal pressure gradients that is needed to realize a level of zero horizontal pressure gradient at $z = \eta_{\rm nm}$ (i.e., a *level of no motion*). The compensation shown here is taken from equation (28.65a) with a zero applied pressure gradient, $\nabla p_{\rm a} = 0$. Hence, compensation is between an external pressure gradient from the sea level that exactly balances the internal pressure gradient from horizontal density gradients. The relative slope of the free surface is exagerated here, with actual slopes scaling as in equation (28.68), which are generally much smaller than the slope of density surfaces.

28.3.6 Horizontal hydrostatic pressure gradient in a mass conserving fluid

As a follow up to the discussion in Section 28.3.5, we here consider a specific example that is emblematic of how one determines the sign for horizontal gradients in a mass conserving fluid that maintains an approximate hydrostatic balance, and thus to determine the direction for the pressure force. The example is posed for a bounded column of fluid, as in the ocean, but analogous considerations hold for the atmosphere where the upper boundary is the top of the atmosphere (i.e., effectively unbounded). Furthermore, we consider a flow that conserves the mass of fluid elements, so that the flow generally has a nonzero divergence. In Section 30.2.6 we reconsider this example for an oceanic Boussinesq fluid, whereby the flow is non-divergent so that fluid elements conserve their volume.

Two columns with equal mass yet different densities

Consider two adjacent columns of seawater with equal mass but with distinct density; assume the density in each column is constant throughout the respective columns; and assume the atmospheric pressure is equal above the two water columns. Figure 28.6 offers a schematic, where we make the additional assumption that the two columns sit on a flat bottom. We can imagine setting up this configuration by starting with uniform density water, then warming the water in column B more than column A while maintaining constant mass in the two columns. This process sets up a horizontal density gradient with an associated horizontal gradient in the hydrostatic pressure. Furthermore, the less dense water in column B occupies more volume so that its free surface sits higher

$$\rho_{\rm B} < \rho_{\rm A} \Longrightarrow \eta_{\rm B} > \eta_{\rm A}. \tag{28.69}$$

What is the sign of the horizontal hydrostatic pressure gradient? As we show in the following, column B (the low density column) has larger hydrostatic pressure than column A (the high density column) for every point in the column, except at the bottom where the two bottom pressures are identical since the two columns have equal mass. The bottom thus represents a level of no motion.

Computing pressure starting from the equal bottom pressures

Since the two columns have equal mass and equal cross-sectional area, the hydrostatic pressures (weight per unit area) at the bottom of the two columns are equal and given by

$$p_{\text{bot}} = g\,\rho_{\text{A}}\,(\eta_{\text{A}} - \eta_{\text{b}}) = g\,\rho_{\text{B}}\,(\eta_{\text{B}} - \eta_{\text{b}}), \tag{28.70}$$

where $z = \eta_{\text{b}}(x, y)$ is the vertical position at the bottom, $z = \eta_{\text{A}}(x, y, t)$ is the top of column A, and $z = \eta_{\text{B}}(x, y, t)$ is the top of column B. Since the bottom pressures are identical, there is no horizontal pressure gradient at the bottom so that all pressure gradients exist above the bottom.

The hydrostatic pressure at an arbitrary position within column A is given by

$$p_{\text{A}}(z) = g\,\rho_{\text{A}}\,(\eta_{\text{A}} - z) = p_{\text{bot}} - g\,\rho_{\text{A}}\,(-\eta_{\text{b}} + z), \tag{28.71}$$

where we only expose here the z dependence to reduce clutter. The second equality arose by substituting the bottom pressure from equation (28.70) to eliminate the surface height η_{A}. Doing so is useful since we know that $\eta_{\text{A}} \neq \eta_{\text{B}}$, and yet the bottom pressure is the same for the two columns. The same approach for pressure in column B yields

$$p_{\text{B}}(z) = g\,\rho_{\text{B}}\,(\eta_{\text{B}} - z) = p_{\text{bot}} - g\,\rho_{\text{B}}\,(-\eta_{\text{b}} + z). \tag{28.72}$$

We can now take the difference between the two hydrostatic pressures to find

$$p_{\text{B}}(z) - p_{\text{A}}(z) = g\,(-\eta_{\text{b}} + z)\,(\rho_{\text{A}} - \rho_{\text{B}}) > 0. \tag{28.73}$$

Since $\rho_{\text{A}} > \rho_{\text{B}}$ and $z \geq \eta_{\text{b}}$ we see that at any point above the bottom, the hydrostatic pressure in column B (the lighter column) is greater than that in column A (the denser column). This horizontal difference in the hydrostatic pressure renders a force pointing from column B to column A. Vertically integrating this pressure difference over the thickness of column A leads to the net force per horizontal length

$$F_{\text{pressure B to A}} = \int_{\eta_{\text{b}}}^{\eta_{\text{A}}} [p_{\text{B}}(z) - p_{\text{A}}(z)]\,\mathrm{d}z = (g/2)\,(\rho_{\text{A}} - \rho_{\text{B}})\,(\eta_{\text{A}} - \eta_{\text{b}})^2 > 0. \tag{28.74}$$

Inferring pressure gradients starting from the top

Another way to understand why the pressure force points from column B to column A is to note that at the top of both columns the pressures are the same (and equal to the uniform atmospheric pressure). However, since column B sits higher than column A, as we move down from $z = \eta_{\text{B}}$ the pressure increases in column B immediately, whereas the pressure in column A remains at the atmospheric pressure until entering the water column at $z = \eta_{\text{A}} < \eta_{\text{B}}$. So it is clear that the pressure in column B is greater than A starting from the surface and moving down. Since the two bottom pressures are equal, then we infer the pressure isolines as drawn in Figure 28.6.

28.4 Homogeneous fluid in a rotating tank

As an application of the ideas developed in this chapter and in earlier chapters, we develop the equations for a homogeneous fluid in a rotating tank such as occurs in laboratory studies of rotating fluids. One point of departure from planetary applications concerns the choice of vertical coordinate. Recall we introduced geopotential surfaces in Section 13.10.4, on which the effective gravitational force (sum of central gravity plus planetary centrifugal) is constant. Correspondingly,

FIGURE 28.6: Two seawater columns on a flat bottom with equal mass but different densities with $\rho_{\mathrm{A}} > \rho_{\mathrm{B}}$. We assume the atmosphere above the columns has the same pressure over both columns, thus offering zero horizontal pressure force. Furthermore, the horizontal cross-sectional area of the two columns are the same so that the less dense water in column B has more volume and thus a greater thickness: $\eta_{\mathrm{B}} > \eta_{\mathrm{A}}$. Since the column masses are the same, the hydrostatic pressures (weight per horizontal area) at the bottom of the two columns are equal: $p_{\mathrm{A}}(z = \eta_{\mathrm{b}}) = p_{\mathrm{B}}(z = \eta_{\mathrm{b}}) = p_{\mathrm{bot}}$. In oceanographic parlance, the bottom offers a "level of no motion" from which to reference the pressure field. At any position z above the bottom, equation (28.73) shows that the hydrostatic pressure in column B is greater than A: $p_{\mathrm{B}}(z) - p_{\mathrm{A}}(z) = g\,(-\eta_{\mathrm{b}} + z)\,(\rho_{\mathrm{A}} - \rho_{\mathrm{B}}) > 0$. The horizontal gradient in hydrostatic pressure thus points from column B towards column A. The red lines show lines of constant pressure (isobars), which are horizontal next to the bottom but which slope upward to the right moving towards the surface. This configuration provides salient points about hydrostatic pressure relevant for the slightly more complex reduced gravity example in Figure 36.5. Also, it is useful to compare this schematic to Figure 32.4, which discusses the depth dependence of the horizontal gradient in hydrostatic pressure as per $\partial(\nabla_z p)/\partial z = -g\,\nabla_z \rho$.

we introduced geopotential coordinates in Section 13.11.3 to simplify the equations for planetary fluid dynamics. In contrast, for the rotating tank we do not make use of geopotential coordinates. Instead, we expose the centrifugal acceleration (due to rotation of the tank), which allows for a clear display of the parabolic shape for the free surface when the fluid is in rigid-body motion.

28.4.1 What about the planet's rotation?

Do we need to worry about the planet's rotation? To answer this question, consider a typical record player with an angular speed of 45 revolutions per minute

$$\Omega_{\mathrm{record}} = 0.75\ \mathrm{s}^{-1}. \tag{28.75}$$

This angular speed is roughly 10^4 times faster than the earth's angular speed of $7.29 \times 10^{-5}\ \mathrm{s}^{-1}$ (equation (13.1)). For a tank rotating at a rate on the same order as a record player, we are justified ignoring the rotating earth in comparison to the rotating tank. That is, we can safely ignore planetary Coriolis and planetary centrifugal accelerations, allowing us to instead focus on the non-inertial accelerations arising just from the tank rotating on a laboratory turntable.

28.4.2 Formulating the equations of motion

In an inertial reference frame, a fluid element feels the gravitational force, pressure force, and friction, thus leading to the Cartesian coordinate equations of motion

$$\frac{\mathrm{D}u_{\mathrm{I}}}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + F^x \tag{28.76}$$

$$\frac{\mathrm{D}v_{\mathrm{I}}}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + F^y \tag{28.77}$$

$$\frac{\mathrm{D}w_{\mathrm{I}}}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial z} - g + F^z, \tag{28.78}$$

where $\boldsymbol{v}_{\mathrm{I}}$ is the inertial velocity, ρ is the constant density, and we orient the coordinates so that the z-axis extends vertically upward from the center of the tank and parallel to the gravity acceleration. Correspondingly, the rotation vector for the tank is

$$\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}} = (f/2)\,\hat{\boldsymbol{z}}. \tag{28.79}$$

To derive the rotating frame equations, return to some of the kinematics from Chapter 13, in which we write the position of a fluid particle as

$$\boldsymbol{X}(t) = X\,\hat{\boldsymbol{x}} + Y\,\hat{\boldsymbol{y}} + Z\,\hat{\boldsymbol{z}}. \tag{28.80}$$

We assume that the Cartesian unit vectors are fixed in the rotating frame and thus move as a rigid-body with the rotating tank. The inertial velocity is thus given by

$$\frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \left[\frac{\mathrm{d}X}{\mathrm{d}t}\right]\hat{\boldsymbol{x}} + \left[\frac{\mathrm{d}Y}{\mathrm{d}t}\right]\hat{\boldsymbol{y}} + \left[\frac{\mathrm{d}Z}{\mathrm{d}t}\right]\hat{\boldsymbol{z}} + \boldsymbol{\Omega}\times\boldsymbol{X}. \tag{28.81}$$

Correspondingly, the acceleration is given by

$$\frac{\mathrm{d}^2\boldsymbol{X}}{\mathrm{d}t^2} = \left[\frac{\mathrm{d}^2X}{\mathrm{d}t^2}\right]\hat{\boldsymbol{x}} + \left[\frac{\mathrm{d}^2Y}{\mathrm{d}t^2}\right]\hat{\boldsymbol{y}} + \left[\frac{\mathrm{d}^2Z}{\mathrm{d}t^2}\right]\hat{\boldsymbol{z}} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} + \boldsymbol{\Omega}\times(\boldsymbol{\Omega}\times\boldsymbol{X}), \tag{28.82}$$

where we defined the rotating frame Cartesian velocity as

$$\boldsymbol{v} = \left[\frac{\mathrm{d}X}{\mathrm{d}t}\right]\hat{\boldsymbol{x}} + \left[\frac{\mathrm{d}Y}{\mathrm{d}t}\right]\hat{\boldsymbol{y}} + \left[\frac{\mathrm{d}Z}{\mathrm{d}t}\right]\hat{\boldsymbol{z}}. \tag{28.83}$$

Setting the inertial acceleration equal to the inertial force per mass leads to the equations of motion in the rotating frame

$$\frac{\mathrm{D}u}{\mathrm{D}t} - 2\,\Omega\,v = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \Omega^2\,x + F^x \tag{28.84}$$

$$\frac{\mathrm{D}v}{\mathrm{D}t} + 2\,\Omega\,u = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \Omega^2\,y + F^y \tag{28.85}$$

$$\frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial z} - g + F^z, \tag{28.86}$$

which take on the vector form

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{v} = -\nabla\left[p/\rho + g\,z - \Omega^2\,(x^2+y^2)/2\right] + \boldsymbol{F}. \tag{28.87}$$

As expected, we encounter both a Coriolis and centrifugal acceleration due to the rotation of the tank.

28.4.3 Rigid-body rotation and parabolic free surface shape

Consider a fluid at rest in a non-rotating tank, and then start the tank rotating. As in our discussion of Couette flow in Section 26.8.2, viscous effects transfer motion from the outside tank wall (where a no-slip boundary condition makes the fluid move with the wall) into the interior of the fluid. Given sufficient time and a constant rotation rate, the fluid reaches a steady state in rigid-body motion. Recall that rigid-body motion means that the velocity vanishes in the rotating reference frame.

As an application of the above equations of motion, we here determine the shape of the upper free surface for this steady rigid-body motion, offering two related derivations. Note that when the fluid reaches rigid-body motion, all strains vanish within the fluid so that frictional stresses vanish (see Section 26.8). Hence, the steady force balance is fully inviscid although the steady state required viscosity to reach it. The ability to ignore friction in the steady state greatly simplifies the analysis.

Component equations of motion

The velocity and acceleration in the rotating frame are zero when the fluid is in rigid-body rotation. The vertical momentum equation (28.86) thus reduces to the approximate hydrostatic balance

$$\frac{\partial p}{\partial z} = -\rho\, g. \tag{28.88}$$

In general we do not have hydrostatic balance for motion in a tank that deviates from rigid-body. However, when that motion is close to a rigid-body rotation, then the fluid is in an approximate hydrostatic balance. As seen in Section 28.2, this situation corresponds to the large-scale ocean and atmosphere.

Hydrostatic balance with a constant density means that the pressure is a linear function of depth

$$p(x, y, z) = \rho\, g\, (\eta - z), \tag{28.89}$$

where $z = \eta(x, y)$ is the vertical position of the free surface. The horizontal momentum equations (28.84)-(28.85) reduce to a balance between the pressure gradient and centrifugal accelerations

$$\frac{\partial p}{\partial x} = \rho\, x\, \Omega^2 \qquad \text{and} \qquad \frac{\partial p}{\partial y} = \rho\, y\, \Omega^2. \tag{28.90}$$

Pressure thus increases when moving radially away from the center. Substituting in the pressure as given by the hydrostatic relation (28.89) leads to relations satisfied by the rigid-body free surface

$$g\, \frac{\partial \eta}{\partial x} = x\, \Omega^2 \qquad \text{and} \qquad g\, \frac{\partial \eta}{\partial y} = y\, \Omega^2. \tag{28.91}$$

Integration leads to the quadratic expression for the free surface

$$\eta = \eta(0) + \frac{\Omega^2\, (x^2 + y^2)}{2\, g}, \tag{28.92}$$

where $\eta(0)$ is the free surface at the center of the tank where $x = y = 0$. The rigid-body rotating fluid thus has a quadratic free surface with the height of the surface increasing away from the

center, as depicted in Figure 28.7. Notice how the fluid density dropped out from the problem, so that this parabolic shape holds for any homogeneous fluid in rigid-body motion.

FIGURE 28.7: Rotating tank of homogeneous fluid that has reached a steady state with a parabolic free surface.

Vector force balance

A more telescopic means to determine the free surface shape is to set the forces to zero on the right hand side of the vector equation of motion (28.87) so that

$$p/\rho + g\, z - \Omega^2 (x^2 + y^2)/2 = p_0/\rho, \tag{28.93}$$

where p_0 is a constant pressure to be specified below. Furthermore, we set friction to zero since the fluid is in rigid-body motion. Everywhere along the free surface, with $z = \eta$, the pressure equals to that applied to the free surface by the overlying media, $p = p_{\mathrm{a}}$ (e.g., atmospheric pressure). Hence, setting $z = \eta$ in equation (28.93) and solving for η yields

$$\eta = \frac{p_0 - p_{\mathrm{a}}}{\rho\, g} + \frac{\Omega^2 (x^2 + y^2)}{2\, g}. \tag{28.94}$$

For simplicity, assume the applied pressure is spatially constant. Hence, setting p_0 according to the free surface at $x = y = 0$ brings the free surface to the parabolic form in equation (28.92)

$$\frac{p_0 - p_{\mathrm{a}}}{\rho\, g} = \eta(0) \Longrightarrow \eta = \eta(0) + \frac{\Omega^2 (x^2 + y^2)}{2\, g}. \tag{28.95}$$

28.4.4 Further study

We study the angular momentum for the shallow water version of this system in Section 37.8. See section 6.6.4 of *Marshall and Plumb* (2008) for more discussion of laboratory rotating tank experiments.

28.5 Exercises

EXERCISE 28.1: PRIMITIVE EQUATIONS AND AXIAL ANGULAR MOMENTUM

The axial angular momentum of a fluid element satisfying the primitive equations is given by

$$L^z = (\rho\, \delta V)\, R_\perp\, (u + R_\perp\, \Omega) \equiv (\rho\, \delta V)\, l^z \tag{28.96}$$

where

$$R_\perp = R_\mathrm{e} \cos\phi \tag{28.97}$$

is the distance from the polar rotation axis to a point on the sphere with radius R_e, and

$$l^z = R_\perp \left(u + R_\perp \Omega\right) \tag{28.98}$$

is the angular momentum per unit mass. For this exercise, we develop some results for the axial angular momentum in the primitive equations. For this purpose, it can be useful to recall the discussion of axial angular momentum in Section 25.7, in which we did not assume primitive equations.

(a) Consider a constant mass fluid element in the absence of friction. Show that the primitive equation zonal momentum equation (28.7) implies that the material evolution of axial angular momentum per mass is given by

$$\frac{\mathrm{D}l^z}{\mathrm{D}t} = -\frac{1}{\rho}\frac{\partial p}{\partial \lambda}. \tag{28.99}$$

(b) Assume the zonal pressure gradient vanishes. Move the fluid element vertically while maintaining a fixed latitude. What happens to the zonal momentum of this primitive equation fluid element? Hint: be sure to remain within the "world" of the primitive equations.

(c) Give a very brief symmetry argument for why the axial angular momentum is materially conserved when $\partial p/\partial\lambda = 0$. Hint: recall the discussion of Noether's Theorem in Section 14.2.1.

(d) Consider the material evolution of primitive equation axial angular momentum per mass in the case where the zonal momentum equation retains the unapproximated form of the Coriolis acceleration. Discuss the resulting material evolution equation. Does this equation make sense based on the symmetry argument given in the previous part of this exercise?

EXERCISE 28.2: MASS BALANCE FOR A HYDROSTATIC OCEAN COLUMN

Equation (20.88) provides a kinematic expression for the column mass budget. Show that for a hydrostatic fluid flow, the mass balance for a fluid column (equation (20.100)) takes the form

$$\partial_t(p_\mathrm{b} - p_\mathrm{a}) = -g\,\nabla\cdot\boldsymbol{U}^\rho + g\,Q_\mathrm{m}, \tag{28.100}$$

where

$$\boldsymbol{U}^\rho = \int_{\eta_\mathrm{b}}^{\eta} \mathbf{u}\,\rho\,\mathrm{d}z \tag{28.101}$$

is the depth integrated horizontal mass transport,

$$p_\mathrm{b} = p_\mathrm{a} + g\int_{\eta_\mathrm{b}}^{\eta} \rho\,\mathrm{d}z \tag{28.102}$$

is the hydrostatic pressure at the ocean bottom, and $p_\mathrm{a}(x,y,t)$ is the pressure applied to the ocean surface from the overlying atmosphere or sea ice.

EXERCISE 28.3: EVOLUTION OF ATMOSPHERIC BOTTOM HYDROSTATIC PRESSURE

In deriving equation (28.30) we assumed the lower limit on the integral to be a horizontal constant. However, when integrating over the full atmospheric column, the lower limit varies horizontally

given that the earth boundary is not flat. Return to equation (28.29b) and derive the evolution equation for the bottom pressure

$$\partial_t p_{\rm bot} = -g\,\nabla_z \cdot \boldsymbol{U}^\rho, \tag{28.103}$$

where

$$p_{\rm bot}(x,y,t) = p[x,y,z=\eta_{\rm b}(x,y),t] \tag{28.104}$$

is the atmospheric pressure at the solid earth at $z=\eta_{\rm b}(x,y)$,

$$\boldsymbol{U}^\rho = \int_{\eta_{\rm b}}^{z_{\rm top}} \boldsymbol{u}\,\rho\,{\rm d}z' \tag{28.105}$$

is the depth integrated horizontal mass transport, and $z_{\rm top}$ is the vertical position of the atmospheric top that is assumed to be independent of horizontal position.

Chapter 29

Pressure form stress

As introduced in our discussion of Cauchy's stress principle in Section 26.2, pressure form stress is the horizontal stress arising from pressure that acts on a sloped surface or interface. As a contact force per area, Newton's third law describes how form stress renders a transfer of pressure forces across interfaces, with pressure form stress affecting a vertical transfer of horizontal pressure forces. Hence, it provides an inviscid/reversible mechanism for the vertical transfer of horizontal momentum, thus complementing the vertical transfer associated with viscosity in the presence of tangential shear stresses (Section 26.8.2).

In this chapter we study pressure form stresses on the variety of interfaces encountered in geophysical fluids. We then develop two case studies to expose the role of pressure form stress in the force balances affecting motion of an ocean fluid column. The first case study is concerned with the evolution of vertically integrated horizontal linear momentum per mass. The second case study focuses on the axial angular momentum budget as a framework to study the dominant force balances in ocean channel flow and ocean gyre flow.

CHAPTER GUIDE

In this chapter we build from the study of stresses in Chapter 26, with an understanding of pressure form stress greatly enhancing our understanding of horizontal forces acting in geophysical fluids. The focus on horizontal forces in this chapter complements our studies in Chapter 31, whereby the net vertical acceleration from pressure and gravitational forces is repackaged into the buoyancy force.

29.1 Pressure form stresses at an interface

As depicted in Figure 29.1, there are three surfaces or interfaces across which we commonly study form stresses in geophysical fluids.

- ATMOSPHERE-OCEAN FORM STRESS: A form stress occurs at the air-sea interface. From the perspective of the ocean, the nonzero atmospheric pressure applied to the sea surface (the *sea level pressure*) provides a pressure acting on the sloped upper ocean free surface, thus rendering an *atmospheric form stress* acting on the ocean. Through *Newton's third law* (see Section 11.5.2), this form stress is met by the equal in magnitude but oppositely directed *ocean form stress* acting on the atmosphere.

- INTERIOR FLUID INTERFACIAL FORM STRESS: A form stress occurs on an internal interface within the fluid, and we study such *interfacial form stresses* in Section 29.3. Although the interface is arbitrary, it is dynamically very interesting to study form stresses acting on buoyancy isosurfaces. The reason is that buoyancy interfaces are directly connected to the geostrophic motion studied in Chapter 32. In particular, in Section 32.6 we study form stresses associated with buoyancy interfaces found in geostrophic flows.

- FLUID-TOPOGRAPHY FORM STRESS: A form stress exists at a solid/fluid boundary, at which the ocean or atmosphere impart a pressure force on the solid earth. Through Newton's third law, the pressure force imparted by the fluid on the solid earth is met equally in magnitude but oppositely in direction by a force provided by the solid earth onto the fluid. The horizontal projection of this force per area acting from the earth on the fluid is the *topographic form stress* and it is considered in Section 29.2.

29.1.1 Concerning the sign of a form stress

As a vector, pressure form stress has a direction and a magnitude, with three examples depicted in Figure 29.1. Even so, keeping track of the direction can be confusing if it is unclear who is the giver of the form stress and who is the receiver. To help in understanding the sign, imagine pushing against a heavy rock or boulder: you exert a force on the rock in one direction whereas, through Newton's third law, the rock exerts an equal and opposite force on you. Clarity is realized

FIGURE 29.1: Illustrating the three interfaces of concern in geophysical fluid mechancs for the discussion of form stresses. Continuity of pressure at the interface, through Newtons' third law, means that the form stress on one side of the interface is equal and opposite to that acting on the other side. Left panel: a curved atmosphere-ocean interface leads to an atmospheric form stress acting on the ocean, $\boldsymbol{F}^{\text{form}}_{\text{atm to ocn}}$, and its equal and opposite oceanic form stress acting on the atmosphere, $\boldsymbol{F}^{\text{form}}_{\text{ocn to atm}} = -\boldsymbol{F}^{\text{form}}_{\text{atm to ocn}}$. Middle panel: a curved interior ocean interface (e.g., a buoyancy surface) leads to an interfacial form stress acting on the lower layer, $\boldsymbol{F}^{\text{form}}_{\text{k}\to\text{k+1}}$, and its equal and opposite interfacial form stress acting on the upper layer, $\boldsymbol{F}^{\text{form}}_{\text{k+1}\to\text{k}} = -\boldsymbol{F}^{\text{form}}_{\text{k}\to\text{k+1}}$. Right panel: a curved fluid-solid earth interface leads to a fluid form stress acting on the solid earth, $\boldsymbol{F}^{\text{form}}_{\text{fluid to earth}}$, and its equal and opposite oceanic form stress acting on the fluid, $\boldsymbol{F}^{\text{form}}_{\text{earth to fluid}} = -\boldsymbol{F}^{\text{form}}_{\text{fluid to earth}}$. The magnitude of the form stresses is a function of the pressure acting at the interface as well as the slope of the interface (steeper slopes lead to larger magnitude).

by specifying the origin of the force in order to determine its sign. For example, as illustrated in Figure 29.2, is one concerned with the force applied by the ocean bottom pressure onto the earth (liquid ocean is giver and solid earth is receiver), or instead with the force from the earth applied onto the ocean fluid (earth is giver and ocean is receiver)? These forces have equal magnitude but opposite direction. Knowing the direction requires knowing the force giver and/or the force receiver.

FIGURE 29.2: Contact forces, such as pressure, satisfy Newton's third law. Hence, the contact force at a point imparted by region A onto region B, $\boldsymbol{F}^{\text{A onto B}}$, is equal and opposite to the force imparted by region B onto region A so that $\boldsymbol{F}^{\text{A onto B}} = -\boldsymbol{F}^{\text{B onto A}}$. In the case where A=fluid (ocean or atmosphere) and B=solid earth, we generally to refer to the horizontal portion of $\boldsymbol{F}^{\text{earth onto fluid}}$, per horizontal area, as the *topographic form stress*.

29.1.2 Mathematical expression for form stress

To expose the mathematics of form stress, consider a surface, $\mathcal{S}$, such as that shown in Figure 29.3. To kinematically decompose the pressure force, assume the surface has no vertical section, with this assumption commonly satisfied by surfaces of interest for geophysical flows.

Assuming the surface has no vertical sections allows us to write the vertical position of a point on the surface as[1]

$$z = \eta(x, y, t). \tag{29.1}$$

[1]See the geometry discussion in Chapter 7 for more on the maths of such surfaces. Also see the discussion of generalized vertical coordinates in Chapters 59 and 60.

FIGURE 29.3: The pressure force acting on an arbitrary surface is given by $\boldsymbol{F}^{\text{press}} = -p\,\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}$, where $\mathrm{d}\mathcal{S}$ is the surface area element. We here depict the pressure acting on the top side of a surface, $\boldsymbol{F}^{\text{press}}_{\text{top}}$. Through Newton's third law, the pressure force vector acting on the top side of the interface is equal and opposite to the pressure force acting on the bottom side: $\boldsymbol{F}^{\text{press}}_{\text{top}} = -\boldsymbol{F}^{\text{press}}_{\text{b}}$. The horizontal component of this force vector arises from the slope; i.e., the geometric *form* of the surface. We thus refer to the horizontal pressure force per area as the *form stress*, $\boldsymbol{F}^{\text{form}}_{\text{top}} = -\boldsymbol{F}^{\text{form}}_{\text{b}}$. The area element on the surface, $\mathrm{d}\mathcal{S}$, has a horizontal projection given by $\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y = \cos\vartheta\,\mathrm{d}\mathcal{S}$, with the angle assumed to be within the range $-\pi/2 < \vartheta < \pi/2$ so that the surface is nowhere vertical.

The outward normal pointing away from the top side of the surface is given by

$$\hat{\boldsymbol{n}}_{\text{top}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{\hat{\boldsymbol{z}} - \nabla\eta}{\sqrt{1+|\nabla\eta|^2}}. \tag{29.2}$$

Multiplying the pressure times the horizontal area element on the surface, $\mathrm{d}\mathcal{S}$, leads to the net pressure force acting at a point on the top side of the surface

$$\boldsymbol{F}^{\text{press}} = -p\,\hat{\boldsymbol{n}}_{\text{top}}\,\mathrm{d}\mathcal{S} = -p\,(\hat{\boldsymbol{z}} - \nabla\eta)\,\mathrm{d}A = -p\,(-\partial_x\eta\,\hat{\boldsymbol{x}} - \partial_y\eta\,\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}})\,\mathrm{d}A. \tag{29.3}$$

In this equation we used the identity[2]

$$\mathrm{d}\mathcal{S} = |\nabla(z-\eta)|\,\mathrm{d}A = \sqrt{1+|\nabla\eta|^2}\,\mathrm{d}A, \tag{29.4}$$

with

$$\mathrm{d}A = \mathrm{d}x\,\mathrm{d}y \tag{29.5}$$

the horizontal projection of the surface area element (see Figure 29.3). We identify the form stress acting on the top side of this interface as

$$\text{pressure form stress acting on top side of interface} \equiv p\,\nabla\eta. \tag{29.6}$$

The name follows since the stress is determined by the "form" of the surface as measured by its slope, $\nabla\eta$. We can thus write the pressure force acting on the top side of the surface as the sum of a vertical pressure force plus a horizontal pressure form stress

$$\boldsymbol{F}^{\text{press}}_{\text{top}} = \hat{\boldsymbol{z}}\,[\hat{\boldsymbol{z}}\cdot\boldsymbol{F}^{\text{press}}_{\text{top}}] + \boldsymbol{F}^{\text{form}}_{\text{top}} = p\,(-\hat{\boldsymbol{z}} + \nabla\eta)\,\mathrm{d}A \qquad \text{pressure force on top of interface.} \tag{29.7}$$

Newton's third law, as manifested by Cauchy's Stress principle (Section 26.2) says that there is a local mechanical equilibrium of pressure contact forces within a fluid. Additionally, as seen in our discussion of stress on an interface in Section 26.10, this local equilibrium holds for pressure forces acting on interfaces separating two fluids, such as the atmosphere and ocean, as well as a fluid and the solid earth. Thus, the contact pressure force acting on the bottom side of the interface is equal in magnitude but oppositely directed to the contact force acting on the top side

[2]The identity (29.4) follows from trigonometry summarized in Figure 29.3. See further details in the kinematic boundary conditions of Section 20.4 and the analogous dia-surface transport in Section 60.3.

(see Section 26.8.2)

$$\boldsymbol{F}^{\text{press}}_{\text{bot}} = \hat{\boldsymbol{z}}\,[\hat{\boldsymbol{z}} \cdot \boldsymbol{F}^{\text{press}}_{\text{bot}}] + \boldsymbol{F}^{\text{form}}_{\text{bot}} = p\,(+\hat{\boldsymbol{z}} - \nabla\eta)\,\mathrm{d}A \qquad \text{pressure force on bottom of interface.} \tag{29.8}$$

29.1.3 Comments

We here offer three comments in regards to pressure form stress.

- MYSTERIOUS NOTION: The form stress, particularly interfacial form stress, can appear mysterious in some presentations. Part of the reason is that it sometimes appears seemingly without prior motivation as part of mathematical manipulations of the momentum equation. We illustrate these manipulations in Sections 29.2, 29.3, and 29.5, yet aim to offer sufficient physical motivation to help guide the maths. Another reason for the mystery is that the signs ascribed to form stress are often not clearly specified, with such ambiguities motivating the somewhat pedantic discussion in Section 29.1.1.

- UNBALANCED FORM STRESSES AND MOTION: Consider a container filled with water at rest. The horizontal pressure forces acting on the container sides are pressure form stresses between the water and the container. As discussed in Section 26.5, without motion we know that the form stresses balance over the whole of the fluid-container boundary, whereas horizontal motion occurs if the form stresses are out of balance. Quite generally, when concerned with fluid motion, we are interested in processes that lead to unbalanced form stresses. For example, when studying bottom topographic form stresses in the ocean, the bulk of the form stress acts to support the ocean water within the ocean basin. The dynamically active portion of the topographic form stress, associated with the fluid motion, is a small residual of the total form stress. Careful analysis is required to diagnose dynamically relevant patterns, with *Molemaker et al.* (2015) and *Gula et al.* (2015) presenting one method, and we explore their method as part of Exercise 41.12.

- DUAL FORM STRESS OFTEN CONFUSED WITH FORM STRESS: It is notable that much of the literature refers to $-\eta\nabla p$ as a form stress. However, as emphasized in Section 29.4.4, $-\eta\nabla p$ is not a form stress but is a *dual form stress*. Even though both have dimensions of a pressure, the dual form stress is not a pressure force in the sense that it does not act to accelerate a fluid element.

  The confusion between form stress and dual form stress perhaps originates from the common application of zonal averages. In this case we may wish to study the dynamics of the zonally averaged flow, particularly domains that are zonally periodic, in which we have the identity

  $$\oint p\,\partial_x\eta\,\mathrm{d}x = -\int \eta\,\partial_x p\,\mathrm{d}x. \tag{29.9}$$

  Hence, the zonally integrated form stress (left hand side) equals to the zonally integrated dual form stress (right hand side). However, care must be exercised in applying this identity in non-zonally periodic domains (we further pursue this point in Section 29.4). Even more fundamentally, $p\,\nabla\eta \neq -\eta\,\nabla p$. Consequently, it is generally necessary to distinguish the pressure form stress, which is a horizontal force per area that acts to accelerate fluid elements through Newton's law of motion, from the dual form stress, which does not appear in the equation of motion.

29.2 Form stresses on solid-fluid boundaries

In this section we focus on form stress arising from the shape of the solid earth interface with the atmosphere and ocean; i.e., the *fluid-topographic form stress*. As we are normally interested in the form stress applied to the fluid, we focus on the *topographic form stress*. We also encounter the form stress associated with undulations in the ocean free surface and the atmospheric pressure at that interface, with the *atmospheric form stress* the stress imparted to the ocean from the atmosphere.

29.2.1 Zonally symmetric ridge

In Figure 29.4 we depict an idealized ridge with an example oceanic pressure field to illustrate the nature of topographic form stress acting on the ocean. Rather than assuming exact hydrostatic equilibrium as in Figure 26.5, with zero horizontal pressure gradients, we here consider pressure to be higher to the west of the ridge than to the east. Since the ridge is assumed to be symmetric in the zonal direction, we conclude that the topographic form stress, which acts just at the fluid-solid interface, is higher on the west side of the ridge than on the east. In turn, the net topographic form stress acting on the fluid is to the west, whereas the net oceanic form stress acting on the solid earth is to the east. We encounter this situation in Section 29.5.10 when studying the force balances for steady circulation in a zonally periodic channel.

29.2.2 Form stress transfer between the fluid and its boundaries

We now illustrate how topographic form stress appears mathematically in the study of momentum balances acting on a fluid. For definiteness, consider a column of ocean fluid extending from the bottom at $z = \eta_{\mathrm{b}}(x, y)$ to the free surface at $z = \eta(x, y, t)$, and focus on the zonal force balance such as depicted in Figure 29.4. In computing the acceleration acting on this column at a particular horizontal position, we need to determine the depth integrated zonal pressure gradient

$$\text{depth integrated zonal pressure gradient} = -\int_{\eta_{\mathrm{b}}}^{\eta} \frac{\partial p}{\partial x}\, \mathrm{d}z. \tag{29.10}$$

We expose the contact force version of the pressure force by making use of Leibniz's Rule (Section 20.5) to write

$$-\int_{\eta_{\mathrm{b}}}^{\eta} \frac{\partial p}{\partial x}\, \mathrm{d}z = \underbrace{-\frac{\partial}{\partial x}\int_{\eta_{\mathrm{b}}}^{\eta} p\, \mathrm{d}z}_{\text{zonal deriv depth integrated pressure}} + \underbrace{\frac{\partial \eta}{\partial x}\, p_{\mathrm{a}}}_{\text{atmospheric form stress}} - \underbrace{\frac{\partial \eta_{\mathrm{b}}}{\partial x}\, p_{\mathrm{b}}}_{\text{topographic form stress}}, \tag{29.11}$$

where p_{a} is the pressure applied to the ocean at its surface, $z = \eta$, and p_{b} is the pressure at the ocean bottom, $z = \eta_{\mathrm{b}}$. The decomposition identifies the following three pressure contributions to the pressure force acting on the fluid column.

- ZONAL DERIVATIVE OF THE COLUMN INTEGRATED PRESSURE: The first term in equation (29.11) arises from the zonal derivative of pressure across the vertical sides of the column

$$\text{zonal derivative of layer integrated pressure} = -\frac{\partial}{\partial x}\int_{\eta_{\mathrm{b}}}^{\eta} p\, \mathrm{d}z. \tag{29.12}$$

  This term leads to a net eastward acceleration if the depth integrated pressure is higher to the west than the east.

FIGURE 29.4: Depicting contact forces acting at a fluid-solid interface. The topographic form stress acts on the fluid and the equal in magnitude but oppositely directed fluid form stress acts on the solid earth. In this illustration the topography is assumed to be a ridge in the shape of an equilateral triangle. We also assume there is higher pressure to the west of the ridge than to the east as per the zonal balance discussed in Figure 29.8 for a Southern Ocean ridge. Hence, the topographic form stress has a larger magnitude on the western side of the ridge than on the eastern side. When integrated over the full ridge, there will be a net westward topographic form stress acting on the fluid and a net eastward fluid form stress acting on the solid earth. If the ridge was free to move, it would move to the east. The thin gray column extends from the solid earth bottom to the ocean free surface. As this column sits on the western side of the ridge, topographic form stress provides a westward acceleration at the column bottom. The net acceleration of the column is determined by integrating the contact forces around the column boundary and body forces throughout the column interior. We study the axial angular momentum budget for a fluid column in Section 29.5, with form stresses appearing in that budget.

- ATMOSPHERIC FORM STRESS AT THE FREE SURFACE: In the presence of a sloping free surface interface, equation (29.11) reveals that $\partial\eta/\partial x \neq 0$, the atmospheric pressure, p_{a}, imparts an atmospheric form stress onto the ocean

$$\text{zonal atmospheric form stress acting on ocean} = \frac{\partial \eta}{\partial x}\, p_{\text{a}}. \tag{29.13}$$

For example, if the free surface slopes up to the east, $\partial\eta/\partial x > 0$, then the atmosphere provides a positive (eastward) zonal form stress onto the ocean. In turn, through Newton's third law, the ocean provides a westward zonal form stress to the atmosphere.

- TOPOGRAPHIC FORM STRESS ON OCEAN: Equation (29.11) also reveals that the bottom pressure, p_{b}, present at $z = \eta_{\text{b}}$ imparts a form stress to the solid earth

$$\text{zonal oceanic form stress acting on solid earth} = \frac{\partial \eta_{\text{b}}}{\partial x}\, p_{\text{b}}. \tag{29.14}$$

In turn, through Newton's third law, the topographic form stress acting on the ocean is equal in magnitude but oppositely directed

$$\text{zonal topographic form stress acting on ocean} = -\frac{\partial \eta_{\mathrm{b}}}{\partial x}\, p_{\mathrm{b}}. \tag{29.15}$$

For example, if the bottom rises to the east, so that $\partial \eta_{\mathrm{b}}/\partial x > 0$, then the oceanic form stress acting on the solid earth is eastward whereas the topographic form stress acting on the ocean is westward. As a check, we verify that the signs of these form stresses are consistent with those in Figure 29.4.

29.2.3 Decomposing topographic form stress

We follow the approach used in Section 28.3.2 to decompose here the contributions to the bottom pressure. Assuming the fluid maintains an approximate hydrostatic balance, and focusing on the oceanic case, allows us to decompose the bottom pressure according to

$$p_{\mathrm{b}} = p_{\mathrm{a}} + g \int_{\eta_{\mathrm{b}}}^{\eta} \rho \, \mathrm{d}z \tag{29.16a}$$

$$= \underbrace{g\,\rho_0\,[\eta + p_{\mathrm{a}}/(g\,\rho_0)]}_{\text{external}} \; \underbrace{-g\,\rho_0\,\eta_{\mathrm{b}}}_{\text{topog}} \; + \; \underbrace{g \int_{\eta_{\mathrm{b}}}^{\eta} (\rho - \rho_0)\, \mathrm{d}z}_{\text{internal}} \tag{29.16b}$$

$$\equiv p_{\mathrm{ext}} + p_{\mathrm{topog}} + p_{\mathrm{int}}. \tag{29.16c}$$

We refer to the contribution from applied surface pressure plus surface height undulations as *external*, whereas those arising from density deviations relative to a constant reference density are termed *internal*. There is a further contribution from bottom topography itself.

Multiplying the decomposed pressure (29.16c) by the slope of the bottom topography renders an expression for the various contributions to topographic form stress

$$-p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} = -p_{\mathrm{ext}} \nabla \eta_{\mathrm{b}} - p_{\mathrm{topog}} \nabla \eta_{\mathrm{b}} - p_{\mathrm{int}} \nabla \eta_{\mathrm{b}}. \tag{29.17}$$

The topographic term is static whereas the other two terms are time dependent. External contributions arise from undulations in the free surface as well as the applied pressure. This contribution fluctuates due to motions occuring on the relatively rapid time scales associated with external gravity waves or atmospheric pressure fluctuations such as through synoptic weather patterns. Internal contributions arise from the relatively slow internal movements of density surfaces, such as from internal gravity waves or even slower motions due to advection and diffusion. The study from *McCabe et al.* (2006) pursues this decomposition of the topographic form stress as part of their analysis of flow around a headland.

29.3 Interfacial form stress

In this section we focus on the form stress acting at an interface within the fluid itself, which is known as the *interfacial form stress*. As part of this discussion we expose some of the common manipulations found when considering finite volume integrated momentum budgets, whereby we decompose the horizontal pressure gradient acceleration acting on an infinitesimal column of fluid within the layer, as depicted in Figure 29.5. These manipulations are analogous to those considered in Section 29.2 for the topographic and atmospheric form stresses.

FIGURE 29.5: A schematic of the contact pressure force per area acting on the boundaries of a vertical column region within a fluid layer. The horizontal cross-sectional area of the column is depth independent. The interface at the lower boundary is at the vertical position $z = \eta_{\text{k}+1/2}(x, y, t)$, and the upper interface is at $z = \eta_{\text{k}-1/2}(x, y, t)$. In accordance with Newton's third law, pressures are continuous across each of the $\eta_{\text{k}\pm 1/2}$ layer interfaces so that the pressure forces are equal in magnitude yet oppositely directed on the opposite sides to the interfaces. The boundaries of the dark gray columnar region feel a contact pressure force acting inward, as per the compressive nature of pressure. The left side of the column experiences a pressure, p_L; the right side experiences, p_R; the upper interface has a pressure, $p_{\text{k}-1/2}$, acting between the layer $\text{k} - 1$ and layer k, and the lower interface has a pressure, $p_{\text{k}+1/2}$, acting between the layer $\text{k} + 1$ and layer k. The interfacial form stress (IFS) is the name given to the horizontal pressure stress acting on the upper and lower layer interfaces. Through Newton's third law, the IFS imparted to layer k at the $z = \eta_{\text{k}-1/2}$ interface is equal and opposite to the IFS imparted to layer $\text{k} - 1$ at this same interface. The same holds for the IFS at the $\text{k} + 1/2$ interface. It is common to define the layers according to buoyancy (see Section 32.6) given its direct connection to pressure and dynamics. Even so, the ideas of pressure contact forces are generic and thus hold for arbitrarily defined layers. This figure is adapted from Figure A1 in *Loose et al.* (2023).

29.3.1 Interfacial form stresses transferred between layers

When studying the momentum of a column of fluid within a chosen layer, we need to compute the depth integrated zonal pressure gradient over a layer at a particular horizontal point

$$\text{layer integrated zonal pressure gradient} = -\int_{\eta_{\text{k}+1/2}}^{\eta_{\text{k}-1/2}} \frac{\partial p}{\partial x}\, \mathrm{d}z, \tag{29.18}$$

where $z = \eta_{\text{k}-1/2}(x, y, t)$ is the vertical position for the interface at the top of the fluid layer and $z = \eta_{\text{k}+1/2}(x, y, t)$ is the vertical position for the bottom interface. If the layer integrated pressure gradient is downgradient to the east, then pressure accelerates the column to the east, and conversely when the layer integrated pressure gradient is downgradient to the west.

Although the depth integrated pressure gradient expression (29.18) is straightforward to understand, we also find it useful to consider the complementary perspective by studying the contact force version of the pressure acceleration. Proceeding as in Section 29.2 for topographic and at-

mospheric form stresses, we make use of Leibniz's Rule for a fluid layer

$$-\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \frac{\partial p}{\partial x}\,\mathrm{d}z = \underbrace{-\frac{\partial}{\partial x}\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} p\,\mathrm{d}z}_{\text{zonal deriv layer integrated pressure}} + \underbrace{\frac{\partial \eta_{\mathrm{k}-1/2}}{\partial x}\,p_{\mathrm{k}-1/2}}_{\text{IFS at k-1/2 interface}} - \underbrace{\frac{\partial \eta_{\mathrm{k}+1/2}}{\partial x}\,p_{\mathrm{k}+1/2}}_{\text{IFS at k+1/2 interface}}, \tag{29.19}$$

where we introduced the pressures acting at a point on the interfaces

$$p_{\mathrm{k}-1/2} = p(x, y, z = \eta_{\mathrm{k}-1/2}, t) \qquad \text{and} \qquad p_{\mathrm{k}+1/2} = p(x, y, z = \eta_{\mathrm{k}+1/2}, t). \tag{29.20}$$

The decomposition identifies the following three pressure contributions, analogous to the decomposition in Section 29.2 for the topographic and atmospheric form stresses.

- ZONAL DERIVATIVE OF THE COLUMN INTEGRATED PRESSURE: The first term arises from the zonal derivative of pressure across the vertical sides of the column within the layer

$$\text{zonal derivative of layer integrated pressure} = -\frac{\partial}{\partial x}\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} p\,\mathrm{d}z. \tag{29.21}$$

- INTERFACIAL FORM STRESS AT UPPER INTERFACE: The pressure at the $z = \eta_{\mathrm{k}-1/2}$ interface is given by $p_{\mathrm{k}-1/2}$. In the presence of a sloping interface, $\partial\eta_{\mathrm{k}-1/2}/\partial x \neq 0$, this pressure imparts the following interfacial form stress (IFS) to layer-k:

$$\text{IFS on layer-k from the } \eta_{\mathrm{k}-1/2} \text{ interface} = \frac{\partial \eta_{\mathrm{k}-1/2}}{\partial x}\,p_{\mathrm{k}-1/2}. \tag{29.22}$$

  For example, if the upper layer interface slopes up to the east, $\partial\eta_{\mathrm{k}-1/2}/\partial x > 0$, then the interfacial form stress provides a positive (eastward) zonal force to layer-k. In turn, through Newton's third law, the layer above, labelled $\mathrm{k}-1$, feels an interfacial form stress directed to the west.

- INTERFACIAL FORM STRESS AT LOWER INTERFACE: The pressure, $p_{\mathrm{k}+1/2}$, present at the $z = \eta_{\mathrm{k}+1/2}$ interface imparts an interfacial form stress to layer-k given by

$$\text{IFS on layer-}k \text{ from } \eta_{\mathrm{k}+1/2} \text{ interface} = -\frac{\partial \eta_{\mathrm{k}+1/2}}{\partial x}\,p_{\mathrm{k}+1/2}. \tag{29.23}$$

  For example, if the layer slopes down to the east, $\partial\eta_{\mathrm{k}+1/2}/\partial x < 0$, then the interfacial form stress accelerates layer-k to the east. In turn, through Newton's third law, the interfacial form stress acts to accelerate the layer below, labelled $\mathrm{k}+1$, to the west.

Now apply the above to a column of ocean fluid, and extend the integration to include the full ocean column from the free upper surface to the rigid solid earth bottom. Evidently, all the intermediate interfacial form stresses vanish in the depth integral, with this cancellation a result of Newton's third law. Hence, accumulation of the interfacial form stresses throughout the ocean column leaves only the interfacial form stress at the top ($z = \eta$) and at the bottom ($z = \eta_{\mathrm{b}}$). The corresponding boundary form stresses arise from mechanical interactions with the atmosphere ($z = \eta$) and solid earth ($z = \eta_{\mathrm{b}}$), as discussed in Section 29.2. This result was already encountered in a more general context of contact forces in Section 26.2. It will also be found in our analysis of the depth integrated axial angular momentum budget in Section 29.5.

29.3.2 Zonally integrated interfacial form stress

Besides studying the force acting on a column at a particular horizontal position, it is interesting to study the net zonal force acting on the layer. For pressure, we thus need to consider the zonal integral of the layer integrated zonal pressure gradient

$$-\int \left[\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \frac{\partial p}{\partial x} \, \mathrm{d}z \right] \mathrm{d}x = \int \left[-\frac{\partial}{\partial x} \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} p \, \mathrm{d}z + \frac{\partial \eta_{\mathrm{k}-1/2}}{\partial x} \, p_{\mathrm{k}-1/2} - \frac{\partial \eta_{\mathrm{k}+1/2}}{\partial x} \, p_{\mathrm{k}+1/2} \right] \mathrm{d}x. \tag{29.24}$$

If the domain is zonally periodic or is bounded by sloping shorelines (see Figure 29.6 discussed in Section 29.4.6), then the first term vanishes so that the zonally integrated pressure acting on the layer arises just from the interfacial form stresses

$$-\int \left[\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \frac{\partial p}{\partial x} \, \mathrm{d}z \right] \mathrm{d}x = \int \left[\frac{\partial \eta_{\mathrm{k}-1/2}}{\partial x} \, p_{\mathrm{k}-1/2} - \frac{\partial \eta_{\mathrm{k}+1/2}}{\partial x} \, p_{\mathrm{k}+1/2} \right] \mathrm{d}x. \tag{29.25}$$

This zonal integral is only affected by zonal anomalies for the layer vertical positions and pressures

$$-\int \left[\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \frac{\partial p}{\partial x} \, \mathrm{d}z \right] \mathrm{d}x = \int \left[\frac{\partial \eta'_{\mathrm{k}-1/2}}{\partial x} \, p'_{\mathrm{k}-1/2} - \frac{\partial \eta'_{\mathrm{k}+1/2}}{\partial x} \, p'_{\mathrm{k}+1/2} \right] \mathrm{d}x \tag{29.26a}$$

$$= \int \left[-\eta'_{\mathrm{k}-1/2} \frac{\partial p'_{\mathrm{k}-1/2}}{\partial x} + \eta'_{\mathrm{k}+1/2} \frac{\partial p'_{\mathrm{k}+1/2}}{\partial x} \right] \mathrm{d}x, \tag{29.26b}$$

where primes denote deviations from the zonal mean. In Section 29.5.9 we offer details to prove that it is only the zonal anomalies that contribute to the zontal integral in a zonally periodic channel, or for domains with sloping shorelines. Furthermore, note that for the second equality we introduced the alternative expressions for the form stresses afforded by zonal periodicity or zonal sloped shorelines. We offer cautionary remarks on this replacement in Section 29.5.8 regarding this second equality.

29.3.3 Comments

Interfacial form stress acts on any arbitrary surface drawn in a fluid. Interfaces defined by buoyancy surfaces make the connection between the general concepts presented here to geostrophic mechanics, and they do so given the connection between buoyancy slopes and thermal wind (Section 32.4.4). Most studies of interfacial form stress are thus concerned with isopycnal interfacial form stress, with a discussion given in Section 32.6.

29.4 Depth integrated momentum for the primitive equations

In this section we develop the evolution equation for the depth integrated horizontal momentum per volume in a column of ocean fluid

$$\boldsymbol{U}^{\rho} = \int_{\eta_{\mathrm{b}}}^{\eta} \rho \, \boldsymbol{u} \, \mathrm{d}z, \tag{29.27}$$

extending from the ocean bottom at $z = \eta_{\mathrm{b}}(x, y)$ to the ocean surface at $z = \eta(x, y, t)$. As we will see, the evolution equation clearly exposes how form stresses acting at the ocean surface

and ocean bottom contribute to the column force balance. A study of the depth integrated momentum equation is commonly considered when the ocean fluid maintains an approximate hydrostatic balance (see Sections 28.2 and 30.2), and the shallow fluid approximation (Section 28.1.2). These two approximations constitute the hydrostatitc primitive equations (Section 28.1), which we assume holds in this section.

An important technical feature of the primitive equations is that the horizontal gradient operator, ∇_z, is depth independent, which is a property we use to develop the budget equations in this section. In particular, we need this assumption for equation (29.30c) below. We also made use of this property of ∇_z in Section 28.1.6 to derive the depth integrated kinetic energy budget for the primitive equations.

29.4.1 Flux-form horizontal momentum equation

Our starting point is the flux-form horizontal momentum equation (26.63) as specialized to a simple geopotential, $\Phi = g\,z$,

$$\frac{\partial(\rho\,\boldsymbol{u})}{\partial t} + \nabla\cdot[\rho\,\boldsymbol{v}\otimes\boldsymbol{u}] + f\,\hat{\boldsymbol{z}}\times(\rho\,\boldsymbol{u}) = -\nabla_z p + \rho\,\boldsymbol{F}. \tag{29.28}$$

In this equation, $\rho\,\boldsymbol{F}$ is the horizontal friction vector, and the outer product provides components to the kinetic stress (Section 26.6)

$$\rho\,[\boldsymbol{v}\otimes\boldsymbol{u}]_{mi} = \rho\,v_m\,u_i = -\mathbb{T}^{\text{kinetic}}_{mi}, \tag{29.29}$$

with $m = 1, 2, 3$ (for the full velocity vector, $\boldsymbol{v}$) extending over the full range whereas $i = 1, 2$ (for the horizontal velocity vector, $\boldsymbol{u}$) extending just over the horizontal range.

29.4.2 Leibniz's rule for the inertial and Coriolis accelerations

Leibniz's rule (Section 21.2.4) renders the following expressions for the depth integrated inertial acceleration and Coriolis acceleration

$$\int_{\eta_\text{b}}^{\eta} \frac{\partial(\rho\,\boldsymbol{u})}{\partial t}\,\mathrm{d}z = \partial_t \boldsymbol{U}^\rho - [\rho\,\boldsymbol{u}\,\partial_t\eta]_{z=\eta} \tag{29.30a}$$

$$\int_{\eta_\text{b}}^{\eta} \frac{\partial(w\,\rho\,\boldsymbol{u})}{\partial z}\,\mathrm{d}z = [w\,\rho\,\boldsymbol{u}]_{z=\eta} - [w\,\rho\,\boldsymbol{u}]_{z=\eta_\text{b}} \tag{29.30b}$$

$$\int_{\eta_\text{b}}^{\eta} \nabla_z\cdot[\rho\,\boldsymbol{u}\otimes\boldsymbol{u}]\,\mathrm{d}z = \nabla_z\cdot\left[\int_{\eta_\text{b}}^{\eta}\rho\,\boldsymbol{u}\otimes\boldsymbol{u}\,\mathrm{d}z\right] - [\boldsymbol{u}\cdot\nabla\eta\,(\rho\,\boldsymbol{u})]_{z=\eta} + [\boldsymbol{u}\cdot\nabla\eta_\text{b}\,(\rho\,\boldsymbol{u})]_{z=\eta_\text{b}} \tag{29.30c}$$

$$\int_{\eta_\text{b}}^{\eta} f\,\hat{\boldsymbol{z}}\times(\rho\,\boldsymbol{u})\,\mathrm{d}z = f\,\hat{\boldsymbol{z}}\times\boldsymbol{U}^\rho. \tag{29.30d}$$

Use of the surface and bottom kinematic boundary conditions from Section 20.4

$$\partial_t\eta + \boldsymbol{u}\cdot\nabla\eta = w + \rho^{-1}\,Q_\text{m} \quad \text{for } z = \eta \tag{29.31a}$$

$$\boldsymbol{u}\cdot\nabla\eta_\text{b} = w \quad \text{for } z = \eta_\text{b} \tag{29.31b}$$

leads to the depth integrated inertial and Coriolis accelerations

$$\int_{\eta_\mathrm{b}}^{\eta} [\partial_t(\rho\,\boldsymbol{u}) + \nabla\cdot[\boldsymbol{v}\otimes(\rho\,\boldsymbol{u})] + f\,\hat{\boldsymbol{z}}\times\rho\,\boldsymbol{u}]\,\mathrm{d}z$$
$$= (\partial_t + f\,\hat{\boldsymbol{z}}\times)\,\boldsymbol{U}^\rho - \boldsymbol{u}(\eta)\,Q_\mathrm{m} - \nabla_z\cdot\int_{\eta_\mathrm{b}}^{\eta}\mathbb{T}_\mathrm{hor}^\mathrm{kinetic}\,\mathrm{d}z, \quad (29.32)$$

where we introduced the horizontal kinetic stress tensor

$$\mathbb{T}_\mathrm{hor}^\mathrm{kinetic} = -\rho\,\boldsymbol{u}\otimes\boldsymbol{u}. \quad (29.33)$$

29.4.3 External and internal decomposition of the kinetic stress

For some applications it can be useful to introduce the density weighted depth averaged horizontal velocity

$$\overline{\boldsymbol{u}} = \frac{\int_{\eta_\mathrm{b}}^{\eta}\rho\,\boldsymbol{u}\,\mathrm{d}z}{\int_{\eta_\mathrm{b}}^{\eta}\rho\,\mathrm{d}z} = \frac{\boldsymbol{U}^\rho}{(p_\mathrm{b}-p_\mathrm{a})/g}, \quad (29.34)$$

where p_b is the hydrostatic pressure at the ocean bottom, and p_a is the pressure applied to the ocean surface. The depth averaged velocity is referred to as the *external velocity*, whereas the deviation from the depth average

$$\boldsymbol{u}' = \boldsymbol{u} - \overline{\boldsymbol{u}}, \quad (29.35)$$

is referred to it as the *internal velocity*.[3] It follows by definition that the internal velocity has a zero density weighted vertical integral

$$\int_{\eta_\mathrm{b}}^{\eta}\rho\,\boldsymbol{u}'\,\mathrm{d}z = \int_{\eta_\mathrm{b}}^{\eta}\rho\,(\boldsymbol{u}-\overline{\boldsymbol{u}})\,\mathrm{d}z = 0. \quad (29.36)$$

Consequently, by making use of $\boldsymbol{u} = \overline{\boldsymbol{u}} + \boldsymbol{u}'$ we find the depth integrated kinetic stress

$$\int_{\eta_\mathrm{b}}^{\eta}\mathbb{T}_\mathrm{hor}^\mathrm{kinetic}\,\mathrm{d}z = -g^{-1}\,(p_\mathrm{b}-p_\mathrm{a})\,[\overline{\boldsymbol{u}}\otimes\overline{\boldsymbol{u}} + \overline{\boldsymbol{u}'\otimes\boldsymbol{u}'}]. \quad (29.37)$$

Note that absence of cross-terms (i.e., no internal-external correlation terms) appearing in the depth integrated stress (29.37). In this manner we have separated the contributions from kinetic stresses due to depth averaged horizontal velocities from those arising from depth-dependent horizontal velocities.

29.4.4 Decomposing the depth integrated horizontal pressure gradient

Consider the depth integrated pressure

$$P = \int_{\eta_\mathrm{b}}^{\eta} p\,\mathrm{d}z, \quad (29.38)$$

and the corresponding depth integrated horizontal pressure gradient

$$\int_{\eta_\mathrm{b}}^{\eta}\nabla_z p\,\mathrm{d}z. \quad (29.39)$$

[3] It is also common in the oceanography literature to refer to $\boldsymbol{u}'$ as the *baroclinic velocity* and $\overline{\boldsymbol{u}}$ as the *barotropic velocity*. We avoid that nomenclature since we prefer to use baroclinic and barotropic in reference to vorticity mechanics in Section 41.4.

Assuming each fluid column maintains an approximate hydrostatic balance allows us to decompose these integrals into elemental constituents.

Depth integrated pressure

For the pressure, write its depth integral as

$$P = \int_{\eta_\mathrm{b}}^{\eta} p \, \mathrm{d}z = \int_{\eta_\mathrm{b}}^{\eta} [\mathrm{d}(p\, z) - z \, \mathrm{d}p] = p_\mathrm{a} \, \eta - p_\mathrm{b} \, \eta_\mathrm{b} + \mathscr{P}, \tag{29.40}$$

where we used the hydrostatic balance for a vertical fluid column to write[4] $\mathrm{d}p = -g \, \rho \, \mathrm{d}z$, and we introduced the potential energy per horizontal area of a fluid column

$$\mathscr{P} = \int_{\eta_\mathrm{b}}^{\eta} g \, \rho \, z \, \mathrm{d}z. \tag{29.41}$$

Evidently, equation (29.40) decomposes the depth integrated pressure into a contribution from the applied surface pressure acting at the free surface, the bottom pressure acting at the ocean bottom (recall that $\eta_\mathrm{b} < 0$), and the potential energy per horizontal area of a fluid column.

Depth integrated horizontal pressure gradient

For the depth integrated horizontal pressure gradient, we start by using Leibniz's rule to render

$$\nabla_z P = \nabla_z \int_{\eta_\mathrm{b}}^{\eta} p \, \mathrm{d}z = p_\mathrm{a} \, \nabla \eta - p_\mathrm{b} \, \nabla \eta_\mathrm{b} + \int_{\eta_\mathrm{b}}^{\eta} \nabla_z p \, \mathrm{d}z. \tag{29.42}$$

Making use of the decomposition (29.40) leads to

$$-\int_{\eta_\mathrm{b}}^{\eta} \nabla_z p \, \mathrm{d}z = -\nabla_z P + p_\mathrm{a} \nabla_z \eta - p_\mathrm{b} \nabla_z \eta_\mathrm{b} \tag{29.43a}$$

$$= -\nabla_z \left[p_\mathrm{a} \, \eta - p_\mathrm{b} \, \eta_\mathrm{b} + \mathscr{P} \right] + p_\mathrm{a} \nabla_z \eta - p_\mathrm{b} \nabla_z \eta_\mathrm{b} \tag{29.43b}$$

$$= -\nabla_z \mathscr{P} - \eta \nabla_z p_\mathrm{a} + \eta_\mathrm{b} \nabla_z p_\mathrm{b}. \tag{29.43c}$$

These are such important results that we write them again in a single equation

$$-\int_{\eta_\mathrm{b}}^{\eta} \nabla_z p \, \mathrm{d}z = -\nabla_z P + p_\mathrm{a} \nabla_z \eta - p_\mathrm{b} \nabla_z \eta_\mathrm{b} = -\nabla_z \mathscr{P} - \eta \nabla_z p_\mathrm{a} + \eta_\mathrm{b} \nabla_z p_\mathrm{b}. \tag{29.44}$$

Equation (29.43a) exposes contributions from surface and bottom form stresses,

$$\text{surface and bottom form stresses} = p_\mathrm{a} \nabla_z \eta - p_\mathrm{b} \nabla_z \eta_\mathrm{b}, \tag{29.45}$$

along with the horizontal gradient of the depth integrated pressure. As a complement, equation (29.43c) exposes the *dual form stress*,

$$\text{surface and bottom dual form stresses} = -\eta \nabla_z p_\mathrm{a} + \eta_\mathrm{b} \nabla_z p_\mathrm{b}, \tag{29.46}$$

[4] More generally, the differential of pressure is given by $\mathrm{d}p = \nabla p \cdot \mathrm{d}\boldsymbol{x}$ when probing three-dimensional spatial increments, $\mathrm{d}\boldsymbol{x}$. However, the integral in equation (29.40) is vertical, in which case $\mathrm{d}p = (\partial p / \partial z) \, \mathrm{d}z$. For the approximate hydrostatic fluid we thus have the transformation $\mathrm{d}p = -g \, \rho \, \mathrm{d}z$.

plus the gradient of the potential energy. The role of these accelerations is further studied for the axial angular momentum budget in Section 29.5, and then within the column vorticity balance in Section 41.9.

Constraints when the fluid is exactly hydrostatic and thus motionless

As discussed in Section 25.6, the horizontal pressure gradient everywhere vanishes for a fluid in exact hydrostatic balance, $\nabla_z p = 0$. Correspondingly, the free surface and surface applied pressure are spatially constant in order to maintain zero pressure gradients throughout the fluid. For the depth integral pressure gradient, the decompositions (29.43a) and (29.43c) lead to the exact hydrostatic fluid identities maintained at each vertical fluid column

$$\nabla_z P = -p_{\mathrm{b}} \, \nabla_z \eta_{\mathrm{b}} \tag{29.47a}$$

$$\nabla_z \mathscr{P} = \eta_{\mathrm{b}} \, \nabla_z p_{\mathrm{b}}. \tag{29.47b}$$

The first identity says that the horizontal gradient of the depth integrated hydrostatic pressure exactly balances the topographic form stress. The second identity says that the horizontal gradient of the potential energy per area balances the dual topographic form stress.

Since the curl of the left hand side vanishes for both of equation (29.47a) and (29.47a), we find that the bottom pressure must be aligned with the bottom topography in order to maintain zero flow

$$\hat{\boldsymbol{z}} \cdot (\nabla \eta_{\mathrm{b}} \times \nabla p_{\mathrm{b}}) = 0. \tag{29.48}$$

In the language of vorticity, we say that there is no bottom pressure torque when the flow is exactly hydrostatic (see Section 41.8.3). Conversely, nonzero flow is signaled by a misalignment of bottom pressure and bottom topography contours. We can also arrive at the identity (29.48) by taking the horizontal derivative of the bottom pressure. Since the fluid is static we have a spatially constant free surface and applied pressure, and a density that is horizontally uniform. Consequently,

$$\nabla_z p_{\mathrm{b}} = g \, \nabla_z \int_{\eta_{\mathrm{b}}}^{0} \rho \, \mathrm{d}z = -g \, \rho(z = \eta_{\mathrm{b}}) \, \nabla_z \eta_{\mathrm{b}}, \tag{29.49}$$

thus revealing that bottom pressure contours are indeed parallel to bottom topography contours when the fluid is in exact hydrostatic balance.

29.4.5 Depth integrated momentum equation

Bringing the pieces together leads to the depth integrated horizontal momentum equation for an approximate hydrostatic fluid

$$(\partial_t + f \, \hat{\boldsymbol{z}} \times) \, \boldsymbol{U}^{\rho} = \boldsymbol{u}(\eta) \, Q_{\mathrm{m}} - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} - \nabla_z \mathscr{P} + \nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}_{\mathrm{hor}}^{\mathrm{kinetic}} \, \mathrm{d}z \right] + \int_{\eta_{\mathrm{b}}}^{\eta} \rho \, \boldsymbol{F} \, \mathrm{d}z. \tag{29.50}$$

For many applications we focus on the vertical divergence of horizontal frictional stress plus a term arising from horizontal strains, in which case

$$\int_{\eta_{\mathrm{b}}}^{\eta} \rho \, \boldsymbol{F} \, \mathrm{d}z = \int_{\eta_{\mathrm{b}}}^{\eta} (\rho \, \boldsymbol{F}_{\mathrm{horz}} + \partial_z \boldsymbol{\tau}) \, \mathrm{d}z = \boldsymbol{D} + \boldsymbol{\tau}^{\eta} - \boldsymbol{\tau}^{\eta_{\mathrm{b}}} \equiv \boldsymbol{D} + \Delta \boldsymbol{\tau}, \tag{29.51}$$

where $\boldsymbol{\tau}^{\eta}$ is the horizontal stress at the surface (e.g., wind stress on the ocean surface), $\boldsymbol{\tau}^{\eta_{\rm b}}$ is the horizontal stress at the bottom (e.g., turbulent drag at the fluid-solid earth boundary), and

$$\boldsymbol{D} = \int_{\eta_{\rm b}}^{\eta} \rho\, \boldsymbol{F}_{\rm horz}\, {\rm d}z \tag{29.52}$$

is the depth integrated friction arising from horizontal stresses within the fluid interior (e.g., viscous stresses as in Section 26.8). In this case the horizontal momentum equation (29.50) takes on the form

$$(\partial_t + f\, \hat{\boldsymbol{z}}\times)\, \boldsymbol{U}^{\rho} = \boldsymbol{u}(\eta)\, Q_{\rm m} - \eta \nabla_z p_{\rm a} + \eta_{\rm b} \nabla_z p_{\rm b} - \nabla_z \mathscr{P} + \boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}. \tag{29.53}$$

where we introduced the shorthand for the nonlinear kinetic stress term

$$\boldsymbol{A} \equiv \nabla_z \cdot \left[\int_{\eta_{\rm b}}^{\eta} \mathbb{T}_{\rm hor}^{\rm kinetic}\, {\rm d}z \right] = -\nabla_z \cdot \left[\int_{\eta_{\rm b}}^{\eta} \rho\, \boldsymbol{u} \otimes \boldsymbol{u}\, {\rm d}z \right]. \tag{29.54}$$

29.4.6 Zonally integrated zonal momentum balance

Zonal integration and zonal averaging offer a common means to summarize elements of the flow, particularly in the atmosphere where zonal motions are much stronger than meridional due to the earth's rotation and the differential solar heating of the planet. Additionally, zonal averaging is of particular interest in the Southern Ocean, where the Drake Passage latitudes offer a zonally unbounded domain for ocean circulation. Even for zonally bounded ocean domains where gyre circulations occur, it is of interest to zonally integrate across the domain to study balances leading to meridional motion across the chosen latitude. We are thus motivated to integrate zonally across the full extent of the domain, with the resulting boundary contributions dependent on the geometry and topology of the domain.

Three canonical domains

We illustrate three canonical domains in Figure 29.6. For the zonally periodic domain, the zonal integral of any zonal derivative vanishes so that, for example,

$$\oint \partial_x P\, {\rm d}x = 0, \tag{29.55}$$

where we write $\oint {\rm d}x$ for integration over a zonally periodic domain. Additionally, zonal derivatives vanish for a zonally bounded domain with sloping shorelines

$$\int \partial_x P\, {\rm d}x = \Delta P = 0. \tag{29.56}$$

The reason this integral vanishes is that any depth integrated quantity, such as P, vanishes at the shoreline edge merely since the layer thickness vanishes at the shoreline edge. The same result holds for any other depth integrated quantity, including depth integrated axial angular momentum, mass transport, and potential energy.

It is only for the zonally bounded domain with vertical sidewalls (third panel in Figure 29.6) that we are unable to drop the zonal integral of the zonal pressure gradient. We observe that vertical sidewalls are common for numerical models and many theories of the ocean circulation. However, vertical sidewalls are the exception in Nature. For this reason, in the following we focus on the more geophysically relevant periodic configuration and the sloping shoreline configuration.

FIGURE 29.6: Three canonical zonal topologies/geometries considered in the study of fluid flow, particularly ocean flows. The light portion of each panel represents the fluid whereas the darker portion is the solid earth bottom topography. Left panel: zonally unbounded and periodic channel. Here, the topography, surface boundary forcing, and flow are zonally periodic. Middle panel: zonally bounded region where the zonal bounds occur along sloping shorelines at which the fluid thickness vanishes. The horizontal position of the vanishing thickness is time dependent since the fluid can move up and down the shoreline. Right panel: zonally bounded region where the fluid encounters a vertical sidewall so that the horizontal position of the fluid boundary is fixed, and so that there is no horizontal position where the fluid thickness vanishes. Fixed vertical sidewall boundaries are commonly found in numerical model simulations and yet they are uncommon in Nature.

Zonally integrated meridional mass transport

A zonal integral, either over a periodic domain or a domain with vanishing layer thickness along the shoreline, renders an expression for the meridional transport across the zonal-depth section

$$f \int V^\rho \, \mathrm{d}x = \int [p_\mathrm{a} \, \partial_x \eta - p_\mathrm{b} \, \partial_x \eta_\mathrm{b} - \partial_t U^\rho - u(\eta) \, Q_\mathrm{m} + (\boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}) \cdot \hat{\boldsymbol{x}}] \, \mathrm{d}x, \tag{29.57}$$

where we set $\int \partial_x P \, \mathrm{d}x = \int \partial_x \mathscr{P} \, \mathrm{d}x = 0$. Note that the Coriolis parameter was pulled outside the zonal integral since it is constant along a constant latitude line. As discussed in Section 29.5, this equation, or its analog for the axial angular momentum, provides a valuable framework for studies of momentum balances in both the Southern Ocean and in ocean gyres. For the special case of a steady state in the absence of surface mass fluxes, so that $\partial_t U^\rho = 0$ and $Q_\mathrm{m} = 0$, and for a domain closed in the north and south, so that mass conservation renders $\int V^\rho \, \mathrm{d}x = 0$, then the balance (29.57) simplifies to

$$\int [p_\mathrm{a} \, \partial_x \eta - p_\mathrm{b} \, \partial_x \eta_\mathrm{b} + (\boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}) \cdot \hat{\boldsymbol{x}}] \, \mathrm{d}x = 0. \tag{29.58}$$

For those cases where nonlinear terms and interior friction are small, we find a balance between pressure form stresses at the boundaries plus boundary turbulent stresses. We defer to Section 29.5 any further remarks on this case.

29.4.7 Balances when $\nabla \cdot \boldsymbol{U}^\rho = 0$

There are many occasions in which the depth integrated flow is close to non-divergent, $\nabla \cdot \boldsymbol{U}^\rho = 0$. Such occurs particularly at the large scale and for cases where we neglect the mass transport accross the ocean surface, $Q_\mathrm{m} = 0$. Following the kinematics from Section 22.4, we introduce a *transport streamfunction* so that

$$\boldsymbol{U}^\rho = \hat{\boldsymbol{z}} \times \nabla \Psi, \tag{29.59}$$

with Ψ having dimensions of mass per time. Use of the transport streamfunction brings the Coriolis contribution to the form

$$f \, \hat{\boldsymbol{z}} \times \boldsymbol{U}^\rho = f \, \hat{\boldsymbol{z}} \times (\hat{\boldsymbol{z}} \times \nabla \Psi) = -f \, \nabla \Psi, \tag{29.60}$$

so that the momentum equation (29.53) becomes

$$\partial_t \boldsymbol{U}^\rho = f\,\nabla_z \Psi - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} - \nabla_z \mathscr{P} + \boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau} \tag{29.61a}$$

$$= f\,\nabla_z \Psi + p_{\mathrm{a}} \nabla_z \eta - p_{\mathrm{b}} \nabla_z \eta_{\mathrm{b}} - \nabla_z P + \boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}. \tag{29.61b}$$

Now consider a steady balance in which

$$-f\,\nabla_z \Psi = p_{\mathrm{a}} \nabla_z \eta - p_{\mathrm{b}} \nabla_z \eta_{\mathrm{b}} - \nabla_z P + \boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}. \tag{29.62}$$

Note that by projecting into the horizontal direction tangent to the bottom topography, denoted by the unit vector $\hat{\boldsymbol{t}}$, we eliminate the $p_{\mathrm{b}} \nabla_z \eta_{\mathrm{b}}$ term to have the steady along-topography balance

$$-f\,\hat{\boldsymbol{t}} \cdot \nabla_z \Psi = \hat{\boldsymbol{t}} \cdot (p_{\mathrm{a}} \nabla_z \eta - \nabla_z P + \boldsymbol{A} + \boldsymbol{D} + \Delta \boldsymbol{\tau}). \tag{29.63}$$

29.5 Axial angular momentum budget for an ocean domain

We here develop the column integrated budget for axial angular momentum in an ocean region, such as shown in Figure 29.7. We then further specialize the budget by zonally integrating. The analysis shares features with the depth integrated linear momentum balance developed in Section 29.4. As in that discussion, we here assume the primitive equations (Section 28.1) so that the horizontal gradient operator is independent of depth (as for Sections 28.1.6 and 29.4, we need this assumption for equation (29.68b) below).

There is a close relation between the zonal momentum and axial angular momentum, with details provided in our study of geophysical particle dynamics in Sections 14.6 and 14.7. We choose to here study axial angular momentum since it has a slightly simpler budget (equation (29.64) discussed below) than the corresponding budget equation (29.53) for zonal linear momentum. The simpler budget follows since axial angular momentum is directly connected to the axial symmetry of the rotating spherical planet (Sections 14.6 and 25.7).

To add a bit more generality to the analysis, we make use of spherical coordinates, though doing so offers only a modest degree of extra details beyond Cartesian coordinates. Although here focused on the ocean, many of the concepts and methods are directly relevant to a study of atmospheric axial angular momentum as introduced in Section 25.7 and discussed in Section 10.3 of *Holton* (1992).

29.5.1 Anticipating the budget

Before diving into the mathematical formulation, let us use some of the understanding gleaned from earlier sections of this chapter to anticipate the basic results. Doing so offers a framework to guide the maths, and to double check that the maths indeed renders a physically sensible budget.

For this purpose, consider a column of fluid such as shown in Figure 29.7. The forces acting on that column arise from contact forces (pressure stress, kinetic stress, and frictional stress) acting on the boundary (sides, top, and bottom), and body forces acting throughout the column (from effective gravity and Coriolis). There are further avenues for momentum to be transported across the ocean surface as part of the mass transported by rain, evaporation, and rivers. Each of these forces contribute a torque to the fluid column computed relative to the earth's rotational axis, thus modifying the axial angular momentum of the fluid column. In the following development, we mathematically express the variety of forces and corresponding torques, thus building up the axial angular mometum budget.

FIGURE 29.7: Schematic of the axial angular momentum for a fluid column, here depicted moving in an ocean with a topographic bump. In Section 29.5 we develop the budget for the depth and zonal integrated axial angular momentum in the ocean, where we see that the axial angular momentum is affected by a variety of boundary processes as well as interior transports and pressures.

29.5.2 Axial angular momentum

The axial angular momentum budget for a fluid element follows that developed in Section 25.7, here written with the addition of zonal friction

$$\rho \frac{\mathrm{D} l^z}{\mathrm{D} t} = -\frac{\partial p}{\partial \lambda} + r_\perp \, \rho \, F^\lambda, \tag{29.64}$$

where

$$l^z = r_\perp \, (u + r_\perp \, \Omega) \tag{29.65}$$

is the axial angular momentum per unit mass, and

$$r_\perp = r \cos \phi \tag{29.66}$$

is the distance to the polar rotation axis (the moment arm). For the primitive equations we set the radial position, r, to the earth radius, R_e, in the following.[5] Use of the Eulerian form of mass conservation (equation (20.6)) leads to the Eulerian flux-form budget

$$\frac{\partial (\rho \, l^z)}{\partial t} + \nabla \cdot (\rho \, \boldsymbol{v} \, l^z) = -\frac{\partial p}{\partial \lambda} + r_\perp \, \rho \, F^\lambda, \tag{29.67}$$

with $l^z \rho \, \mathrm{d}z$ the angular momentum per unit horizontal area. We use this form for the budget to develop the depth integrated axial angular momentum budget.

29.5.3 Depth integrated budget

Vertically integrating equation (29.67) over a column of ocean fluid renders a budget for the column-integrated axial angular momentum. As in Section 29.4.2, we here make use of Leibniz's

[5] See also Exercise 28.1.

Rule to reach the following identities that expose boundary contributions

$$\int_{\eta_b}^{\eta} \frac{\partial(\rho\, l^z)}{\partial t}\, \mathrm{d}z = \frac{\partial}{\partial t}\left[\int_{\eta_b}^{\eta} \rho\, l^z\, \mathrm{d}z\right] - \left[\rho\, l^z\, \frac{\partial \eta}{\partial t}\right]_{z=\eta} \tag{29.68a}$$

$$\int_{\eta_b}^{\eta} \nabla_z \cdot (\rho\, \boldsymbol{u}\, l^z) \mathrm{d}z = \nabla_z \cdot \left[\int_{\eta_b}^{\eta} \rho\, \boldsymbol{u}\, l^z\, \mathrm{d}z\right] - [\rho\, l^z\, \boldsymbol{u} \cdot \nabla \eta]_{z=\eta} + [\rho\, l^z\, \boldsymbol{u} \cdot \nabla \eta_b]_{z=\eta_b} \tag{29.68b}$$

$$\int_{\eta_b}^{\eta} \frac{\partial(\rho\, w\, l^z)}{\partial z}\, \mathrm{d}z = [w\, \rho\, l^z]_{z=\eta} - [w\, \rho\, l^z]_{z=\eta_b}\,. \tag{29.68c}$$

Equation (29.68c) made use of the primitive equations whereby the horizontal divergence operator is depth independent. The surface kinematic boundary condition (20.79) and bottom kinematic boundary condition (20.41) allow us to reach a reasonably tidy expression

$$\frac{\partial}{\partial t}\left[\int_{\eta_b}^{\eta} l^z \rho\, \mathrm{d}z\right] = [l^z Q_m]_{z=\eta} - \nabla_z \cdot \left[\int_{\eta_b}^{\eta} l^z \boldsymbol{u}\, \rho\, \mathrm{d}z\right] + \int_{\eta_b}^{\eta} \left[-\frac{\partial p}{\partial \lambda} + r_\perp\, \rho\, F^\lambda\right] \mathrm{d}z. \tag{29.69}$$

The budget (29.69) says that the depth integrated axial angular momentum per horizontal area in a horizontally fixed fluid column has a time tendency (left hand side) arising from the convergence of horizontal advection of axial angular momentum plus torques due to surface boundary mass fluxes, depth integrated zonal pressure gradients, and depth integrated irreversible stresses. This mathematical expression of the budget meets our expectations based on our understanding of the physical principles discussed in Section 29.5.1.

29.5.4 Atmospheric and topographic form stresses

We can further unpack the contribution from pressure in the budget (29.69) by making use of Leibniz's rule to write

$$-\int_{\eta_b}^{\eta} \frac{\partial p}{\partial \lambda}\, \mathrm{d}z = -\frac{\partial P}{\partial \lambda} + p_a\, \frac{\partial \eta}{\partial \lambda} - p_b\, \frac{\partial \eta_b}{\partial \lambda}, \tag{29.70a}$$

where P is the depth-integrated pressure given by equation (29.38). We studied this decomposition of the pressure force in Section 29.2 and encountered it in Section 29.4.4. Again, we see that the depth integrated zonal pressure gradient has been decomposed into three terms: (i) zonal pressure differences integrated across the depth of the column, (ii) form stress imparted to the ocean from the atmospheric pressure, (iii) form stress imparted by the solid earth bottom topography onto the ocean.

29.5.5 Turbulent stresses at the surface and bottom

For turbulent stresses, we focus on the vertical transfer of zonal momentum arising from the vertical shear of horizontal stresses

$$\rho\, F^\lambda = \frac{\partial \tau^\lambda}{\partial z}, \tag{29.71}$$

where τ^λ is the zonal component to the stress vector.[6] When integrated vertically over an ocean column, $\int_{\eta_b}^{\eta} \rho\, F^\lambda\, \mathrm{d}z$, this friction arises from stresses acting in the ocean surface and bottom

[6] As seen in equation (29.52), there are other turbulent terms associated with interior Reynolds stresses arising from horizontal shears. We omit these terms for the present analysis since they are generally smaller than stresses arising from vertical strains, and smaller than the turbulent stresses associated with surface and bottom boundary processes.

boundary/Ekman layers (Chapter 34), where the stress arises from turbulent motions that transfer momentum vertically through these layers.

For the friction contribution, we make use of the primitive equations so that the axial moment-arm is approximated by its value at the ocean surface

$$r_\perp = r\cos\phi = (z+R)\cos\phi \approx R\cos\phi = R_\perp, \tag{29.72}$$

as per the shallow fluid approximation built into the hydrostatic primitive equations discussed in Section 28.1. This assumption allows us to write the frictional contribution to the angular momentum budget (29.69) in the form

$$\int_{\eta_\mathrm{b}}^{\eta} r_\perp\,\rho\,F^\lambda\,\mathrm{d}z \approx R_\perp \int_{\eta_\mathrm{b}}^{\eta} \rho\,F^\lambda\,\mathrm{d}z = R_\perp\,(\tau_\mathrm{a}^\lambda - \tau_\mathrm{b}^\lambda). \tag{29.73}$$

The final expression introduced τ_a^λ, which is the zonal component to the stress acting on the ocean surface imparted through interactions between the ocean and the overlying atmosphere and/or ice. The signs are such that $\tau_\mathrm{a}^\lambda > 0$ transfers an eastward momentum to the ocean such as via a westerly wind stress. Likewise, the stress τ_b^λ is the zonal stress at the ocean bottom imparted through interactions between the ocean and the solid-earth. The signs are such that $\tau_\mathrm{b}^\lambda > 0$ reflects the transfer of eastward momentum from the ocean to the solid-earth, or conversely the transfer of westward momentum from the earth to the ocean. The net contribution from vertical friction is thus given by the moment arm, $R_\perp$, multiplied by the difference in boundary stresses.

29.5.6 Summary budget for column integrated axial angular momentum

Bringing all the pieces together leads to the depth integrated axial angular momentum budget

$$\frac{\partial}{\partial t}\left[\int_{\eta_\mathrm{b}}^{\eta} l^z\rho\,\mathrm{d}z\right] = -\nabla_z\cdot\left[\int_{\eta_\mathrm{b}}^{\eta} l^z\boldsymbol{u}\,\rho\,\mathrm{d}z\right] - \frac{\partial P}{\partial\lambda} + [l^z Q_\mathrm{m}]_{z=\eta} + p_\mathrm{a}\,\frac{\partial\eta}{\partial\lambda} - p_\mathrm{b}\,\frac{\partial\eta_\mathrm{b}}{\partial\lambda} + R_\perp\,(\tau_\mathrm{a}^\lambda - \tau_\mathrm{b}^\lambda). \tag{29.74}$$

Other than assuming a specific form of the frictional stress given by equation (29.71), this result is the exact budget for the axial angular momentum in a column of ocean fluid satisfying the primitive equations.

Removing zonal means

We further isolate the processes contributing to the budget (29.74) by introducing the zonal mean operator

$$\overline{A} \equiv \frac{1}{L(\phi)}\int A\,\mathrm{d}\lambda, \tag{29.75}$$

where

$$L(\phi) = (R_\mathrm{e}\cos\phi)\,\Delta\lambda = R_\perp\,\Delta\lambda \tag{29.76}$$

is the zonal length of the domain as a function of latitude, ϕ, and $\Delta\lambda$ is the zonal extent of the domain in radians. For a domain that circles the planet, then $\Delta\lambda = 2\pi$. Other domains are possible, such as those in Figure 29.6. The corresponding zonal anomalies to the depth integrated pressure, sea surface height, and bottom topography are thus given by

$$P' = P - \overline{P} \qquad \text{and} \qquad \eta' = \eta - \overline{\eta} \qquad \text{and} \qquad \eta_\mathrm{b}' = \eta_\mathrm{b} - \overline{\eta_\mathrm{b}}, \tag{29.77}$$

in which case equation (29.74) takes the form

$$\frac{\partial}{\partial t}\left[\int_{\eta_{\mathrm{b}}}^{\eta} l^z \rho \,\mathrm{d}z\right] = -\nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} l^z \boldsymbol{u}\, \rho \,\mathrm{d}z\right] - \frac{\partial P'}{\partial \lambda} + [l^z Q_{\mathrm{m}}]_{z=\eta} + p_{\mathrm{a}} \frac{\partial \eta'}{\partial \lambda} - p_{\mathrm{b}} \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} + R_\perp \left(\tau^\lambda_{\mathrm{a}} - \tau^\lambda_{\mathrm{b}}\right). \quad (29.78)$$

Steady state balance

Steady state balances are of particular interest when studying the large-scale low frequency circulation. A steady state holds for the angular momentum budget (29.78) so long as the following balance is maintained

$$\nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} l^z \boldsymbol{u}\, \rho \,\mathrm{d}z\right] = -\frac{\partial P'}{\partial \lambda} + [l^z Q_{\mathrm{m}}]_{z=\eta} + p_{\mathrm{a}} \frac{\partial \eta'}{\partial \lambda} - p_{\mathrm{b}} \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} + R_\perp \left(\tau^\lambda_{\mathrm{a}} - \tau^\lambda_{\mathrm{b}}\right). \quad (29.79)$$

Consequently, a steady state is realized if the horizontal divergence of depth integrated axial angular momentum advection (left hand side) is balanced by torques created by the variety of physical processes on the right hand side. We further examine these physical processes by studying the zonally integrated budget.

29.5.7 Steady domain integrated balance

Consider the area integral of the steady state balance (29.79) over the full ocean domain that is either periodic and/or has sloping side boundaries. In this case the divergence of the angular momentum transport integrates to zero, so that we are left with the balance

$$\int_{\phi_s}^{\phi_n} \left(\int_{\lambda_w(\phi)}^{\lambda_e(\phi)} \left[[l^z Q_{\mathrm{m}}]_{z=\eta} + p'_{\mathrm{a}} \frac{\partial \eta'}{\partial \lambda} - p'_{\mathrm{b}} \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} + R_\perp \left(\tau^\lambda_{\mathrm{a}} - \tau^\lambda_{\mathrm{b}}\right) \right] \mathrm{d}\lambda \right) R_{\mathrm{e}}^2 \cos\phi \,\mathrm{d}\phi = 0. \quad (29.80)$$

In computing the area integral, we chose to first integrate over the longitudinal domain, $\lambda_w(\phi) \leq \lambda \leq \lambda_e(\phi)$, which is a function of latitude, and then to integrate over the full latitudinal domain, $\phi_s \leq \phi \leq \phi_n$. In most applications the surface mass term, $[l^z Q_{\mathrm{m}}]_{z=\eta}$, is smaller than the other terms, in which case the balance is between the boundary form stresses and the boundary turbulent stresses.

In the angular momentum balance (29.80), we introduced the zonal anomalies for the applied surface pressure and the bottom pressure

$$p'_{\mathrm{a}}(\lambda,\phi) = p_{\mathrm{a}}(\lambda,\phi) - \overline{p_{\mathrm{a}}}(\phi) \qquad \text{and} \qquad p'_{\mathrm{b}}(\lambda,\phi) = p_{\mathrm{b}}(\lambda,\phi) - \overline{p_{\mathrm{b}}}(\phi). \quad (29.81)$$

We can introduce these anomalous fields since their zonal averages do not contribute to the budgets in either the periodic or sloping shoreline domains. To verify this property, note that

$$\int \overline{p_{\mathrm{a}}} \frac{\partial \eta'}{\partial \lambda} \,\mathrm{d}\lambda = \int \frac{\partial(\overline{p_{\mathrm{a}}}\, \eta')}{\partial \lambda} \,\mathrm{d}\lambda = 0. \quad (29.82)$$

For a periodic domain this term vanishes by inspection. For a zonally bounded domain with a sloping shoreline, it also vanishes since $\eta' = 0$ at the edge of the shoreline. Likewise, the bottom pressure term satisfies

$$\int \overline{p_{\mathrm{b}}} \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} \,\mathrm{d}\lambda = \int \frac{\partial(\overline{p_{\mathrm{b}}}\, \eta'_{\mathrm{b}})}{\partial \lambda} \,\mathrm{d}\lambda = 0, \quad (29.83)$$

which follows either by periodicity or since $\eta'_{\mathrm{b}} = 0$ along the edge of a sloping shoreline. In conclusion, we see that it is only the zonal anomalies of the atmospheric and bottom pressures,

and free surface and bottom topography, that impact the zonal mean zonal momenum balance (29.85) for the periodic and sloping shoreline domains.

29.5.8 Form stress versus dual form stress

We can further exploit the symmetries of the periodic and sloping shoreline domains by writing the form stresses in equation (29.85) in an alternative manner that makes use of the dual form stress

$$\int \left[p'_{\mathrm{a}} \, \frac{\partial \eta'}{\partial \lambda} - p'_{\mathrm{b}} \, \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} \right] \mathrm{d}\lambda = \int \left[-\frac{\partial p'_{\mathrm{a}}}{\partial \lambda} \, \eta' + \frac{\partial p'_{\mathrm{b}}}{\partial \lambda} \, \eta'_{\mathrm{b}} \right] \mathrm{d}\lambda. \tag{29.84}$$

Diagnostics of zonally integrated form stress can be more convenient using one form or the other, depending on dataset or numerical model framework. We have a choice since the zonal integral is the same, and that freedom is afforded since the spatial integral removes local information that appears as a total zonal derivative. However, we offer two caveats in this regard.

- The identity (29.84) does not hold for the bounded domain with vertical sidewalls (third panel of Figure 29.6). If working in such a domain and if one chooses to study patterns based on the right hand side dual form stress, then its zonal integral will not agree with that of the form stress on the left hand side. Correspondingly, physical interpretations based on the dual form stress are questionable.

- Although the zonal integrals in equation (29.84) agree for the periodic domain and sloping shoreline domain, there is no local identity between terms on the left hand side and right hand side. So if one wishes to make a statement about patterns of local form stresses acting on the depth integrated axial angular momentum, then it is necessary to return to the form stress appearing on the left hand side of equation (29.84).

29.5.9 Steady zonal and depth integrated budget

Now consider just a zonal integral of the steady angular momentum budget (29.79), again over a domain that is either periodic or has sloping shorelines (Figure 29.6). In both of these cases, we are left with the zonal and depth integrated steady angular momentum budget

$$\frac{1}{R \cos \phi} \int \frac{\partial}{\partial \phi} \left[\int_{\eta_{\mathrm{b}}}^{\eta} l^z \, v \, \rho \, \mathrm{d}z \right] \mathrm{d}\lambda = \int \left[[l^z Q_{\mathrm{m}}]_{z=\eta} + p'_{\mathrm{a}} \, \frac{\partial \eta'}{\partial \lambda} - p'_{\mathrm{b}} \, \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} + R_{\perp} \, (\tau^{\lambda}_{\mathrm{a}} - \tau^{\lambda}_{\mathrm{b}}) \right] \mathrm{d}\lambda. \tag{29.85}$$

The meridional divergence of the advective transport of angular momentum is balanced, in the steady state, by the boundary terms on the right hand side.

29.5.10 Southern Ocean balances

Under certain cases the primary balance in equation (29.85) is between the form stress and boundary turbulent stress, whereby

$$\oint \left[p'_{\mathrm{a}} \, \frac{\partial \eta'}{\partial \lambda} + R_{\perp} \, \tau^{\lambda}_{\mathrm{a}} \right] \mathrm{d}\lambda \approx \oint \left[p'_{\mathrm{b}} \, \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} + R_{\perp} \, \tau^{\lambda}_{\mathrm{b}} \right] \mathrm{d}\lambda. \tag{29.86}$$

For much of the large-scale Southern Ocean circulation, the primary balance is even simpler: it is a balance between surface wind stress and topographic form stress

$$\oint \tau^{\lambda}_{\mathrm{a}} \, \mathrm{d}\lambda \approx \oint p'_{\mathrm{b}} \, \frac{1}{R_{\perp}} \, \frac{\partial \eta'_{\mathrm{b}}}{\partial \lambda} \, \mathrm{d}\lambda = - \oint \eta'_{\mathrm{b}} \, \frac{1}{R_{\perp}} \, \frac{\partial p'_{\mathrm{b}}}{\partial \lambda} \, \mathrm{d}\lambda, \tag{29.87}$$

with this balance exemplified in Figure 29.8. We now state in words what this balance means in the presence of a net eastward wind stress, $\oint \tau_{\mathrm{a}}^{\lambda}\, \mathrm{d}\lambda > 0$. The equivalent expressions on the right hand side allow complementary perspectives.

- For the first equality in equation (29.87) we see that a balance is realized if on the upwind side of a topographic bump there is an anomalously high bottom pressure, with the opposite on the downwind side. Correspondingly, there is a net westward topographic form stress imparted by the solid earth onto the ocean that balances the eastward surface wind stress imparted by the atmosphere onto the ocean.

- The second equality in equation (29.87) reveals that for $\eta_{\mathrm{b}}' > 0$ (topographic ridge), a steady angular momentum balance is maintained so long as the bottom pressure decreases across the ridge from west to east, just as depicted in Figure 29.8.

FIGURE 29.8: Depicting the balance between zonal wind stress and topographic form stress for a southern hemisphere zonally periodic ocean channel. For an eastward wind stress, the flow reaches a steady state if the upwind side of a topographic bump sees an anomalously high bottom pressure whereas on the downwind side it is anomalously low. The form stress imparted by the ocean onto the solid earth is eastward since the bottom pressure is higher in the west and lower in the east. Conversely, Newton's third law tells us that the topographic form stress imparted by the solid earth onto the ocean is westward. In this manner, the eastward force imparted by the atmosphere onto the ocean through wind stress is balanced by a westward topographic form stress imparted by the solid earth onto the ocean. Furthermore, the eastward bottom pressure gradient leads to a northward depth integrated geostrophic transport above the southern hemisphere ridge. Signs are swapped when flow moves over a depression, in which a westward bottom pressure gradient leads to southward geostrophic transport over the depression. We revisit these dynamical processes for the shallow water fluid in Figure 37.8.

29.5.11 Topographic form stress and ocean gyres

Hughes (2000) and *Hughes and de Cueves* (2001) are notable for having emphasized the importance of bottom topographic form stress, and the associated bottom pressure torque appearing in the vorticity equation (detailed in see Section 41.9). The key role for topographic form stress is well appreciated for channel flows since the work of *Munk and Palmén* (1951) who studied the Southern Ocean steady force balances (see also *Webb and de Cueves* (2007) for studies of the transient case). However, *Hughes* (2000) and *Hughes and de Cueves* (2001) showed that it is central even for steady ocean gyre circulations when allowing for sloping sides rather than vertical sides.

Hence, sloping sides for the gyre domain allow for a steady momentum balance to occur between bottom form stress and wind stress, and a steady vorticity balance to occur between bottom pressure torque and wind stress curl. As a result, topographic form stress and bottom pressure torques allow for a mostly inviscid balance in ocean gyres much like for the zonally re-entrant Southern Ocean. We return to these points in Section 40.7, in particular in Section 40.7.5, when studying gyre circulations in a shallow water fluid.

29.5.12 Further study

Elements of this section are based on *Hughes* (2000) and *Hughes and de Cueves* (2001), as well as the analogous discussion of the global atmospheric axial angular momentum budget developed in Section 10.3 of *Holton* (1992). *Straub* (1993) provides an analogous analysis with a focus on the Southern Ocean. The physical processes establishing the balances noted for the Southern Ocean remain under investigation, with further resources to the literature including Section 21.7 of *Vallis* (2017), and the reviews by *Rintoul et al.* (2001), *Rintoul and Naveira Garabato* (2013), and *Rintoul* (2018). We further revisit this balance in Section 37.7 for the shallow water system.

Chapter 30

The Boussinesq ocean

In some areas of fluid mechanics the speed of fluid particles can approach the speed of sound. In that case, the *Mach number*, which is the ratio of the fluid particle speed to the speed of sound waves, reaches unity or larger.[1] In such flows it is important to consider the influence of compressibility since the large flow speeds can lead to nontrivial local density changes through the convergence of advective mass fluxes.

Geophysical flows studied in this book have Mach numbers well below unity. Hence, their local density changes are generally much smaller than the mean density.[2] Yet even with a small Mach number, pressure can play a nontrivial role in affecting density changes for those cases where motions extend over vertical distances comparable to the *scale height*. For the atmosphere, the scale height (Section 24.4.10) is roughly 10 km, whereas the ocean's scale height is generally deeper than the ocean. For this reason, compressibility effects are generally important for atmospheric motions, whereas they can be neglected for many purposes in ocean fluid mechanics.

Because compressibility effects are relatively weak in the ocean, the ocean velocity field is well approximated as non-divergent, thus allowing for the volume conserving kinematics from Chapter 22. Even with this approximation, it is crucial to note that the ocean is not an incompressible fluid since density is not uniform, and so we need something more than incompressible fluid mechanics.[3] It is for this purpose that we here develop the *Boussinesq ocean* equations, which sit somewhere between the fully compressible fluids (i.e., *non-Boussinesq* fluids) and incompressible flows.

In brief, the Boussinesq ocean velocity is non-divergent, thus representing an incompressible flow, and yet the Boussinesq ocean fluid admits density variations, as for a compressible fluid. Since the flow is non-divergent, the pressure in the Boussinesq ocean is not the thermodynamic pressure found in the compressible non-Boussinesq fluid studied in Part IV of this book. Rather, Boussinesq pressure serves a purely mechanical role by acting as the Lagrange multipler to constrain the Boussinesq flow to be non-divergent.[4]

READER'S GUIDE TO THIS CHAPTER

We here derive the Boussinesq ocean equations and explore their physical properties, in-

[1] When a jet airplane or rocket moves at a speed greater than Mach one, such super-sonic motion generates a spectacularly loud and powerful sonic boom. In Section 49.5.2 we provide a more precise measure of the Mach number in terms of fluctuations of the density. For purposes of the present chapter, density fluctuations are very small and thus correspond to a tiny Mach number.

[2] In Section 49.5.2 in our study of acoustics, we see precisely how a density fluctuation is related to the Mach number.

[3] The fluid mechanics of constant density fluids is sometimes referred to as *hydrodynamics*. Certain idealized models of geophysical fluid mechanics follow the approaches of hydrodynamics; e.g., the single layer of constant density shallow water fluid studied in Part VI of this book. However, density variations are crucial for many atmosphere and ocean flows.

[4] See Section 59A of *Serrin* (1959) for more on pressure in a non-divergent flow.

cluding energetics. The Boussinesq ocean has broader application than just to the ocean, with many characteristics also holding for atmospheric flow satisfying the anelastic approximation (see Section 2.5 of *Vallis* (2017)). Furthermore, the Boussinesq ocean provides the starting point for many of the geophysical fluid models found later in this book. This is a relatively long chapter due to the broad use of the Boussinesq ocean in this book, which in turn motivates us to explore many of its facets.

30.1 The Boussinesq ocean approximation

For the ocean, density deviates no more than a few percent relative to the volume mean density. Although small, ocean density deviations act over large distances and are crucial for driving large-scale circulations. Such *thermohaline circulations* derive their driving force from variations in temperature and salinity that affect density and, in turn, modify the pressure. A key reason that small density changes can be so pivotal is that the density variations are multiplied by the relatively large gravitational acceleration when computing pressure. The oceanic Boussinesq approximation provides a systematic means to ignore small density deviations where it is safe to do so dynamically, while retaining density variations where they are critical such as when multiplied by gravity. In brief, the oceanic Boussinesq approximation makes use of (a slightly modified) compressibile thermodynamics plus an incompressible kinematics. The use of compressible thermodynamics allows for thermohaline processes to modify density and thus pressure, while the incompressible kinematics removes sound waves and renders the volume of a fluid element materially invariant.

30.1.1 Isolating the dynamically active pressure field

Pressure in a vertically stratified fluid can be decomposed into a static background hydrostatic pressure plus a deviation from the background pressure. We made use of this decomposition in Section 28.2.4 when developing the scaling for the hydrostatic approximation. The decomposition holds even when the fluid is non-hydrostatic. We consider the background pressure to be a function just of depth and as such it is determined by a static and horizontally homogeneous background density field. We are motivated to introduce this decomposition given that the background hydrostatic pressure field (again, it is just a function of depth) is dynamically inactive (as shown below). This decomposition is exact and motivated by the desire to isolate the dynamically active part of the equations of motion.

To achieve the pressure decomposition, start by decomposing density according to

$$\rho(\boldsymbol{x}, t) = \rho_0(z) + \rho'(\boldsymbol{x}, t) \tag{30.1}$$

where the deviation density is much smaller than the reference density

$$\rho' \ll \rho_0. \tag{30.2}$$

The following formulation for the momentum equation holds for the general case of $\rho_0(z)$. However, we note in Section 30.1.2 that setting $\rho_0(z) = \rho_0$ is motivated for studies of potential vorticity in the Boussinesq ocean. Indeed, a space and time constant reference density is generally synonymous with the oceanic Boussinesq approximation.[5]

The corresponding decomposition of pressure is given by the sum of a static and depth dependent background pressure, $p_0(z)$, and a deviation pressure, $p'(\boldsymbol{x}, t)$,

$$p(\boldsymbol{x}, t) = p_0(z) + p'(\boldsymbol{x}, t). \tag{30.3}$$

The background pressure is assumed to be in hydrostatic balance with the reference density

$$\frac{\mathrm{d}p_0}{\mathrm{d}z} = -\rho_0\, g, \tag{30.4}$$

with p_0 and ρ_0 both static. We offer the following points to clarify the decomposition of pressure in equation (30.3).

- Assuming the background pressure, $p_0(z)$, to be hydrostatic does *not* imply that the full pressure, $p(\boldsymbol{x}, t)$, is also hydrostatic. Rather, the decomposition merely serves to remove that portion of the pressure field that plays no role in establishing motion (we see this property below). So this decomposition holds whether the full pressure is approximately hydrostatic or fully non-hydrostatic.

- Furthermore, if $p(\boldsymbol{x}, t)$ is in an approximate hydrostatic balance (Section 28.2), the decomposition (30.3) does *not* remove all of the hydrostatic pressure from $p(\boldsymbol{x}, t)$. Rather, $p'(\boldsymbol{x}, t)$ is generally nonzero whether $p(\boldsymbol{x}, t)$ is in an approximate hydrostatic balance or fully non-hydrostatic.

With the above density and pressure decompositions, the momentum equation

$$\rho \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} \right] = -\nabla p - \hat{\boldsymbol{z}}\, g\, \rho \tag{30.5}$$

takes the equivalent form

$$(\rho_0 + \rho') \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} \right] = -\nabla p' - g\, \rho'\, \hat{\boldsymbol{z}} - \left[\frac{\mathrm{d}p_0}{\mathrm{d}z} + \rho_0\, g \right] \hat{\boldsymbol{z}} \tag{30.6a}$$

$$= -\nabla p' - g\, \rho'\, \hat{\boldsymbol{z}}, \tag{30.6b}$$

where we used the hydrostatic balance (30.4) for the second equality. We thus see that the background hydrostatic pressure, $p_0(z)$, leads to no motion since it drops out from the momentum equation. The gradient pressure force is thus determined solely by the gradient of p'.

[5] Exercise 30.3 offers a modest means to generalize this assumption.

30.1.2 Boussinesq momentum equation

To develop the Boussinesq momentum equation, divide the momentum equation (30.6b) by the density, $\rho = \rho_0 + \rho'$, and write the pressure and gravity terms as

$$\frac{\nabla p' + g\,\rho'\,\hat{\boldsymbol{z}}}{\rho_0 + \rho'} = \frac{\nabla p' + g\,\rho'\,\hat{\boldsymbol{z}}}{\rho_0 + \rho'}\left[\frac{\rho_0 - \rho'}{\rho_0 - \rho'}\right] = \frac{\nabla p' + g\,\rho'\,\hat{\boldsymbol{z}}}{\rho_0^2 - (\rho')^2}\,(\rho_0 - \rho') \approx \frac{\nabla p' + g\,\rho'\,\hat{\boldsymbol{z}}}{\rho_0}, \tag{30.7}$$

where the final approximation results from dropping all terms that are second order in deviation quantities. This approximation then leads to the Boussinesq momentum equation

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\frac{1}{\rho_0}\,\nabla p' + b\,\hat{\boldsymbol{z}}, \tag{30.8}$$

where we introduced the globally referenced *Archimedean buoyancy* (Chapter 31) as defined relative to the constant background density

$$b = -\frac{g\,\rho'}{\rho_0} = -\frac{g\,(\rho - \rho_0)}{\rho_0}. \tag{30.9}$$

Hence, the globally referenced Archimedean buoyancy is positive when the *in situ* density is less than the reference density so that $\rho' = \rho - \rho_0 < 0$. That is, $b > 0$ when the fluid element is lighter (more buoyant) than the background reference density. Buoyancy is the product of the gravitational acceleration, which is a relatively large term, and the small number ρ'/ρ_0. Their product is generally not small so that it generally cannot be neglected from the momentum equation. This is a key point in producing a Boussinesq ocean equation set that contains dynamical processes arising from horizontal buoyancy gradients.

In the special case of a space and time constant reference density, $\rho_0(z) = \rho_0$, it is convenient to introduce the shorthand for the deviation pressure normalized by the reference density

$$\varphi = \frac{p'}{\rho_0} = \frac{p - p_0(z)}{\rho_0}. \tag{30.10}$$

In this case the Boussinesq momentum equation takes the form

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\varphi + b\,\hat{\boldsymbol{z}}. \tag{30.11}$$

30.1.3 A vorticity motivation to set ρ_0 constant

We now anticipate a later discussion of vorticity and potential vorticity to motivate setting $\rho_0(z)$ to a constant. This paragraph is not critical for the remainder of this chapter, but worth returning to after studying baroclinicity for the Boussinesq fluid in Section 41.7.2. For that purpose, we note that the form of the pressure gradient acceleration found in equation (30.11) is particularly useful given that the curl of the right hand side eliminates pressure from the vorticity equation (Section 41.7.1). In contrast, for the more general form with $\rho_0(z)$ in equation (30.8), the Boussinesq baroclinicity vector (equation (41.147)) has a contribution from both pressure and buoyancy (we derive equation (30.12) in Exercise 41.3)

$$\boldsymbol{B} = \nabla\left[b - \frac{p'}{\rho_0^2}\frac{\mathrm{d}\rho_0}{\mathrm{d}z}\right] \times \hat{\boldsymbol{z}}. \tag{30.12}$$

The additional pressure contribution complicates the development of potential vorticity whereby we wish to have $\boldsymbol{B} \cdot \nabla b = 0$ (see Section 42.5.1). We are thus movitated to use a space and time constant reference density so that $\mathrm{d}\rho_0/\mathrm{d}z = 0$. Following this motivation, we generally assume ρ_0 is a constant in this book. Even so, in Exercise 30.3 we discuss a middle ground by defining a slightly more general buoyancy field while retaining a constant ρ_0.

30.1.4 Mass continuity

When decomposing density according to equation (30.1), the mass continuity equation (Section 20.2)

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho \, \nabla \cdot \boldsymbol{v}, \tag{30.13}$$

takes the form

$$\frac{\mathrm{D}\rho'}{\mathrm{D}t} = -(\rho_0 + \rho') \, (\nabla_z \cdot \boldsymbol{u} + \partial_z w). \tag{30.14}$$

For many geophysical flows, the material time derivative on the left hand side is much smaller than either of the two terms appearing on the right hand side. To help formalize this observation it is useful to introduce a time scale for the various terms in this equation

$$\left| \frac{1}{\rho} \frac{\mathrm{D}\rho'}{\mathrm{D}t} \right| \sim \frac{1}{T_\rho} \qquad |\partial_x u| \sim T_u^{-1} \qquad |\partial_y v| \sim T_v^{-1} \qquad |\partial_z w| \sim T_w^{-1}. \tag{30.15}$$

Quite often we find flows in which the time scales associated with the spatial deformations of the flow, in the direction of the flow, are much smaller than time scales for the material changes in density, whereby

$$T_u^{-1}, T_v^{-1}, T_w^{-1} \gg T_\rho^{-1}. \tag{30.16}$$

In this case the only way for the mass balance equation (30.14) to hold is for the three terms contributing to the divergence to balance one another

$$\partial_x u + \partial_y v + \partial_z w \approx 0. \tag{30.17}$$

Taking this balance to the limit motivates setting the velocity field for the Boussinesq ocean to be non-divergent

$$\nabla \cdot \boldsymbol{v} = 0. \tag{30.18}$$

Note that for density stratified flows we generally find the horizontal divergence of the horizontal velocity balancing the vertical convergence of the vertical velocity. For a Boussinesq ocean this balance is exact

$$\nabla_z \cdot \boldsymbol{u} = -\partial_z w. \tag{30.19}$$

30.1.5 Dependence on reference density

How does the solution compare when considering two distinct reference densities, say $\rho_0 \neq \rho_1$? To answer this question, write the inviscid Boussinesq velocity equation in the form

$$(\partial_t + \boldsymbol{v}_0 \cdot \nabla) \, \boldsymbol{v}_0 + 2 \, \boldsymbol{\Omega} \times \boldsymbol{v}_0 = -\nabla \varphi_0 + b_0 \, \hat{\boldsymbol{z}} \tag{30.20a}$$

$$(\partial_t + \boldsymbol{v}_1 \cdot \nabla) \, \boldsymbol{v}_1 + 2 \, \boldsymbol{\Omega} \times \boldsymbol{v}_1 = -\nabla \varphi_1 + b_1 \, \hat{\boldsymbol{z}}. \tag{30.20b}$$

Consider an initial condition in which

$$\rho_0 \, \boldsymbol{v}_0 = \rho_1 \, \boldsymbol{v}_1, \tag{30.21}$$

and with pressure and buoyancy initialized so that

$$\rho_0\,(-\nabla\varphi_0 + b_0\,\hat{\boldsymbol{z}}) = \rho_1\,(-\nabla\varphi_1 + b_1\,\hat{\boldsymbol{z}}) = -\nabla p - g\,\rho\,\hat{\boldsymbol{z}}. \tag{30.22}$$

Hence, the difference between equations (30.20a) and (30.20b) takes the form

$$\partial_t(\rho_0\,\boldsymbol{v}_0 - \rho_1\,\boldsymbol{v}_1) = -(\rho_0\,\boldsymbol{v}_0\cdot\nabla)\,\boldsymbol{v}_0 + (\rho_1\,\boldsymbol{v}_1\cdot\nabla)\,\boldsymbol{v}_1 \tag{30.23a}$$

$$= -[(\rho_1-\rho_0)/\rho_0]\,(\boldsymbol{v}_1\cdot\nabla)\,\boldsymbol{v}_1. \tag{30.23b}$$

The difference in reference densities allows for the nonlinear self-advection to evolve the difference $\rho_0\,\boldsymbol{v}_0 - \rho_1\,\boldsymbol{v}_1$. This property of the oceanic Boussinesq equations must be kept in mind if comparing numerical solutions using distinct reference densities. Namely, a Boussinesq ocean is dependent on the reference density through the nonlinear advection term.

30.1.6 Version I of the Boussinesq ocean equations

The first form of the oceanic Boussinesq equations emphasizes the role of buoyancy computed relative to a reference state of constant density, $\rho = \rho_0$. This form facilitates a focus on that portion of the pressure field giving rise to internal or baroclinic pressure gradients; i.e., those pressure gradients that generate motion independent of free surface undulations. The oceanic Boussinesq equations thus take the form

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} = -\nabla\varphi + b\,\hat{\boldsymbol{z}} + \boldsymbol{F} \qquad \text{velocity equation} \tag{30.24a}$$

$$\nabla\cdot\boldsymbol{v} = 0 \qquad \text{continuity equation} \tag{30.24b}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = \dot{b} \qquad \text{buoyancy equation} \tag{30.24c}$$

$$b = -\frac{g\,\rho'}{\rho_0} = -\frac{g\,(\rho-\rho_0)}{\rho_0} \qquad \text{buoyancy defined} \tag{30.24d}$$

$$\varphi = \frac{p'}{\rho_0} = \frac{p - p_0(z)}{\rho_0} \qquad \text{dynamic pressure defined} \tag{30.24e}$$

$$\rho = \rho_0\,(1 - \alpha\,\Theta + \beta\,S) \qquad \text{linear equation of state} \tag{30.24f}$$

$$\frac{\mathrm{d}p_0}{\mathrm{d}z} = -\rho_0\,g \qquad \text{background hydrostatic pressure.} \tag{30.24g}$$

We offer the following comments on these equations.

- MATERIAL EVOLUTION OF BUOYANCY: The term $\dot{b}$ on the right hand side of the buoyancy equation (30.24c) is a placeholder for any process leading to a material change in buoyancy. We discuss some explicit examples of $\dot{b} \neq 0$ in Section 30.7.1.

- EQUATION OF STATE: The equation of state, (30.24f), is written as a linear function of salinity and Conservative Temperature, with the thermal expansion coefficient, α, and haline contraction coefficient, β, assumed constant.[6] This form for the equation of state eliminates processes such as cabbeling and thermobaricity, which are discussed in Section 67.3. These processes are important for certain features of the ocean, thus prompting the more general equation set written in Section 30.1.7. However, the linear equation of state is sufficient

[6] It is unfortunate that β is used for two prominent but very distinct properties of geophysical fluids. First, it is the meridional derivative of the Coriolis parameter: $\beta = \partial_y f$. Second, it is the haline contraction coefficient: $\beta = \rho^{-1}\partial\rho/\partial S$. These distinct uses will be clearly defined so to avoid confusion.

for many of our studies in this book, as is the further simplified form with zero haline contraction, $\beta = 0$.

- APPROXIMATED HYDROSTATIC BALANCE: Most numerical models of the large-scale ocean circulation are in approximate hydrostatic balance. Assuming this balance holds in the velocity equation (30.24a) leads to the split into a horizontal velocity equation plus a vertical hydrostatic balance

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla_z \varphi + \boldsymbol{F}^h \qquad \text{horizontal velocity equation} \tag{30.25a}$$

$$\frac{\partial \varphi}{\partial z} = b \qquad \text{approximate hydrostatic balance,} \tag{30.25b}$$

where ∇_z is the horizontal gradient operator and $\boldsymbol{F}^h$ is the horizontal frictional acceleration. As emphasized in Section 28.1 when deriving the hydrostatic primitive equations, that approximate hydrostatic approximation leads to a vertical velocity equation with no friction nor Coriolis contribution. Rather, when making the hydrostatic approximation we just retain a balance between the vertical pressure gradient and gravity/buoyancy.

30.1.7 Version II of the Boussinesq ocean equations

The non-hydrostatic Boussinesq equations (30.24a)-(30.24g) are suited for many purposes in this book. However, the following form is better suited to studying or simulating realistic Boussinesq ocean flows, with such flows involving separate prognostic equations for salinity and Conservative Temperature rather than a single prognostic equation for buoyancy. We are thus movitated to consider the Boussinesq ocean equations in the form

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -(1/\rho_0)\,(\nabla p + \rho\,\nabla\Phi) + \boldsymbol{F} \qquad \text{velocity equation} \tag{30.26a}$$

$$\nabla \cdot \boldsymbol{v} = 0 \qquad \text{continuity equation} \tag{30.26b}$$

$$\frac{\mathrm{D}S}{\mathrm{D}t} = \dot{S} \qquad \text{salinity equation} \tag{30.26c}$$

$$\frac{\mathrm{D}\Theta}{\mathrm{D}t} = \dot{\Theta} \qquad \text{Conservative Temperature equation} \tag{30.26d}$$

$$\rho = \rho(S, \Theta, \Phi) \qquad \text{equation of state.} \tag{30.26e}$$

We make the following comments concerning these equations.

- GEOPOTENTIAL: The geopotential is here considered to be a function of space and time, as relevant when studying the role of astronomical tidal forcing or changes to the mass distribution of the planet (see Chapter 35)

$$\Phi = \Phi(\boldsymbol{x}, t). \tag{30.27}$$

- EQUATION OF STATE: The equation of state is a function of salinity, Conservative Temperature, and geopotential, thus allowing for processes such as cabelling and thermobaricity (see Section 67.3). Furthermore, the pressure dependence in the equation of state is computed as per a homogeneous and resting hydrostatic fluid

$$\rho(S, \Theta, \Phi) = \rho(S, \Theta, p = -\rho_0\,\Phi). \tag{30.28}$$

In Section 30.8 we provide an energetic argument for why it is appropriate to take this functional form rather than the more general form discussed in Section 31.3, in which density is a function of the full *in situ* pressure: $\rho = \rho(S, \Theta, p)$.

- HYDROSTATIC APPROXIMATION: As for version I of the Boussinesq ocean equations, we here list the equations when making the hydrostatic approximation in the vertical momentum equation, in which case the velocity equation (30.26a) splits into a horizontal velocity equation and hydrostatic balance

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -(1/\rho_0)\,(\nabla_z p + \rho\,\nabla_z \Phi) + \boldsymbol{F}^h \qquad \text{horizontal velocity equation} \tag{30.29a}$$

$$\frac{\partial p}{\partial z} = -g\,\rho \qquad \text{hydrostatic balance.} \tag{30.29b}$$

30.1.8 Boussinesq inertial mass is not the gravitational mass

The *inertial mass* is the mass multiplying acceleration on the right hand side Newton's law of motion, $\boldsymbol{F} = m\,\boldsymbol{a}$, and it is correspondingly used to measure kinetic energy. The *gravitational mass* is the mass used to compute the gravitational force, and so it is the mass used when computing weight and gravitational potential energy. The *principle of equivalence*, originating from the work of Galileo and forming a key element to Einstein's relativity theory, states that the gravitational mass and the inertial mass are the same. The principle of equivalance is greatly embedded into the use of Newtonian mechanics, so much so that we routinely assume that inertial mass and gravitational mass are identical.

A Boussinesq ocean fluid element materially conserves its volume since the velocity is non-divergent (recall the kinematics of non-divergent flows studied in Chapter 22). In turn, the inertial mass of a Boussinesq fluid element is measured by multiplying its volume by the constant reference density, ρ_0. In contrast, whenever there is a gravitational acceleration multiplying density, it is crucial to retain the full *in situ* density to measure the weight of the fluid element. Use of *in situ* density for the gravitational mass ensures an accurate representation of the gravitational force, hydrostatic pressure (Section 30.2.7), and the gravitational potential energy (Sections 30.6 and 30.8). Evidently, the Boussinesq ocean *does not* respect the principle of equivalance since it distinguishes between the inertial mass and the gravitational mass.

The following offers a summary of various properties of a Boussinesq fluid element related to its distinct inertial mass and gravitational mass:

$$\text{inertial mass density} = \rho_0 \tag{30.30a}$$

$$\text{inertial mass} = \rho_0\,\delta V \tag{30.30b}$$

$$\text{linear momentum} = \boldsymbol{v}\,\rho_0\,\delta V \tag{30.30c}$$

$$\text{kinetic energy} = \rho_0\,\delta V\,\boldsymbol{v}\cdot\boldsymbol{v}/2 \tag{30.30d}$$

$$\text{tracer mass} = C\,\rho_0\,\delta V \tag{30.30e}$$

$$\text{enthalpy content} = c_{\mathrm{p}}\,\Theta\,\rho_0\,\delta V \tag{30.30f}$$

$$\text{gravitational mass density} = \rho \tag{30.30g}$$

$$\text{gravitational mass} = \rho\,\delta V \tag{30.30h}$$

$$\text{gravitational force (weight)} = -\rho\,\delta V\,\nabla\Phi \tag{30.30i}$$

$$\text{gravitational force (weight) with simple geopotential} = -g\,\rho\,\delta V\,\hat{\boldsymbol{z}} \tag{30.30j}$$

$$\text{gravitational potential energy} = \Phi\,\rho\,\delta V \tag{30.30k}$$

$$\text{gravitational potential energy with simple geopotential} = g\,z\,\rho\,\delta V. \tag{30.30l}$$

The distinction between inertial mass and gravitational mass can be the source for confusion when working with the Boussinesq ocean.

30.1.9 Summary points

We close this section by summarizing a number of conceptual points characterizing the Boussinesq ocean. It is useful to return to this list to help avoid common conceptual confusions.

Divergent and non-divergent velocity components

The velocity that results from the Boussinesq momentum equation (i.e., the prognostic Boussinesq velocity) is non-divergent. This is the velocity used for transport as per the material time derivative operator. Additionally, there is a divergent velocity field, $\boldsymbol{v}^{\mathrm{d}}$, that balances the material evolution of density

$$\frac{1}{\rho'}\frac{\mathrm{D}\rho'}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{v}^{\mathrm{d}} \neq 0. \tag{30.31}$$

The divergent velocity is not used for any of the Boussinesq dynamical equations. Nonetheless, $\boldsymbol{v}^{\mathrm{d}} \neq 0$, as its divergence balances the material evolution of density according to equation (30.31). Consequently, there are acoustic waves (Chapter 49) supported by $\boldsymbol{v}^{\mathrm{d}}$ in a Boussinesq ocean.

Concerning density evolution and thermohaline circulation

The use of a non-divergent velocity for the Boussinesq ocean equations does not mean that the material time evolution of ρ vanishes. Instead, the scaling in Section 30.1.4 focuses just on the mass continuity equation. We must additionally acknowledge that as temperature and salinity evolve, so too does *in situ* density as determined through the equation of state. Indeed, equation (30.31) provides one expression for this evolution. Changes to density translate into changes in pressure, which in turn drive the large-scale *thermohaline circulation*.

The thermodynamic equation for Conservative Temperature or potential temperature is needed to determine density. There are various forms for the relation between temperature and density that depend on thermodynamic assumptions. We discuss the flavors for density in Section 31.3. For purposes of realistic ocean modeling, an accurate expression for density is critical, whereas for idealized modeling it is common to assume density equals to a constant times the temperature.

Buoyancy

We note the rather trivial point that there is identically zero buoyancy, $b = -g\,(\rho - \rho_0)/\rho_0$, in a fully homogeneous fluid where density is constant, $\rho = \rho_0$, everywhere. Hence, for an exactly incompressible fluid, where density is a fixed and uniform constant, there are no buoyancy forces. Such fluids serve many purposes, as exemplified by studies of a single layer of shallow water fluid in Part VI of this book. However, buoyancy forces are of primary importance for many other purposes in geophysical fluid mechanics. The Boussinesq ocean accounts for buoyancy forces, and the changes arising from processes such as heating and freshening, while making use of the more convenient kinematics of a non-divergent flow. We have far more to say concerning buoyancy in Chapter 31.

Distinguishing the Boussinesq ocean from the traditional Boussinesq approximation

The Boussinesq ocean equations are more general than the traditional Boussinesq approximation considered in other areas of fluid mechanics (e.g., *Chandrasekhar*, 1961). In particular, the traditional Boussinesq approximation typically assumes a linear equation of state. However, as we

saw in Section 30.1.7, the Boussinesq ocean generally has a nonlinear equation of state, which is essential for realistic ocean circulation studies.

Connection to anelastic atmosphere

The atmosphere is far more compressible than the ocean, so that density variations cannot be neglected and the divergent nature of the velocity is important. However, there are some cases in which an atmospheric analog to the oceanic Boussinesq approximation can be useful. The analog is known as the *anelastic approximation* and it is mathematically isomorphic to the oceanic Boussinesq approximation, in which case $\nabla \cdot (\rho \boldsymbol{v}) = 0$ is assumed. Section 2.5 of *Vallis* (2017) offers more details for the atmospheric anelastic approximation.

30.1.10 Further study

Section 2.4 of *Vallis* (2017) offers more details to show that density variations are small within the ocean. Further discussion of the oceanic Boussinesq approximation also can be found in Section 9.3 of *Griffies and Adcroft* (2008). This video from SciencePrimer provides a concise summary of ocean circulation arising from differences in density created by both thermal and haline (salinity) processes.

30.2 Scaling for the hydrostatic approximation

In Section 28.2 we considered a rudimentary scale analysis justifying the hydrostatic approximation for large-scale ocean and atmospheric flow. However, in that discussion we noted the need to remove a dynamically inactive hydrostatic pressure before addressing the question of whether the dynamically active pressure field is indeed approximately hydrostatic. That decomposition of pressure was performed in Section 30.1.1 as part of deriving the Boussinesq ocean equations. Hence, it is convenient to now return to the question of hydrostatic scaling within the context of the perfect non-rotating Boussinesq ocean equations.

30.2.1 Stratified non-rotating Boussinesq ocean equations

The stratified perfect Boussinesq equations in a non-rotating reference frame are

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = -\nabla_z \varphi \quad \text{and} \quad \frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{\partial \varphi}{\partial z} + b \quad \text{and} \quad \nabla \cdot \boldsymbol{v} = 0 \quad \text{and} \quad \frac{\mathrm{D}b}{\mathrm{D}t} = 0. \tag{30.32}$$

To help isolate the dynamically important portion of pressure, we proceed much like in Section 30.1.1 whereby buoyancy is written

$$b = b'(x, y, z, t) + \tilde{b}(z). \tag{30.33}$$

The static buoyancy, $\tilde{b}(z)$, encompasses a background stratification that is in hydrostatic balance with its corresponding portion of the pressure field

$$\frac{\mathrm{d}\tilde{\varphi}}{\mathrm{d}z} = \tilde{b}(z). \tag{30.34}$$

The Boussinesq equations thus take the form

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = -\nabla_z \varphi' \quad \text{and} \quad \frac{\mathrm{D}w}{\mathrm{D}t} = -\frac{\partial \varphi'}{\partial z} + b' \quad \text{and} \quad \nabla \cdot \boldsymbol{v} = 0 \quad \text{and} \quad \frac{\mathrm{D}b'}{\mathrm{D}t} = -w\, N^2, \tag{30.35}$$

where

$$N^2 = \frac{\mathrm{d}\tilde{b}}{\mathrm{d}z} \tag{30.36}$$

is the squared buoyancy frequency from the background vertical stratification.[7] The decomposition into a background stratification helps to isolate the dynamical portion of the horizontal pressure gradient by removing a static depth dependent background. It also allows us to consider the dynamically interesting, but simpler, case in which the background stratification dominates those perturbations around it.

30.2.2 Non-dimensionalization

Now introduce the dimensional scales (in uppercase) and corresponding non-dimensional quantities (with hats)

$$(x, y) = L\,(\widehat{x}, \widehat{y}) \qquad z = H\,\widehat{z} \qquad \boldsymbol{u} = U\,\widehat{\boldsymbol{u}} \qquad w = W\,\widehat{w} \tag{30.37}$$

$$t = T\,\widehat{t} \qquad \varphi' = \Phi\,\widehat{\varphi}' \qquad b' = B\,\widehat{b}' \qquad N^2 = \overline{N}^2\,\widehat{N}^2, \tag{30.38}$$

which yields the equations of motion

$$\frac{U}{T}\frac{\partial \widehat{u}}{\partial \widehat{t}} + \frac{U^2}{L}\widehat{u}\frac{\partial \widehat{u}}{\partial \widehat{x}} + \frac{U^2}{L}\widehat{v}\frac{\partial \widehat{u}}{\partial \widehat{y}} + \frac{UW}{H}\widehat{w}\frac{\partial \widehat{u}}{\partial \widehat{z}} = -\frac{\Phi}{L}\frac{\partial \widehat{\varphi}'}{\partial \widehat{x}} \tag{30.39a}$$

$$\frac{U}{T}\frac{\partial \widehat{v}}{\partial \widehat{t}} + \frac{U^2}{L}\widehat{u}\frac{\partial \widehat{v}}{\partial \widehat{x}} + \frac{U^2}{L}\widehat{v}\frac{\partial \widehat{v}}{\partial \widehat{y}} + \frac{UW}{H}\widehat{w}\frac{\partial \widehat{v}}{\partial \widehat{z}} = -\frac{\Phi}{L}\frac{\partial \widehat{\varphi}'}{\partial \widehat{y}} \tag{30.39b}$$

$$\frac{W}{T}\frac{\partial \widehat{w}}{\partial \widehat{t}} + \frac{UW}{L}\widehat{u}\frac{\partial \widehat{w}}{\partial \widehat{x}} + \frac{UW}{L}\widehat{v}\frac{\partial \widehat{w}}{\partial \widehat{y}} + \frac{WW}{H}\widehat{w}\frac{\partial \widehat{w}}{\partial \widehat{z}} = -\frac{\Phi}{H}\frac{\partial \widehat{\varphi}'}{\partial \widehat{z}} + B\,\widehat{b}' \tag{30.39c}$$

$$\frac{B}{T}\frac{\partial \widehat{b}'}{\partial \widehat{t}} + \frac{UB}{L}\widehat{u}\frac{\partial \widehat{b}'}{\partial \widehat{x}} + \frac{UB}{L}\widehat{v}\frac{\partial \widehat{b}'}{\partial \widehat{y}} + \frac{WB}{H}\widehat{w}\frac{\partial \widehat{b}'}{\partial \widehat{z}} = -W\,\overline{N}^2\,\widehat{w}\,\widehat{N}^2 \tag{30.39d}$$

$$\frac{U}{L}\frac{\partial \widehat{u}}{\partial \widehat{x}} + \frac{U}{L}\frac{\partial \widehat{v}}{\partial \widehat{y}} + \frac{W}{H}\frac{\partial \widehat{w}}{\partial \widehat{z}} = 0. \tag{30.39e}$$

30.2.3 Specifying the scales

We impose the following choices for scales based on the flow regimes of interest.

- TIME SCALE: Asssume that the time scale is determined by the horizontal velocity and the horizontal length scale

$$T = L/U. \tag{30.40}$$

- VERTICAL VELOCITY: It is common to assume the vertical velocity scales according to the continuity equation

$$\nabla_z \cdot \boldsymbol{u} + \frac{\partial w}{\partial z} = 0 \Longrightarrow W = U\,\frac{H}{L} \equiv U\alpha_{\text{aspect}}, \tag{30.41}$$

  where the final equality introduced the vertical to horizontal aspect ratio, α_{aspect}. However, vertical density stratification acts to suppress vertical motion so that we introduce a non-

[7] We discuss buoyancy frequency in Section 31.5.4. For present purposes, we merely note that it provides a measure of the vertical stratification of density, with $N^2 > 0$ signally a gravitationally stable density stratification.

dimensional number, ϵ

$$w = W\,\widehat{w} = \epsilon\left[\frac{HU}{L}\right]\widehat{w}. \tag{30.42}$$

In Section 30.2.5 we motivate choosing ϵ as the squared *Froude number*.

- PRESSURE: Scale the pressure according to the non-rotating balance of the material time change in horizontal velocity and the horizontal pressure gradient

$$\frac{U}{T} + \frac{UU}{L} = \frac{\Phi}{L} \Longrightarrow \Phi = U^2. \tag{30.43}$$

We made use of this *dynamical pressure scaling* in Section 26.9.2 when non-dimensionalizing the Navier-Stokes equation in a non-rotating reference frame. For flows in a rotating reference frame that are in near geostrophic balance, we find that pressure instead scales with the Coriolis acceleration (Sections 34.3.2 and 44.7.4).

- BUOYANCY: We choose to scale buoyancy according to the hydrostatic balance

$$B = \frac{\Phi}{H} = \frac{U^2}{H}, \tag{30.44}$$

which is motivated by the importance of hydrostatic pressure in geophysical flows.

30.2.4 Non-dimensional Boussinesq equations of motion

With these choices, the equations of motion (30.39a)-(30.39e) take on form

$$\frac{\mathrm{D}\widehat{\boldsymbol{u}}}{\mathrm{D}\widehat{t}} = -\widehat{\nabla}\widehat{\varphi'} \tag{30.45}$$

$$\epsilon\,\alpha^2_{\text{aspect}}\,\frac{\mathrm{D}\widehat{w}}{\mathrm{D}\widehat{t}} = -\frac{\partial\widehat{\varphi'}}{\partial\widehat{z}} + \widehat{b'} \tag{30.46}$$

$$\left[\frac{U^2}{\overline{N}^2\,H^2}\right]\frac{\widehat{\mathrm{D}}\widehat{b'}}{\mathrm{D}\widehat{t}} + \epsilon\,\widehat{N}^2\,\widehat{w} = 0 \tag{30.47}$$

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{u}} + \epsilon\frac{\partial\widehat{w}}{\partial\widehat{z}} = 0 \tag{30.48}$$

where we introduced the non-dimensional material time derivative

$$\frac{\mathrm{D}}{\mathrm{D}\widehat{t}} = \frac{\partial}{\partial\widehat{t}} + \widehat{\boldsymbol{u}}\cdot\widehat{\nabla}_z + \epsilon\,\widehat{w}\,\frac{\partial}{\partial\widehat{z}}. \tag{30.49}$$

30.2.5 The role of the Froude number

At this point we make a choice for the parameter, ϵ, noting that there are many choices that one could consider. For our interests it is suitable to set ϵ equal to the squared *Froude number*

$$\epsilon = \mathrm{Fr}^2 = \frac{U^2}{\overline{N}^2\,H^2}. \tag{30.50}$$

The Froude number measures the relative strength of vertical shears (i.e., vertical derivatives) of the horizontal velocity, U/H, versus the buoyancy stratification, N. Alternatively, it measures the ratio of the horizontal speed for a fluid particle, U, to an internal gravity wave speed, $N\,H$ (we study internal gravity waves in Chapter 54). Large Froude numbers indicate large fluid

particle speeds relative to wave speeds, with $\mathrm{Fr} > 1$ a common indicator of hydraulic instability (see Exercise 36.4 for a shallow water example). In contrast, a relatively strong stratification (N^2 large) corresponds to a small Froude number and to flow that is stabilized by vertical stratification. Note that the squared Froude number is the inverse of the *Richardson number*

$$\mathrm{Ri} = \mathrm{Fr}^{-2} = \frac{\overline{N}^2 \, H^2}{U^2}. \tag{30.51}$$

It is a matter of taste whether one works with Fr or Ri.

The choice (30.50) leads to the vertical velocity scale

$$W = \mathrm{Fr}^2 \left[\frac{HU}{L} \right]. \tag{30.52}$$

For $\mathrm{Fr} < 1$, which is the case for stably stratified fluids, this result means that stratification reduces the scale for the vertical velocity. The corresponding non-dimensional Boussinesq equations take the form

$$\frac{\mathrm{D}\widehat{u}}{\mathrm{D}\widehat{t}} = -\widehat{\nabla}_z \widehat{\varphi'} \tag{30.53}$$

$$\mathrm{Fr}^2 \, \alpha_{\text{aspect}}^2 \, \frac{\mathrm{D}\widehat{w}}{\mathrm{D}\widehat{t}} = -\frac{\partial \widehat{\varphi'}}{\partial \widehat{z}} + \widehat{b'} \tag{30.54}$$

$$\frac{\widehat{\mathrm{D}}\widehat{b'}}{\mathrm{D}\widehat{t}} + \widehat{N}^2 \, \widehat{w} = 0 \tag{30.55}$$

$$\widehat{\nabla} \cdot \widehat{\boldsymbol{u}} + \mathrm{Fr}^2 \, \frac{\partial \widehat{w}}{\partial \widehat{z}} = 0. \tag{30.56}$$

The condition for hydrostatic balance in a stratified fluid thus takes the form

$$\mathrm{Fr}^2 \, \alpha_{\text{aspect}}^2 \ll 1. \tag{30.57}$$

This result supports our initial suspicion that stratification suppresses vertical motion, thus reducing the vertical acceleration terms that break hydrostatic balance. That is, hydrostatic balance is more readily achieved for a stratified flow than for an unstratified flow. Note also that the horizontal divergence of the horizontal flow is reduced by the presence of stratification, which thus leads to a nearly horizontally non-divergent flow

$$\left| \widehat{\nabla} \cdot \widehat{\boldsymbol{u}} \right| = \left| \mathrm{Fr}^2 \, \frac{\partial \widehat{w}}{\partial \widehat{z}} \right| \ll \left| \frac{\partial \widehat{w}}{\partial \widehat{z}} \right|. \tag{30.58}$$

Finally, this scaling reveals how the hydrostatic approximation becomes less accurate when $\mathrm{Fr}^2 \, \alpha_{\text{aspect}}^2 \sim 1$, which occurs when stratification is weak and/or the aspect ratio order unity.

30.2.6 Horizontal hydrostatic pressure gradient

In Section 30.2.6 we studied the horizontal pressure gradient between two columns of constant density for a hydrostatic fluid. In that example, the two columns were assumed to have equal mass, so the fluid is non-Boussinesq. Here, we reconsider that example for a Boussinesq ocean where volume is conserved rather than mass.

The expression for the hydrostatic pressure at a point within the fluid takes on the same form

as that for a non-Boussinesq fluid (Section 28.2.1)

$$p_{\mathrm{h}}(x,y,z,t) = p_{\mathrm{a}}(x,y,t) + g\int_z^{\eta} \rho(x,y,z',t)\,\mathrm{d}z', \tag{30.59}$$

and the horizontal pressure gradient is thus given by

$$\nabla_z p_{\mathrm{h}} = \nabla_z p_{\mathrm{a}} + g\,\rho(\eta)\,\nabla_z\eta + g\int_z^{\eta} \nabla_z\rho\,\mathrm{d}z'. \tag{30.60}$$

For many studies with Boussinesq ocean, we are interested in the horizontal pressure gradients in the presence of a rigid lid ocean surface whereby $\eta = 0$. In this case we compute the *internal pressure gradient*

$$\nabla_z p_{\mathrm{h}} = g\int_z^{0} \nabla_z\rho\,\mathrm{d}z' \quad \text{rigid lid ocean.} \tag{30.61}$$

Hence, the internal horizontal pressure gradient at a vertical position z equals to the horizontal density gradient vertically integrated above that point. For example, if density increases poleward, then so too does the internal hydrostatic pressure.

30.2.7 Evolution of hydrostatic pressure

In Section 28.2.2 we developed the Eulerian evolution equation for hydrostatic pressure in a mass conserving non-Boussinesq fluid. Here we discuss the evolution in a Boussinesq ocean of the hydrostatic pressure at a point. To do so we take the Eulerian time tendency of the hydrostatic pressure (30.59), in which case

$$\partial_t p = \partial_t p_{\mathrm{a}} + g\,\rho(\eta)\,\partial_t\eta + \int_z^{\eta} \partial_t\rho(x,y,z',t)\,\mathrm{d}z'. \tag{30.62}$$

This equation holds for both the Boussinesq and non-Boussinesq ocean. However, it is only for the mass conserving non-Boussinesq ocean that we can use mass continuity (20.6) to set $\partial_t\rho = -\nabla\cdot(\boldsymbol{v}\,\rho)$. Use of Leibniz's rule then reveals that the hydrostatic pressure evolves due to the convergence of mass onto the fluid column above that point (see Section 28.2.2 for the derivation). This result is expected since the hydrostatic pressure at a point is the weight per area of fluid above that point.

For a Boussinesq ocean, the volume conserving kinematics means that we cannot replace $\partial_t\rho$ with $-\nabla\cdot(\boldsymbol{v}\,\rho)$. Correspondingly, the weight of a fluid column can change merely through *in situ* density changes, so that the weight can change even if the matter content remains fixed; e.g., through heating. We expose details by noting that energetic consistency from Section 30.8 meana that the *in situ* density in a Boussinesq ocean has the functional dependence, $\rho(S,\Theta,\Phi)$, with Φ the geopotential. Hence, the Eulerian time derivative of density is given by

$$\partial_t\rho = (\partial\rho/\partial S)\,\partial_t S + (\partial\Theta/\partial t)\,\partial_t\Theta + (\partial\rho/\partial\Phi)\,\partial_t\Phi. \tag{30.63}$$

With a simple geopotential, $\Phi = g\,z$, we have $\partial_t\Phi = 0$ since the Eulerian time derivative is computed at fixed (x,y,z). This result leads to the time changes in the hydrostatic pressure for a Boussinesq ocean

$$\partial_t p = \partial_t p_{\mathrm{a}} + g\,\rho(\eta)\,\partial_t\eta + \int_z^{\eta} [(\partial\rho/\partial S)\,\partial_t S + (\partial\Theta/\partial t)\,\partial_t\Theta]\,\mathrm{d}z'. \tag{30.64}$$

This equation reveals the direct dependence of the hydrostatic pressure on changes in S and

Θ. Hence, heating and freshening, which alter the *in situ* density, directly alter the hydrostatic pressure in a Boussinesq ocean by altering the fluid's weight per area. This result contrasts to the mass conserving non-Boussinesq fluid, whose weight per area changes only through changes to its mass per area.[8]

30.3 How pressure enforces non-divergent flow

We return now to the case of a non-hydrostatic fluid and consider the Boussinesq momentum equation (30.26a) written in the tangent plane form

$$\rho_0 \left(\partial_t + \boldsymbol{v} \cdot \nabla\right) \boldsymbol{v} + f\, \boldsymbol{z} \times \rho_0\, \boldsymbol{v} = -\nabla p - \rho\, g\, \hat{\boldsymbol{z}} + \rho_0\, \boldsymbol{F}. \tag{30.65}$$

The non-divergence constraint on the velocity, $\nabla \cdot \boldsymbol{v} = 0$, must be maintained at each point in the fluid and at each time instance. How is that constraint maintained? As we show in this section, pressure provides the force that maintains non-divergence. Furthermore, pressure is determined through solving an elliptic boundary value problem. As we discussed in Section 3.4, elliptic partial differential equations transfer information instantaneously. Physically, this situation corresponds to the transition from a compressible non-Boussinesq fluid, in which pressure signals propagate via acoustic waves (Chapter 49), to the incompressible flow of a Boussinesq ocean, in which pressure adjusts instantaneously just as if the acoustic waves traveled at infinite speed. The Boussinesq ocean sits between the compressible fluid and incompressible flow. That is, the Boussinesq prognostic velocity is non-divergent, and so it does not support acoustic waves, whereas the full velocity is divergent (Section 30.1.9), and this divergent portion supports acoustic waves, although such waves are never felt by the Boussinesq dynamical fields.

30.3.1 Poisson equation for pressure

To derive the pressure equation, we find it convenient to expose Cartesian tensor labels on the momentum equation (30.65)

$$\partial_t v_m + v_n \partial_n v_m + f\, \epsilon_{mnp}\, \delta_{3n}\, v_p = -\partial_m p/\rho_0 - \delta_{3m}\, g\, \rho/\rho_0 + F_m. \tag{30.66}$$

The time derivative is eliminated by taking the divergence through contracting with the operator ∂_m,

$$\partial_m \partial_t v_m = \partial_t \partial_m v_m = 0, \tag{30.67}$$

thus leading to

$$-\nabla^2 p/\rho_0 = \partial_m (v_n \partial_n v_m + f\, \epsilon_{m3p}\, v_p + \delta_{3m}\, g\, \rho/\rho_0 - F_m), \tag{30.68}$$

where the Laplacian operator is

$$\nabla^2 = \partial_m \partial_m. \tag{30.69}$$

Equation (30.68) can be written as the Poisson equation

$$-\nabla^2 p = \rho_0 \nabla \cdot \boldsymbol{G}, \tag{30.70}$$

with the vector $\boldsymbol{G}$ given by

$$G_m = v_n \partial_n v_m + f\, \epsilon_{m3p}\, v_p + \delta_{3m}\, g\, \rho/\rho_0 - F_m \tag{30.71a}$$

$$\boldsymbol{G} = (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{v} + g\, (\rho/\rho_0)\, \hat{\boldsymbol{z}} - \boldsymbol{F}. \tag{30.71b}$$

[8] I believe we return to this point, but do not know where. Need to cross-reference.

As when studying Green's functions in Chapter 5, it is useful to maintain the minus sign on the left hand side of equation (30.70) so that a positive divergence ($\nabla \cdot \boldsymbol{G} > 0$) represents a positive source for p. Equivalently, for a wavelike pressure perturbation we have

$$-\nabla^2 p \propto p, \tag{30.72}$$

so that a positive source, $-\nabla^2 p = \rho_0 \nabla \cdot \boldsymbol{G} > 0$, leads to a local positive pressure anomaly, and conversely for a negative source.

30.3.2 Boundary conditions

To derive the boundary conditions for the Poisson equation (30.70), we find it useful to write the velocity equation as

$$\partial_t \boldsymbol{v} = -\nabla p/\rho_0 - \boldsymbol{G}. \tag{30.73}$$

We consider a variety of boundaries in the following.

Static material surface

For a static material boundary we can make use of the no normal flow kinematic boundary condition (Section 20.4.1), in which case

$$\hat{\boldsymbol{n}} \cdot \partial_t \boldsymbol{v} = \partial_t \left(\hat{\boldsymbol{n}} \cdot \boldsymbol{v} \right) = 0 \Longrightarrow \left(\nabla p + \rho_0 \, \boldsymbol{G} \right) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{for static material boundaries.} \tag{30.74}$$

This boundary condition takes the form

$$\hat{\boldsymbol{n}} \cdot \nabla p = -\rho_0 \, \boldsymbol{G} \cdot \hat{\boldsymbol{n}} \qquad \text{for static material boundaries.} \tag{30.75}$$

Hence, maintenance of the no normal flow condition along a static material boundary requires a corresponding *Neumann boundary condition* for pressure.

Upper ocean free surface

The ocean free surface is generally dynamic and permeable, so that the velocity does not satisfy a no normal flow condition along this surface (see Section 20.4). To develop the pressure boundary condition at the free surface, we invoke a dynamical principle rather than a kinematic principle. Namely, we invoke continuity of pressure across an interface, which follows from Newton's third law (recall our discussion of stress along an interface in Section 26.10). Hence, the pressure condition at the ocean free surface is the *Dirichlet boundary condition*

$$p = p_{\text{applied}} \quad \text{at } z = \eta(x, y, t), \tag{30.76}$$

where p_{applied} is the pressure applied to the ocean surface from the overlying atmosphere or cryosphere.

30.3.3 Characterizing the pressure sources

The right hand side of the Poisson equation (30.70) contains four sources for the pressure field. Linearity of the Poisson equation allows us to separately study the pressure resulting from these sources, with the net pressure the sum. We here summarize their basic features, borrowing from the treatment given in Section 39.4 for the kinematically simpler non-divergent barotropic model. As we find, three of the pressure sources contribute to non-hydrostatic pressures and

one to hydrostatic pressure. Note that these pressure sources are *associated* with the pressure perturbations rather than *causing* the perturbations. Such is part of the nuance of pressure in a non-divergent flow.

Divergence of self-advection

The first source is given by the divergence of self-advection, which can be written

$$\nabla \cdot \boldsymbol{G}_{\text{self-advect}} = \partial_n(v_m\, \partial_m v_n) = (\partial_n v_m)\,(\partial_m v_n) + v_m\,(\partial_n \partial_m v_n) = (\partial_n v_m)\,(\partial_m v_n), \tag{30.77}$$

where we set

$$v_m\, \partial_n \partial_m v_n = v_m\, \partial_m \partial_n v_n = 0 \tag{30.78}$$

since $\partial_n v_n = 0$ follows from the non-divergent nature of the flow. Furthermore, introducing the strain rate tensor ($\mathbb{S}$ from equation (19.43a)) and rotation tensor ($\mathbb{R}$ equation (19.43b)), renders

$$2\,\mathbb{S}_{mn}\,\mathbb{S}_{mn} = (\partial_m v_n)\,(\partial_m v_n) + (\partial_m v_n)\,(\partial_n v_m) \tag{30.79}$$

$$2\,\mathbb{R}_{mn}\,\mathbb{R}_{mn} = (\partial_m v_n)\,(\partial_m v_n) - (\partial_m v_n)\,(\partial_n v_m), \tag{30.80}$$

so that

$$\nabla \cdot \boldsymbol{G}_{\text{self-advect}} = (\partial_n v_m)\,(\partial_m v_n) = \underbrace{\mathbb{S}_{mn}\,\mathbb{S}_{mn}}_{\text{splat}} - \underbrace{\mathbb{R}_{mn}\,\mathbb{R}_{mn}}_{\text{spin}}. \tag{30.81}$$

The vorticity or spin source provides a negative source to $-\nabla^2 p$. In contrast, the contribution from strain, sometimes referred to as *splat*, provides a positive source.[9] As detailed for horizontally non-divergent barotropic flow in Section 39.4, we understand why there is a negative pressure source from vortical (spinning) motion since, to retain a non-divergent flow, pressure must counteract the centrifugal acceleration arising from curved fluid motion. Likewise, a positive pressure source associated with straining motion is needed to counteract the convergent accelerations induced by strains.

Divergence of the Coriolis acceleration

The divergence of the Coriolis acceleration introduces a pressure source given by

$$-\nabla \cdot \nabla p_{\text{coriolis}} = \nabla \cdot \boldsymbol{G}_{\text{coriolis}} = \nabla \cdot (f\,\hat{\boldsymbol{z}} \times \boldsymbol{v}) = \beta\, u - f\,\zeta, \tag{30.82}$$

where $\zeta = \partial_x v - \partial_y u$ is the vertical component to the relative vorticity, and $\beta = \partial_y f$ is the planetary vorticity gradient. To help understand the $f\,\zeta$ term, consider two-dimensional flow with a cyclonic relative vorticity so that $f\,\zeta > 0$. Cyclonic flow feels an associated centrifugal acceleration directed "outward". To maintain a non-divergent two-dimensional flow requires an oppositely directed "inward" pressure gradient force. Hence, such rotating flow induces a low pressure source as a means to counteract the centrifugal acceleration

$$-\nabla \cdot \nabla p_{\text{coriolis}} < 0. \tag{30.83}$$

See section 39.4.6 for more discussion of this source as found in the non-divergent barotropic fluid.

[9] The whimsically named *splat* source is so-named since it is large when a fluid element is squashed in a manner increasing fluid strains, akin to how strains appear when a fluid impacts or "splats" against a solid obstacle. Imagine a water balloon thrown against a wall.

Divergence of the gravitational force per volume

The divergence of the gravitational force per volume is given by

$$-\nabla \cdot \nabla p_{\text{gravity}} = \rho_0 \nabla \cdot \boldsymbol{G}_{\text{gravity}} = \nabla \cdot (g\,\rho\,\hat{\boldsymbol{z}}) = g\,\partial_z \rho, \tag{30.84}$$

with this pressure source absent in the depth-independent barotropic fluid of Section 39.4. The associated pressure gradient is that arising from the local hydrostatic component of the pressure field in which

$$\nabla \cdot (-\nabla p_{\text{gravity}} + g\,\rho\,\hat{\boldsymbol{z}}) = 0. \tag{30.85}$$

In regions where density decreases upward, $\partial_z \rho < 0$, a compressible fluid element that conserves its mass will expand when moving upward into less dense fluid. For a non-divergent flow that conserves the volume of fluid elements, there must be a counteracting force from pressure to halt the expansion of a fluid element. This counteracting force arises from the hydrostatic component to the pressure field that acts inward to squeeze the fluid element, with this pressure force originating from the negative pressure source, $-\nabla^2 p_{\text{gravity}} = g\,\partial_z \rho < 0$.

Divergence of the friction vector

The third source arises from the divergence of friction,

$$-\nabla \cdot \nabla p_{\text{friction}} = \rho_0 \nabla \cdot \boldsymbol{G}_{\text{friction}} = -\rho_0\,\nabla \cdot \boldsymbol{F}. \tag{30.86}$$

With interior fluid friction arising from a nonzero strain rate (Section 26.8), we expect this pressure source to be most important in regions of large strains. Indeed, for an incompressible flow feeling only molecular viscosity, the friction operator is given by (see Section 26.8.7)

$$\boldsymbol{F} = \nu\,\nabla^2 \boldsymbol{v}, \tag{30.87}$$

where $\nu > 0$ is a constant molecular viscosity. In this case $\nabla \cdot \boldsymbol{F} = 0$, so that viscous friction does not contribute a pressure source. More general cases are considered in applications where the molecular viscosity is replaced by a flow dependent eddy viscosity so that $\nabla \cdot \boldsymbol{F} \neq 0$. For the case of a converging frictional acceleration, $\nabla \cdot \boldsymbol{F} < 0$, friction then leads to a positive pressure source to counteract the friction to thus maintain a non-divergent flow.

30.3.4 Comments and further study

The gravitational source contributes a local hydrostatic component to the pressure field, whereas the other three sources contribute non-hydrostatic pressure sources. In many applications, such as general circulation modeling of the ocean and atmosphere, the fluid is assumed to be approximately hydrostatic (Chapter 28). In this case vertical motion is diagnosed rather than prognosed, and the non-hydrostatic component of pressure is never needed to evolve the fluid motion. Even so, vertical derivatives in the non-hydrostatic pressure provide the vertical force needed for vertical accelerations. We have more to say on vertical motion in Section 31.9.

Markowski and Richardson (2010) provide lucid discussions of pressure forces acting in geophysical fluids. In particular their Section 2.5 inspired much of the current section.

30.4 Helmholtz decomposing the velocity equation

In this section we introduce some mathematical properties of the velocity equation for a Boussinesq ocean in a simply connected ocean domain, $\mathcal{R}$, with boundary, $\partial\mathcal{R}$. For this purpose, we again

assume a tangent plane and so write the velocity equation (30.65) in the form

$$\partial_t \boldsymbol{v} = -\nabla p/\rho_0 - \boldsymbol{G}, \tag{30.88}$$

where $\boldsymbol{G}$, as given by equation (30.71b), contains the various accelerations sans the pressure gradient

$$\boldsymbol{G} = (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{v} + g\,(\rho/\rho_0)\,\hat{\boldsymbol{z}} - \boldsymbol{F}. \tag{30.89}$$

30.4.1 Helmholtz decomposition

The Helmholtz decomposition from Section 3.7 says that on a simply connected domain, an arbitrary vector, such as the acceleration $\boldsymbol{G}$, can be decomposed as

$$\boldsymbol{G} = \boldsymbol{G}^{\text{rot}} + \boldsymbol{G}^{\text{div}} \tag{30.90}$$

where the two vectors on the right hand side satisfy

$$\nabla\cdot\boldsymbol{G}^{\text{rot}} = 0 \quad \text{and} \quad \nabla\times\boldsymbol{G}^{\text{rot}} \neq 0 \qquad \boldsymbol{G}^{\text{rot}} \text{ is divergent-free} \tag{30.91a}$$

$$\nabla\times\boldsymbol{G}^{\text{div}} = 0 \quad \text{and} \quad \nabla\cdot\boldsymbol{G}^{\text{div}} \neq 0 \qquad \boldsymbol{G}^{\text{div}} \text{ is curl-free.} \tag{30.91b}$$

We make use of the Helmholtz decomposition for a Boussinesq ocean by noting that the non-divergent velocity only has a rotational contribution

$$\boldsymbol{v} = \boldsymbol{v}^{\text{rot}}, \tag{30.92}$$

whereas the pressure gradient only has a divergent component

$$\nabla p = (\nabla p)^{\text{div}}. \tag{30.93}$$

In contrast, the acceleration, $\boldsymbol{G}$, generally has a rotational, a divergent, and a harmonic component as written in equation (30.90).

30.4.2 The pressure equation

Making use of the Helmholtz decomposition (30.90) brings the velocity equation (30.88) into the form

$$\partial_t \boldsymbol{v} = -\nabla p/\rho_0 - \boldsymbol{G}^{\text{rot}} - \boldsymbol{G}^{\text{div}}. \tag{30.94}$$

The accelerations, $\partial_t\boldsymbol{v}$, and $\boldsymbol{G}^{\text{rot}}$, are each divergent-free. In contrast, the accelerations, $-\nabla p/\rho_0$ and $\boldsymbol{G}^{\text{div}}$, each have nonzero divergence. Self-consistency is maintained if the sum, $\nabla p/\rho_0 + \boldsymbol{G}^{\text{div}}$, has zero divergence so that

$$\nabla\cdot(\nabla p/\rho_0 + \boldsymbol{G}^{\text{div}}) = 0 \Longrightarrow -\nabla^2 p = \rho_0\,\nabla\cdot\boldsymbol{G}^{\text{div}} = \rho_0\,\nabla\cdot\boldsymbol{G}. \tag{30.95}$$

This is the Poisson equation for the pressure field already derived in Section 30.3.1. We go one further step by observing that $\nabla p/\rho_0 + \boldsymbol{G}^{\text{div}}$ is both curl-free and divergent-free, which we write as

$$\nabla p/\rho_0 + \boldsymbol{G}^{\text{div}} = \boldsymbol{H} \quad \text{with} \quad \nabla\cdot\boldsymbol{H} = \nabla\times\boldsymbol{H} = 0. \tag{30.96}$$

30.4.3 The vorticity equation

As for the pressure equation in Section 30.4.2, we note that the accelerations $\nabla p/\rho_0$, and $\boldsymbol{G}^{\text{div}}$, are each curl-free. In contrast, the accelerations, $\partial_t\boldsymbol{v}$ and $\boldsymbol{G}^{\text{rot}}$, each have nonzero curl. Self-

consistency thus requires $\partial_t \boldsymbol{v} + \boldsymbol{G}^{\text{rot}}$ to be curl-free

$$\nabla \times (\partial_t \boldsymbol{v} + \boldsymbol{G}^{\text{rot}}) = 0 \Longrightarrow \partial_t (\nabla \times \boldsymbol{v}) = -\nabla \times \boldsymbol{G}^{\text{rot}}, \tag{30.97}$$

which is the relative vorticity equation that we further study in Chapter 41. Going one step further we note that the vector $\partial_t \boldsymbol{v} + \boldsymbol{G}^{\text{rot}}$ is both curl-free and divergent-free, which we write as

$$\partial_t \boldsymbol{v} + \boldsymbol{G}^{\text{rot}} = \boldsymbol{I} \quad \text{with} \quad \nabla \cdot \boldsymbol{I} = \nabla \times \boldsymbol{I} = 0. \tag{30.98}$$

30.4.4 The velocity equation

The above considerations have led us to the pressure gradient equation (30.96) and the velocity tendency equation (30.98)

$$\nabla p/\rho_0 + \boldsymbol{G}^{\text{div}} = \boldsymbol{H} \tag{30.99}$$

$$\partial_t \boldsymbol{v} + \boldsymbol{G}^{\text{rot}} = \boldsymbol{I}, \tag{30.100}$$

where both $\boldsymbol{H}$ and $\boldsymbol{I}$ are divergent-free and curl-free. Adding these two equations leads to

$$\partial_t \boldsymbol{v} = -\nabla p/\rho_0 - \boldsymbol{G}^{\text{rot}} - \boldsymbol{G}^{\text{div}} + \boldsymbol{H} + \boldsymbol{I}, \tag{30.101}$$

with this form of the velocity equation equivalent to the original Helmholtz decomposed equation (30.94) if we set

$$\boldsymbol{H} + \boldsymbol{I} = 0. \tag{30.102}$$

30.4.5 Comments

This section was inspired by *Marshall and Pillar* (2011), who applied a Helmholtz decomposition to study the variety of accelerations appearing in the Boussinesq velocity equation. A particularly revealing result of this decomposition, when setting $\boldsymbol{H} = \boldsymbol{I} = 0$, is the ability to make a 1-to-1 connection between terms in the Helmholtz decomposed velocity equation with terms in the relative vorticity equation. This correspondence can support dynamical understanding.

30.5 Tracer budgets in Eulerian regions

We are commonly interested in the tracer budget for a fluid region, and we examined a variety of regions in Section 21.2 for a compressible fluid. Here, we expose issues that arise for tracer budgets in a Boussinesq ocean, whereby the flow is non-divergent. We specialize to the study of an Eulerian region, $\mathcal{R}$, and emphasize how the non-divergent flow constrains the advective tracer transport and affects changes to the volume integrated tracer content.

30.5.1 Formulating the budget equation

Consider a tracer concentration, C, and compute its net content over an Eulerian region, $\mathcal{R}$

$$\rho_0 \int_{\mathcal{R}} C \, \mathrm{d}V = \rho_0 \, V \, \langle C \rangle, \tag{30.103}$$

where C satisfies the tracer equation

$$\partial_t (\rho_0 \, C) + \nabla \cdot (\rho_0 \, C \, \boldsymbol{v} + \boldsymbol{J}) = 0, \tag{30.104}$$

and

$$\langle C \rangle = \frac{\int_{\mathcal{R}} C \, \mathrm{d}V}{\int_{\mathcal{R}} \mathrm{d}V} = \frac{1}{V} \int_{\mathcal{R}} C \, \mathrm{d}V \tag{30.105}$$

is the volume averaged tracer concentration within the Eulerian region with fixed volume, $V = \int_{\mathcal{R}} \mathrm{d}V$. Following from the discussion of tracer budgets in Section 21.2, we have

$$\rho_0 \frac{\mathrm{d}(V \langle C \rangle)}{\mathrm{d}t} = \rho_0 \, V \, \frac{\mathrm{d}\langle C \rangle}{\mathrm{d}t} \tag{30.106a}$$

$$= \rho_0 \frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{R}} C \, \mathrm{d}V \tag{30.106b}$$

$$= \int_{\mathcal{R}} \frac{\partial(\rho_0 \, C)}{\partial t} \, \mathrm{d}V \tag{30.106c}$$

$$= - \int_{\mathcal{R}} \nabla \cdot (\rho_0 \, C \, \boldsymbol{v} + \boldsymbol{J}) \, \mathrm{d}V \tag{30.106d}$$

$$= - \oint_{\partial \mathcal{R}} (\rho_0 \, C \, \boldsymbol{v} + \boldsymbol{J}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{30.106e}$$

where we used the divergence theorem on the final equality with $\partial \mathcal{R}$ the boundary of $\mathcal{R}$ and the outward normal $\hat{\boldsymbol{n}}$. Changes in the total tracer contained within the region arise from the convergence of boundary fluxes due to the non-advective flux, $\boldsymbol{J}$, plus convergence of the advective tracer flux, $\rho_0 \, C \, \boldsymbol{v}$. Since the region volume is constant in time, changes in the total tracer content directly affect the volume averaged tracer concentration, $\langle C \rangle$.

At any point along the boundary, the tracer content is modified if there is a non-advective flux, $\boldsymbol{J}$, directed across the boundary. There is no *a priori* constraint on $\boldsymbol{J}$, with local properties determining its sign and magnitude. In contrast, contributions from the boundary advective flux are constrained due to the non-divergent nature of the Boussinesq velocity, which we discuss next.

30.5.2 Interpreting advective tracer contributions

As seen by equation (30.106e), any advective flux, $\rho_0 \, \boldsymbol{v} \, C$, that is directed into the region adds tracer to the region, whereas a flux directed outward reduces the region's tracer content. However, because the velocity is non-divergent, the tracer contained within the region is unaffected if we modify the advective tracer flux along the boundary by adding a number that is constant over the region $\mathcal{R}$. We see this property for any closed Eulerian region by writing[10]

$$0 = \int_{\mathcal{R}} \nabla \cdot \boldsymbol{v} \, \mathrm{d}V = \oint_{\partial \mathcal{R}} \boldsymbol{v} \cdot \boldsymbol{n} \, \mathrm{d}\mathcal{S}. \tag{30.107}$$

Hence, the velocity is, at each time instance, constrained so that the non-divergent flow cannot lead to the accumulation of fluid within any closed and static region. Correspondingly, the amount of fluid entering $\mathcal{R}$ exactly and instantaneously balances the amount of fluid leaving $\mathcal{R}$. We can thus add any spatial constant, k, to the advective flux without affecting the net tracer content change

$$\oint_{\partial \mathcal{R}} (C + k) \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{R}} C \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} + k \oint_{\partial \mathcal{R}} \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{R}} C \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{30.108}$$

Boundary advection occuring with $C = k$ has no affect on the net tracer within a region since an equal amount of fluid enters as leaves.

[10] We considered property (30.107) in Exercise 22.4.

To help interpret the role of advective fluxes on integrated tracer content, we find it useful to set the arbitrary spatial constant to $k = -\langle C \rangle$. In this manner, the advective contribution to the tracer budget takes the form

$$V \left[\frac{\mathrm{d}\langle C \rangle}{\mathrm{d}t} \right]_{\text{advective}} = -\oint_{\partial \mathcal{R}} C \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = -\oint_{\partial \mathcal{R}} (C - \langle C \rangle) \, \boldsymbol{v} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{30.109}$$

Hence, advective transport through the region boundary changes the region integrated C, and thus the volume mean $\langle C \rangle$, only if the boundary transport occurs with C values that differ from the region average, $\langle C \rangle$.

30.5.3 A rectangular region example

FIGURE 30.1: A rectangular ocean region for considering the tracer budget in a Boussinesq ocean. We assume the only open boundaries of the region are along the southern boundary and top boundary, with the remaining boundaries closed. Note that the top boundary can generally be within the ocean interior, and so does not need to be the top of the ocean. The non-divergent nature of the flow means that any fluid entering through the southern boundary must leave through the top boundary, and conversely. This constraint on the flow impacts on how the advective tracer transport affects changes to the volume integrated tracer within the region.

Consider the rectangular region of Figure 30.1 that is closed along its bottom, northern, eastern, and western boundaries, yet that is open along its top boundary and southern boundary. Specify flow along the southern boundary to be northward and let it bring fluid into the region with $C_{\text{south}} > \langle C \rangle$, thus acting to increase $\langle C \rangle$. Due to the non-divergent nature of the velocity, the northward transport of fluid through the southern boundary is exactly balanced by a vertically upward transport of fluid out of the top boundary. What does that vertical transport of fluid imply about changes to $\langle C \rangle$? The answer depends on the tracer concentration on the top boundary.

- If $C_{\text{top}} > \langle C \rangle$, then the relatively high values of tracer that leave through the top boundary act to decrease the net C within the region, thus counteracting the contribution of $C_{\text{south}} > \langle C \rangle$ that enters through the southern boundary. For the special case of equal C transports through the two boundaries, then there is no accumulation of C within the region so that $\langle C \rangle$ remains unchanged.

- If $C_{\text{top}} = \langle C \rangle$, then $\langle C \rangle$ increases due to the transport of C through the southern boundary, with no net transport across the top boundary.

- If $C_{\text{top}} < \langle C \rangle$, then the vertical transport of $C_{\text{top}} < \langle C \rangle$ increases $\langle C \rangle$ acting just like the $C_{\text{south}} > \langle C \rangle$ fluid that enters through the southern boundary. That is, we can increase $\langle C \rangle$ in the region by bringing fluid into the domain with C greater than $\langle C \rangle$, or by exporting fluid with C less than $\langle C \rangle$.

30.5.4 Comments

Constraints introduced by the non-divergent nature of the Boussinesq ocean render subtleties to the physical interpretation of how tracer fluxes affect the budget of tracer within a region. These constraints are absent from the compressible fluid, whose flow is generally divergent. The discussion in this section was motivated by Appendix B of *Gregory* (2000), who studied heat (enthalpy) budgets within a numerical Boussinesq ocean circulation model.

30.6 Mechanical energy analysis: Part I

The volume of a fluid element in a non-divergent flow remains materially invariant even as pressure acts on the element. Hence, pressure cannot perform mechanical work on the fluid. Consequently, a non-divergent flow supports no pressure work conversion between internal energy and kinetic energy, which contrasts to the case in a non-Boussinesq fluid (see Section 27.4). In this section we formulate a mechanical energy budget for the Boussinesq ocean, and find that this budget is closed for a perfect fluid so long as the geopotential is time-independent and there are no boundary effects. Many of the steps are directly analogous to those in a non-Boussinesq fluid detailed in Chapter 27, though with some important distinctions that are emphasized in this section as well as Section 30.8.

30.6.1 Governing equations

We develop the mechanical energy budget for an unforced non-hydrostatic Boussinesq ocean with density a function only of salinity and Conservative Temperature,

$$\rho = \rho(S, \Theta). \tag{30.110}$$

The more general pressure-dependent equation of state is considered in Section 30.8. Furthermore, we work with the velocity, density, and continuity equations in the form

$$\rho_0 \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} \right] = -\nabla p - \rho\,\nabla\Phi \tag{30.111a}$$

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{\partial \rho}{\partial S}\frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial \rho}{\partial \Theta}\frac{\mathrm{D}\Theta}{\mathrm{D}t} = \dot{\rho} \tag{30.111b}$$

$$\nabla \cdot \boldsymbol{v} = 0. \tag{30.111c}$$

Note that the geopotential, Φ, is generally a function of space and time, $\Phi = \Phi(\boldsymbol{x}, t)$, with thiisi dependence appropriate when studying astronomical tides or mass inhomogeneities creating spatial variations in the gravity field (see Chapter 35).

30.6.2 Kinetic energy

To obtain a kinetic energy equation, start by taking the dot product of the velocity, $\boldsymbol{v}$, and the momentum equation (30.111a) and note that the Coriolis acceleration drops out since it is

orthogonal to the velocity

$$\boldsymbol{v} \cdot (2\,\boldsymbol{\Omega} \times \boldsymbol{v}) = 0. \tag{30.112}$$

The material time derivative takes the form

$$v_i \left[\frac{\partial v_i}{\partial t} + v_j \partial_j v_i \right] = \frac{\partial \mathcal{K}}{\partial t} + \boldsymbol{v} \cdot \nabla \mathcal{K} = \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t}, \tag{30.113}$$

where we introduced the kinetic energy per mass

$$\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2. \tag{30.114}$$

The equation for the Boussinesq kinetic energy per volume thus takes the form

$$\rho_0 \, \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\boldsymbol{v} \cdot \nabla p - \rho \, \boldsymbol{v} \cdot \nabla \Phi. \tag{30.115}$$

Alternatively, we can write this equation in the flux-form

$$\frac{\partial (\rho_0 \, \mathcal{K})}{\partial t} + \nabla \cdot [\boldsymbol{v} \, (\rho_0 \, \mathcal{K} + p)] = -\rho \, \boldsymbol{v} \cdot \nabla \Phi, \tag{30.116}$$

where we used $\nabla \cdot \boldsymbol{v} = 0$ to write $\boldsymbol{v} \cdot \nabla p = \nabla \cdot (\boldsymbol{v} \, p)$. Note that in Exercise 30.4 we show that the kinetic energy evolution derived here for the non-hydrostatic fluid holds also for the hydrostatic fluid, yet with the kinetic energy in the hydrostatic fluid determined solely by the horizontal velocity.

The term $-\rho \, \boldsymbol{v} \cdot \nabla \Phi$ in the kinetic energy equation (30.116) is a source/sink that arises from fluid motion crossing surfaces of constant geopotential. Moving a fluid element down the geopotential gradient ($\boldsymbol{v} \cdot \nabla \Phi < 0$) increases the kinetic energy, and conversely when the fluid moves up the geopotential gradient. We sometimes refer to this process as *buoyancy work*, particularly when considered in the context of a vertically stratified fluid. We can further exemplify this term by taking the simplified form of the geopotential, $\Phi = g \, z$, in which $\boldsymbol{v} \cdot \nabla \Phi = g \, w$.

30.6.3 Gravitational potential and mechanical energies

We here develop the gravitational energy budget and then add to the kinetic energy to derive the mechanical energy budget.

Gravitational potential energy

A fluid element has a gravitational potential energy per mass given by the geopotential, Φ, which has a material time derivative

$$\frac{\mathrm{D}\Phi}{\mathrm{D}t} = \partial_t \Phi + \boldsymbol{v} \cdot \nabla \Phi. \tag{30.117}$$

The time-dependent geopotential provides an external source of potential energy to the system. Additionally, motion moving up the gradient of the geopotential ($\boldsymbol{v} \cdot \nabla \Phi > 0$) increases the potential energy per mass, and conversely for motion down the geopotential gradient.

Mechanical energy budget

Adding the gravitational potential energy equation (30.117) to the kinetic energy equation (30.115) renders the material evolution

$$\rho_0 \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} + \rho \frac{\mathrm{D}\Phi}{\mathrm{D}t} = -\nabla \cdot (\boldsymbol{v}\, p) + \rho\, \partial_t \Phi. \tag{30.118}$$

Note how the buoyancy work source, $\rho\, \boldsymbol{v} \cdot \nabla \Phi$, dropped out from this budget. Consequently, this term provides a reversible transfer of mechanical energy between gravitational potential energy per volume and the kinetic energy per volume. We saw the same transfer in Section 27.4 when studying the mechanical energy budget for a compressible non-Boussinesq fluid.

Equation (30.118) has nearly the same form as that for the non-Boussinesq fluid given by equation (27.49). However, for the Boussinesq ocean it does not lead to a flux-form conservation law for mechanical energy, even for the perfect fluid. Operationally, the derivations diverge at this point since for the non-Boussinesq fluid we make use of the mass continuity equation (20.6) to write the material evolution of density. In contrast, material density evolution in a Boussinesq ocean is determined by material changes in temperature, salinity, and pressure.

To develop a closed Boussinesq mechanical energy budget, add $\Phi\, \mathrm{D}\rho/\mathrm{D}t = \Phi\, \dot{\rho}$ to both sides of equation (30.118) to render the material evolution for the mechanical energy *per volume*

$$\frac{\mathrm{D}}{\mathrm{D}t} [\rho_0\, \mathcal{K} + \rho\, \Phi] = -\nabla \cdot (\boldsymbol{v}\, p) + \rho\, \partial_t \Phi + \dot{\rho}\, \Phi, \tag{30.119}$$

which has the flux-form expression

$$\partial_t\, (\rho_0\, \mathcal{M}) + \nabla \cdot [\boldsymbol{v}\, (\rho_0\, \mathcal{M} + p)] = \rho\, \partial_t \Phi + \dot{\rho}\, \Phi, \tag{30.120}$$

where we defined the Boussinesq mechanical energy per volume as

$$\rho_0\, \mathcal{M} = \rho_0\, \mathcal{K} + \rho\, \Phi. \tag{30.121}$$

Note the ρ_0 determining the kinetic energy per volume, whereas ρ determines the gravitational potential energy. These distinct density factors result from the distinction made in the Boussinesq ocean between inertial mass and gravitational mass. We discussed this point in the opening to this chapter.

30.6.4 Finite volume mechanical energy bugdet

Recall that a scalar tracer concentration, C, satisfies a flux-form equation of the form (30.104)

$$\partial_t(\rho_0\, C) + \nabla \cdot (\rho_0\, C\, \boldsymbol{v} + \boldsymbol{J}) = 0, \tag{30.122}$$

where $\boldsymbol{J}$ is a subgrid tracer flux. Comparing to the mechanical energy equation (30.120), we see that mechanical energy has a non-zero source on the right hand side that cannot be written as the divergence of a flux. Additionally, the tracer vector, $\boldsymbol{J}$, corresponds in the energy equation to the pressure flux, $p\, \boldsymbol{v}$. With these correspondences between the tracer equation and mechanical energy equation, we can make direct use of the Leibniz-Reynolds transport theorem in the form of equation (21.49) to render the finite volume mechanical energy budget

$$\frac{\mathrm{d}}{\mathrm{d}t} \left[\int_{\mathcal{R}} \rho_0\, \mathcal{M}\, \mathrm{d}V \right] = -\oint_{\partial\mathcal{R}} \rho_0\, \mathcal{M}\, (\boldsymbol{v} - \boldsymbol{v}^{(\mathrm{b})}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \oint_{\partial\mathcal{R}} p\, \boldsymbol{v} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{R}} [\rho\, \partial_t \Phi + \dot{\rho}\, \Phi]\, \mathrm{d}V, \tag{30.123}$$

where $\mathcal{R}$ is the finite volume region, $\partial\mathcal{R}$ is its boundary, $\boldsymbol{v}^{(\mathrm{b})}$ is the velocity of a point on the boundary, and $\hat{\boldsymbol{n}}$ is the outward normal on the boundary. The first term on the right hand side arises from the advective transport of mechanical energy across the moving region boundary, taking into account the difference between the fluid velocity and boundary velocity. The second term arises from the work done by pressure on the boundary, and the final term arises from time dependence to the geopotential plus material changes in density. It is notable that the flow is non-divergent at each point, so that pressure cannot do work in the interior of the region. Even so, pressure can do work on the boundary of the region where $\boldsymbol{v}\cdot\hat{\boldsymbol{n}} \neq 0$. Observe that the budget (30.123) for a Boussinesq fluid corresponds to the budget (27.55) for a non-Boussinesq fluid.

A material region is characterized by $(\boldsymbol{v}-\boldsymbol{v}^{(\mathrm{b})})\cdot\hat{\boldsymbol{n}} = 0$ on the boundaries, in which case there is no transport of mechanical energy across the boundary. We are thus left with the mechanical energy budget (30.123)

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho_0\, \mathcal{M}\, \mathrm{d}V\right] = -\oint_{\partial\mathcal{R}} p\, \boldsymbol{v}\cdot\hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{R}} (\rho\, \partial_t\Phi + \dot{\rho}\, \Phi)\, \mathrm{d}V. \tag{30.124}$$

Recall we are assuming $\rho = \rho(S,\Theta)$ in this section, so that

$$\dot{\rho} = (\partial\rho/\partial S)\, \dot{S} + (\partial\rho/\partial\Theta)\, \dot{\Theta}. \tag{30.125}$$

Hence, for a time-independent geopotential ($\partial_t\Phi = 0$) and in the absence of processes that contribute to a material evolution of S and Θ (i.e., $\dot{S} = 0$ and $\dot{\Theta} = 0$), then the finite volume Boussinesq mechanical energy for a material fluid region is affected only by pressure work on the boundaries.[11]

30.7 Boussinesq energetics with molecular dissipation

The ocean is a forced-dissipative system, with mechanical and buoyant forcing predominantly at the surface and bottom boundaries and mechanical dissipation via molecular viscosity. In this section we extend the discussion from Section 30.6 to here develop the mechanical energy budget in a Boussinesq ocean affected by forcing and dissipation. Much of this discussion represents a specialization of the more general presentation of energetics in Chapter 27, here focusing on the ocean interior and considering the addition of buouyancy sources.

In particular, we examine energetics for the Boussinesq ocean equations written in their form with Archimedean buoyancy

$$\mathrm{D}\boldsymbol{v}/\mathrm{D}t + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} = -\nabla\varphi + \hat{\boldsymbol{z}}\, b + \nabla\cdot\mathbb{T}/\rho_0 \tag{30.126a}$$

$$\mathrm{D}b/\mathrm{D}t = -\nabla\cdot\boldsymbol{F}^{\mathrm{b}} + Q_{\mathrm{b}} \tag{30.126b}$$

$$\nabla\cdot\boldsymbol{v} = 0. \tag{30.126c}$$

The term $\nabla\cdot\mathbb{T}/\rho_0$ is the divergence of a friction stress tensor, $-\nabla\cdot\boldsymbol{F}^{\mathrm{b}}$ is the convergence of a buoyancy flux vector, and Q_{b} is a buoyancy source either at the boundaries or the interior. The new element in this discussion, relative to Chapter 27, concerns the role of the buoyancy flux. One operational point to note is that for all subgrid scale and boundary conditions in a Boussinesq ocean, appearances of the *in situ* density present in a non-Boussinesq fluids are here converted to the Boussinesq reference density, ρ_0.

[11] We find that $\dot{S}$ and $\dot{\Theta}$ are nonzero in the presence of boundary processes (e.g., heat fluxes, fresh water fluxes) and in the presence of mixing (e.g., as parameterized by diffusion). We study diffusion in Chapter 64 and then in Chapter 68 we provide a detailed look at the suite of processes contributing to nonzero $\dot{S}$ and $\dot{\Theta}$.

30.7.1 Forms for the buoyancy flux

Buoyancy flux for large-scale flows

For large-scale flows a particularly common form for the buoyancy flux is taken as

$$\boldsymbol{F}^{\mathrm{b}} = -\kappa\, \partial_z b\, \hat{\boldsymbol{z}} + \boldsymbol{v}^* b. \tag{30.127}$$

The first term is a downgradient vertical diffusive flux with the vertical *eddy diffusivity*, $\kappa > 0$, a function of the flow state so that

$$\kappa = \kappa(\boldsymbol{x}, t). \tag{30.128}$$

The second term is an advective flux, where the advective velocity, $\boldsymbol{v}^* = (\boldsymbol{u}^*, w^*)$, is assumed to be non-divergent

$$\nabla \cdot \boldsymbol{v}^* = \nabla_z \cdot \boldsymbol{u}^* + \partial_z w^* = 0. \tag{30.129}$$

The velocity, $\boldsymbol{v}^*$, is commonly termed the *eddy-induced* velocity, with a particular choice for its parameterization discussed in Exercise 30.9 and further examined in Section 66.1.

Boundary conditions

The normal component of the buouyancy flux vanishes at boundaries

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{F}^{\mathrm{b}} = 0, \tag{30.130}$$

so that boundary buoyancy fluxes are assumed to sit within the source term, Q_{b}, via

$$Q_{\mathrm{b}} = Q^{\mathrm{surf}} \qquad \text{at } z = \eta(x, y, t) \tag{30.131a}$$

$$Q_{\mathrm{b}} = Q^{\mathrm{bot}} \qquad \text{at } z = \eta_{\mathrm{b}}(x, y) \tag{30.131b}$$

$$\boldsymbol{v}^* \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{all boundaries,} \tag{30.131c}$$

where Q^{surf} is the surface buoyancy flux, Q^{bot} is the bottom buoyancy flux (e.g., geothermal heating), and $\hat{\boldsymbol{n}}$ is the outward normal at the boundaries. Both Q^{surf} and Q^{bot} are positive when directed upward. In Section 67.6 we detail the plethora of processes leading to boundary fluxes of buoyancy.

Molecular buoyancy flux assumed in this section

In the remainder of this section, we are most interested in the energetic role of molecular diffusion of buoyancy rather than turbulent mixing. In this case the buoyancy flux takes on the downgradient diffusive form

$$\boldsymbol{F}^{\mathrm{b}} = -\kappa\, \nabla b. \tag{30.132}$$

30.7.2 Mechanical forcing and dissipation

Following our discussion of frictional stresses in Section 26.8, we here write the frictional acceleration, $\boldsymbol{F}$, in the Boussinesq ocean as the divergence of the frictional stress tensor, $\mathbb{T}$,

$$\rho_0\, \boldsymbol{F} = \nabla \cdot \mathbb{T}. \tag{30.133}$$

Friction in large scale flows

For many large scale flows, the dominant contribution to frictional stresses arises from the vertical divergence of horizontal subgrid stresses, in which case the horizontal frictional acceleration vector takes the form

$$\rho_0 \, \boldsymbol{F}^h = \partial_z \boldsymbol{\tau} = \rho_0 \, \frac{\partial}{\partial z} \left[\nu^{\text{eddy}} \, \frac{\partial \boldsymbol{u}}{\partial z} \right], \tag{30.134}$$

where

$$\boldsymbol{\tau} = \rho_0 \, \nu^{\text{eddy}} \, \partial_z \boldsymbol{u} \tag{30.135}$$

is the horizontal turbulent stress vector whose vertical derivative contributes to the vertical transfer of horizontal momentum. Whereas the molecular viscosity, ν, is a function of the fluid composition (Section 26.8), the *eddy viscosity*, ν^{eddy}, is a function of the flow so that

$$\nu^{\text{eddy}} = \nu^{\text{eddy}}(\boldsymbol{x}, t) \geq 0. \tag{30.136}$$

The eddy viscosity is typically many orders of magnitude larger than the molecular viscosity in regions of strong turbulent mixing.

Boundary stresses

Boundary stresses are written as

$$\hat{\boldsymbol{n}} \cdot \mathbb{T} = \boldsymbol{\tau}^{\text{surf}} \qquad \text{at } z = \eta(x, y, t) \tag{30.137a}$$

$$(-\hat{\boldsymbol{n}}) \cdot \mathbb{T} = \boldsymbol{\tau}^{\text{bott}} \qquad \text{at } z = \eta_{\text{b}}(x, y). \tag{30.137b}$$

The surface boundary stress vector, $\boldsymbol{\tau}^{\text{surf}}$, arises from the transfer of momentum between the ocean and atmosphere (or the ocean and ice). In numerical modeling practice, this stress is computed by a boundary layer parameterization that ingests the momentum from the atmosphere or ice and computes a stress that is transferred to the ocean through these boundary conditions. As per Newton's third law (the action/reaction law; see Section 26.10), the stress imparted to the ocean is equal and opposite the stress imparted to the atmosphere at its lower boundary.

The bottom stress vector, $\boldsymbol{\tau}^{\text{bott}}$, is often parameterized via a quadratic bottom drag

$$\boldsymbol{\tau}^{\text{bott}} = -C_{\text{D}} \, \rho_0 \, \boldsymbol{v} \, |\boldsymbol{v}|, \tag{30.138}$$

where $C_{\text{D}} > 0$ is a dimensionless *drag coefficient* that is sometimes assumed to be a function of the bottom topographic roughness. This bottom stress acts to drag the ocean bottom velocity towards a state of rest. It is equal and opposite to the frictional stress transferred to the solid earth from the ocean. Note that this bottom drag acts similarly to the linear Rayleigh drag in equation (26.71). However, the bottom drag in equation (30.138) is nonlinear, whereas the Rayleigh drag is linear

$$\boldsymbol{F}_{\text{Rayleigh}} = -\gamma \, \boldsymbol{v}. \tag{30.139}$$

Molecular Laplacian friction assumed in this section

In the following, we are most interested in the energetic role of molecular viscosity rather than turbulent viscosity. In this case the frictional acceleration takes on the form

$$\boldsymbol{F} = \nu \, \nabla^2 \boldsymbol{v}. \tag{30.140}$$

Additionally, we ignore all boundary contributions in order to focus on the contributions from molecular viscosity.

30.7.3 Governing equations with molecular friction and diffusion

Assuming frictional acceleration given by molecular viscosity (30.140), and a buoyancy flux given by downgradient molecular diffusion (30.132), leads to the simplified form of the governing equations (30.126a)-(30.126c)

$$\mathrm{D}\boldsymbol{v}/\mathrm{D}t + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} = -\nabla\varphi + \hat{\boldsymbol{z}}\,b + \nu\,\nabla^2\boldsymbol{v} \tag{30.141a}$$

$$\mathrm{D}b/\mathrm{D}t = \kappa\,\nabla^2 b + Q_{\mathrm{b}} \tag{30.141b}$$

$$\nabla\cdot\boldsymbol{v} = 0. \tag{30.141c}$$

These are the equations to which we now examine energetics.

30.7.4 Kinetic energy evolution

To obtain a kinetic energy evolution equation, start by taking the dot product of the velocity, $\boldsymbol{v}$, with the momentum equation (30.141a). Since the Coriolis term drops out

$$\boldsymbol{v}\cdot(2\,\boldsymbol{\Omega}\times\boldsymbol{v}) = 0, \tag{30.142}$$

the material time derivative takes the form (assuming Cartesian tensors for simplicity)

$$v_i\,[\partial_t v_i + v_j\partial_j v_i] = \partial_t\mathcal{K} + \boldsymbol{v}\cdot\nabla\mathcal{K} = \mathrm{D}\mathcal{K}/\mathrm{D}t, \tag{30.143}$$

where we introduced the kinetic energy per mass

$$\mathcal{K} = \boldsymbol{v}\cdot\boldsymbol{v}/2. \tag{30.144}$$

Hence, the kinetic energy equation takes the form

$$\mathrm{D}\mathcal{K}/\mathrm{D}t = -\nabla\cdot(\boldsymbol{v}\,\varphi) + w\,b + \nu\,\boldsymbol{v}\cdot\nabla^2\boldsymbol{v}, \tag{30.145}$$

where we used $\nabla\cdot\boldsymbol{v} = 0$ to write $\boldsymbol{v}\cdot\nabla\varphi = \nabla\cdot(\boldsymbol{v}\,\varphi)$. Equation (30.145) says that the kinetic energy per mass of a Boussinesq fluid element is modified due to the advection of pressure, vertical motion in a buoyancy stratified fluid, and the projection of the velocity onto the frictional acceleration.

30.7.5 Frictional dissipation

Use of Cartesian coordinates allows us to write the Laplacian acting on a vector as (see Section 26.8.8)

$$\nabla^2\boldsymbol{v} = -\nabla\times\boldsymbol{\omega}, \tag{30.146}$$

which then brings the Laplacian friction to the form

$$
\begin{aligned}
-\boldsymbol{v}\cdot\nabla^2\boldsymbol{v} &= \boldsymbol{v}\cdot\nabla\times\boldsymbol{\omega} && (30.147a)\\
&= v_m\,\epsilon_{mnp}\,\partial_n\omega_p && (30.147b)\\
&= \partial_n(\epsilon_{mnp}\,v_m\,\omega_p) - \epsilon_{mnp}\,\omega_p\,\partial_n v_m && (30.147c)\\
&= -\partial_n(\epsilon_{nmp}\,v_m\,\omega_p) + \epsilon_{nmp}\,(\partial_n v_m)\,\omega_p && (30.147d)\\
&= -\partial_n(\boldsymbol{v}\times\boldsymbol{\omega})_n + \omega_p\,\omega_p && (30.147e)\\
&= -\nabla\cdot(\boldsymbol{v}\times\boldsymbol{\omega}) + \boldsymbol{\omega}\cdot\boldsymbol{\omega}. && (30.147f)
\end{aligned}
$$

The kinetic energy equation (30.145) can thus be written

$$
\begin{aligned}
\mathrm{D}\mathcal{K}/\mathrm{D}t &= -\nabla\cdot(\boldsymbol{v}\,\varphi) + w\,b - \nu\,\boldsymbol{v}\cdot(\nabla\times\boldsymbol{\omega}) && (30.148a)\\
&= -\nabla\cdot[\boldsymbol{v}\,\varphi + \nu\,(\boldsymbol{v}\times\boldsymbol{\omega})] + w\,b - \nu\,\boldsymbol{\omega}\cdot\boldsymbol{\omega}. && (30.148b)
\end{aligned}
$$

The physical dimensions for all terms in these equations are $\mathrm{L}^2\ \mathrm{T}^{-3}$: squared length per cubed time, which is the dimensions of energy per mass per time.

30.7.6 Domain integrated kinetic energy

Consider a region of fluid with no boundary contributions. Performing a volume average over that region leads to

$$
\frac{\mathrm{d}}{\mathrm{d}t}\langle\mathcal{K}\rangle = \langle w\,b\rangle - \epsilon, \tag{30.149}
$$

where the angle-brackets denote volume averaging

$$
\langle A\rangle = \frac{\int A\,\mathrm{d}V}{\int \mathrm{d}V}. \tag{30.150}
$$

To reach equation (30.149), we dropped all boundary terms, including the term $\hat{\boldsymbol{n}}\cdot(\boldsymbol{v}\times\boldsymbol{\omega})$, and introduced

$$
\epsilon = \frac{\nu\int\boldsymbol{\omega}\cdot\boldsymbol{\omega}\,\mathrm{d}V}{\int\mathrm{d}V} = \nu\,\langle\boldsymbol{\omega}\cdot\boldsymbol{\omega}\rangle \geq 0, \tag{30.151}
$$

which is the volume averaged kinetic energy dissipation rate arising from viscous effects (dimensions of $\mathrm{L}^2\ \mathrm{T}^{-3}$). We thus see that there is more kinetic energy dissipation for a Boussinesq flow with larger domain averaged $\boldsymbol{\omega}\cdot\boldsymbol{\omega}$, and zero dissipation for flow with zero mean square vorticity.

Equation (30.149) says that the domain averaged kinetic energy per mass is reduced by viscous dissipation acting within the fluid domain. Furthermore, the averaged kinetic energy is increased in regions where buoyancy and vertical motion are positively correlated, $\langle w\,b\rangle > 0$, in which case light water preferentially moves vertically up and heavy water down. Conversely, the averaged kinetic energy is decreased when buoyancy and vertical motion are negatively correlated (light water preferentially moves down and heavy water up).

30.7.7 Potential energy evolution

Assuming the simple form of the geopotential

$$
\Phi = g\,z \tag{30.152}
$$

leads to

$$
\mathrm{D}\Phi/\mathrm{D}t = g\,w = \boldsymbol{v}\cdot\nabla\Phi = \nabla\cdot(\boldsymbol{v}\,\Phi), \tag{30.153}
$$

where the second equality follows from the definition of the material derivative, and since $\partial\Phi/\partial t = 0$. Multiplying the buoyancy equation (30.126b) by Φ, and the Φ equation (30.153) by b, then adding, leads to

$$\mathrm{D}(\Phi\, b)/\mathrm{D}t = g\, b\, w + \Phi\, (Q_{\mathrm{b}} + \kappa\, \nabla^2 b) \tag{30.154a}$$
$$= g\, b\, w + \Phi\, Q_{\mathrm{b}} + \nabla\cdot(\kappa\, \Phi\, \nabla b) - \kappa\, \nabla\Phi\cdot\nabla b \tag{30.154b}$$
$$= g\, b\, w + \Phi\, Q_{\mathrm{b}} + \nabla\cdot(\Phi\, \kappa\, \nabla b) - g\, \kappa\, \partial_z b, \tag{30.154c}$$

so that

$$\mathrm{D}P^{\mathrm{b}}/\mathrm{D}t = -b\, w - g^{-1}\, \Phi\, Q_{\mathrm{b}} - \nabla\cdot(g^{-1}\, \Phi\, \kappa\, \nabla b) + \kappa\, \partial_z b. \tag{30.155}$$

The product

$$P^{\mathrm{b}} = -g^{-1}\, \Phi\, b = z\, g\, \delta\rho/\rho_0 \tag{30.156}$$

is the gravitational potential energy per mass associated with the deviation of density from the Boussinesq reference density, ρ_0. Equation (30.155) says that the gravitational potential energy per mass of a fluid element changes depending on the vertical motion of buoyancy (the $-b\, w$ term); from diabatic sources (the $\Phi\, Q_{\mathrm{b}}$ term); from a total divergence associated with buoyancy diffusion; and from the vertical diffusive flux of buoyancy. The diabatic source and diffusion are both irreversible terms, whereas the vertical motion term is reversible.

Writing the material evolution (30.155) in its flux-form leads to the Eulerian balance equation for the potential energy per mass

$$\partial_t P^{\mathrm{b}} + \nabla\cdot[\boldsymbol{v}\, P^{\mathrm{b}} + g^{-1}\, \Phi\, \kappa\, \nabla b] = -b\, w - g^{-1}\, \Phi\, Q_{\mathrm{b}} + \kappa\, \partial_z b. \tag{30.157}$$

Integrating over a region of constant volume and with zero boundary fluxes (other than fluxes associated with Q_{b}), leads to

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle P^{\mathrm{b}}\rangle = -\langle b\, w\rangle - g^{-1}\langle \Phi\, Q_{\mathrm{b}}\rangle + \kappa \left\langle \frac{\partial b}{\partial z}\right\rangle. \tag{30.158}$$

The domain averaged potential energy per mass evolves according to the correlation between vertical motion and buoyancy; the correlation between heating and depth; and the domain averaged vertical diffusive flux of buoyancy. We now comment on the right hand side terms.

Downgradient diffusion in the vertical

In a stably stratified ocean, buoyancy is larger in the upper ocean than deeper ocean, in which case

$$\partial b/\partial z > 0 \qquad \text{stably stratified.} \tag{30.159}$$

A downgradient vertical diffusive flux acts to homogenize in the vertical. Consequently, when acting on a stably stratified fluid, diffusion moves buoyancy down from the upper ocean (where buoyancy is large) into the interior ocean (where buoyancy is less). Conversely, it moves low buoyancy upward. Consequently, diffusion makes the upper ocean less buoyant (heavier) and the deeper ocean more buoyant (lighter). We thus see that diffusion raises the ocean center of mass and as such it increases the domain averaged gravitational potential energy via equation (30.158).

As a further comment, recall that diffusion in a compressible fluid does not move mass (Section 21.1), but it generally does move volume. Conversely, for a Boussinesq ocean (which has a non-divergent flow, $\nabla\cdot\boldsymbol{v} = 0$), diffusion does not move volume but it generally does move mass. So since the flow is non-divergent, vertical diffusion can raise the center of mass through buoyancy diffusion even while it does not create any volume transport.

Diabatic heating

The diabatic heating term in equation (30.158), $-g^{-1}\langle \Phi\, Q_{\mathrm{b}}\rangle$, increases potential energy if there is a positive correlation between vertical position, $-g^{-1}\,\Phi = -z$, and heating

$$-g^{-1}\langle \Phi\, Q_{\mathrm{b}}\rangle = -\langle z\, Q_{\mathrm{b}}\rangle > 0. \tag{30.160}$$

That is, domain averaged potential energy increases if heating, $Q_{\mathrm{b}} > 0$, preferentially occurs in regions deeper than cooling. This situation is not typical in the ocean, where heating is generally shallower than cooling. Geothermal heating at the ocean bottom is perhaps the only example where heating is deeper than cooling.

Vertical motion

The vertical motion term appearing in equation (30.158),

$$b\, w = -g\, w\, \delta\rho/\rho_o \tag{30.161}$$

has a positive sign in the kinetic energy equation (30.145), wherea is has a negative sign in the potential energy equation (30.155). To help understand this term, consider the specific case of a negatively buoyant fluid element

$$b = -g\, \delta\rho/\rho_o < 0. \tag{30.162}$$

If this fluid element moves vertically upward, $w > 0$, the fluid acquires positive gravitational potential energy since relatively heavy water is moving upwards. This increase in potential energy is reflected in the term $-w\, b > 0$ appearing in the potential energy equation (30.155). This increase in gravitational potential energy is associated with a decrease in kinetic energy through the $w\, b < 0$ term appearing in equation (30.145). The conversion between potential and kinetic energy associated with the $w\, b$ term is a key process arising from vertical motion.

30.7.8 Mechanical energy

Adding the equation for kinetic energy per mass (30.145) to the potential energy equation (30.155) leads to the material evolution for the mechanical energy per mass

$$\frac{\mathrm{D}(\mathcal{K} + P^{\mathrm{b}})}{\mathrm{D}t} = -\nabla\cdot[\boldsymbol{v}\,\varphi + \nu\,\boldsymbol{v}\times\boldsymbol{\omega} + g^{-1}\,\kappa\,\Phi\,\nabla b] - \nu\,\boldsymbol{\omega}\cdot\boldsymbol{\omega} - g^{-1}\,\Phi\,Q_{\mathrm{b}} + \kappa\,\partial_z b. \tag{30.163}$$

Notice how the term $w\, b$ cancelled as it provides for a reversible transfer of mechanical energy between gravitational potential and kinetic. This reversible transfer has no effect on the mechanical energy. As emphasized by *Gent* (1993), frictional dissipation appears only in the equation for kinetic energy per mass (30.145), whereas buoyancy diffusion and sources only appear in the potential energy equation (30.155). When forming the mechanical energy equation, these terms appear together.

Writing the budget (30.163) in flux-form leads to

$$\frac{\partial(\mathcal{K} + P^{\mathrm{b}})}{\partial t} = -\nabla\cdot[\boldsymbol{v}\,(\mathcal{K} + P^{\mathrm{b}} + \varphi) + \nu\,\boldsymbol{v}\times\boldsymbol{\omega} + g^{-1}\,\kappa\,\Phi\,\nabla b] - \nu\,\boldsymbol{\omega}\cdot\boldsymbol{\omega} - g^{-1}\,\Phi\,Q_{\mathrm{b}} + \kappa\,\partial_z b. \tag{30.164}$$

The sum $\mathcal{K} + P^{\mathrm{b}} + \varphi$ appearing on the right hand side is the *Bernoulli function* for a Boussinesq fluid (see Section 27.7 for the non-Boussinesq form of the Bernoulli function). Integrating the local mechanical energy budget (30.164) over a region with constant volume, and dropping surface

terms, leads to the domain averaged mechanical energy budget

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle \mathcal{K} + P^{\mathrm{b}} \rangle = -\epsilon - \langle z\, Q_{\mathrm{b}} \rangle + \kappa \left\langle \frac{\partial b}{\partial z} \right\rangle . \tag{30.165}$$

30.7.9 Conditions for steady state mechanical energy

A steady state mechanical energy balance for the full ocean domain is realized when there is a balance between changes in domain averaged kinetic energy and changes in domain averaged potential energy

$$\frac{\mathrm{d}\langle \mathcal{K} \rangle}{\mathrm{d}t} = -\frac{\mathrm{d}\langle P^{\mathrm{b}} \rangle}{\mathrm{d}t}. \tag{30.166}$$

Setting the domain integrated mechanical energy time tendency to zero in equation (30.165) leads to the balance

$$\epsilon = -\langle z\, Q_{\mathrm{b}} \rangle + \kappa \left\langle \frac{\partial b}{\partial z} \right\rangle . \tag{30.167}$$

Recall from equation (30.151) that frictional dissipation is sign-definite

$$\epsilon \geq 0. \tag{30.168}$$

Consequently, a steady state mechanical energy for the ocean domain requires the right hand side of equation (30.167) to be positive. Such occurs when heating is preferentially below cooling (equation (30.160)), and when the diffusive flux moves buoyancy downward. We already discussed the diffusive flux in relation to equation (30.159) above. For the heat source term Q, we observe that locating a cooling source above the warming source will engender an overturning circulation, thus providing a kinetic energy source to balance the sink from viscous dissipation.

30.7.10 Further reading

Elements of this material originate from *Paparella and Young* (2002), and with Chapter 21 of *Vallis* (2017) offering a pedagogical discussion.

30.8 Mechanical energy analysis: Part II

In this section we build on the analysis from Section 30.6, here allowing density to be a function of salinity, Conservative Temperature, and pressure so that

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{\partial \rho}{\partial S}\frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial \rho}{\partial \Theta}\frac{\mathrm{D}\Theta}{\mathrm{D}t} + \frac{\partial \rho}{\partial p}\frac{\mathrm{D}p}{\mathrm{D}t}. \tag{30.169}$$

Density thus materially evolves even in the absence of mixing or diabatic processes since $\mathrm{D}p/\mathrm{D}t$ is nonzero whenever flow crosses isobars. Hence, the flux-form mechanical energy equation (30.120) now takes on the form

$$\partial_t \left(\rho_0\, \mathcal{K} + \rho\, \Phi\right) + \nabla \cdot \left[\boldsymbol{v}\left(\rho_0\, \mathcal{K} + \rho\, \Phi + p\right)\right] = \rho\, \partial_t \Phi + \Phi \left[\frac{\partial \rho}{\partial S}\, \dot{S} + \frac{\partial \rho}{\partial \Theta}\, \dot{\Theta} + \frac{\partial \rho}{\partial p}\, \dot{p}\right]. \tag{30.170}$$

The right hand side terms provide sources that contribute to the evolution of mechanical energy. In the absence of mixing, diabatic processes, and with a time independent geopotential, the sources reduce to a term arising from motion across pressure surfaces. Such motion can occur for either reversible or irreversible processes. This pressure source term is rather awkward since it means

the mechanical energy budget is not closed even when the flow is reversible (i.e., perfect fluid) and with time independent astronomical forces. We now follow the approach of *Young* (2010) to recover a closed Boussinesq mechanical energy budget by making use of a modified form of the gravitational potential energy.

30.8.1 Boussinesq dynamic enthalpy

In this section we introduce a new thermodynamic function that, in effect, provides us with an integrating factor to render a closed Boussinesq mechanical energy budget. This function is referred to as the *Boussinesq dynamic enthalpy*. Before considering that function we do a brief warm-up to refamiliarize ourself with the necessary thermodynamic formalism from Chapter 23.

Material time changes to a pressure integral of density

Consider a thermodynamic potential, $\widetilde{\Pi}(S, \Theta, p \,|\, p_{\mathrm{r}})$, defined according to the pressure integral of the *in situ* density

$$\widetilde{\Pi}(S, \Theta, p \,|\, p_{\mathrm{r}}) \equiv \int_{p_{\mathrm{r}}}^{p} \rho(S, \Theta, p')\, \mathrm{d}p' \Longrightarrow \left[\frac{\partial \widetilde{\Pi}}{\partial p}\right]_{S,\Theta} = \rho(S, \Theta, p), \tag{30.171}$$

where p_{r} is an arbitrary constant reference pressure. The notation $\widetilde{\Pi}(S, \Theta, p \,|\, p_{\mathrm{r}})$ emphasizes that p_{r} is a specified parameter whereas S, Θ, p are coordinates in thermodynamic configuration space (see Section 23.1.4). The integration in equation (30.171) is taken over pressure in a thermodynamic configuration space rather than an integral over a region in $\boldsymbol{x}$-space.[12] Accordingly, the infinitesimal increment of $\widetilde{\Pi}$ is given by

$$\delta\widetilde{\Pi} = \delta S \left[\frac{\partial \widetilde{\Pi}}{\partial S}\right]_{\Theta,p} + \delta\Theta \left[\frac{\partial \widetilde{\Pi}}{\partial \Theta}\right]_{S,p} + \delta p \left[\frac{\partial \widetilde{\Pi}}{\partial p}\right]_{S,\Theta} \tag{30.172a}$$

$$= \delta S \left[\frac{\partial \widetilde{\Pi}}{\partial S}\right]_{\Theta,p} + \delta\Theta \left[\frac{\partial \widetilde{\Pi}}{\partial \Theta}\right]_{S,p} + \rho(S, \Theta, p)\, \delta p. \tag{30.172b}$$

If the increment is computed following a moving fluid element then we are led to the material time derivative

$$\frac{\mathrm{D}\widetilde{\Pi}}{\mathrm{D}t} = \frac{\mathrm{D}S}{\mathrm{D}t} \left[\frac{\partial \widetilde{\Pi}}{\partial S}\right]_{\Theta,p} + \frac{\mathrm{D}\Theta}{\mathrm{D}t} \left[\frac{\partial \widetilde{\Pi}}{\partial \Theta}\right]_{S,p} + \rho(S, \Theta, p)\, \frac{\mathrm{D}p}{\mathrm{D}t}. \tag{30.173}$$

Material time changes to a geopotential integral of density

Using the same formalism as above, now consider a thermodynamic potential that is a function of salinity, Conservative Temperature, and geopotential

$$\Pi(S, \Theta, \Phi | \Phi_{\mathrm{r}}) \equiv \int_{\Phi_{\mathrm{r}}}^{\Phi} \rho(S, \Theta, \Phi')\, \mathrm{d}\Phi' \Longrightarrow \left[\frac{\partial \Pi}{\partial \Phi}\right]_{S,\Theta} = \rho(S, \Theta, \Phi), \tag{30.174}$$

where Φ_{r} is an arbitrary constant reference geopotential. We offer the following three comments concerning Π.

[12] This is an example where the discussion in Section 27.6.3 is key, whereby we must distinguish between fields in a thermodynamic configuration space versus fields in geographical space and time.

- For density that is independent of the geopotential, then $\Pi \, \mathrm{d}V = (\Phi - \Phi_{\mathrm{r}}) \, \rho \, \mathrm{d}V$, which is the gravitational potential energy relative to a reference state. We thus interpret $\Pi(S, \Theta, \Phi)$ as a generalized gravitational potential energy per volume.

- One might consider Π to be the difference in hydrostatic pressure between Φ and Φ_{r} as per equation (25.56). However, the integral in equation (25.56) occurs in $\boldsymbol{x}$-space between two geopotentials and holding the (x, y) coordinates fixed during the integration, so that this integration generally crosses surfaces of constant S and Θ. In contrast, integration in equation (30.174) is taken from Φ_{r} to Φ within thermodynamic configuration space so that S and Θ are fixed while performing the geopotential integral. In this manner, the geopotential, rather than pressure, provides a coordinate within a Boussinesq thermodynamic configuration space along with S and Θ.

- *Young* (2010) provides motivation for calling Π the *Boussinesq dynamic enthalpy*.

Following the same formalism used to derive $\mathrm{D}\widetilde{\Pi}/\mathrm{D}t$ in equation (30.173), we here compute the material time derivative of the Boussinesq dynamic enthalpy

$$\frac{\mathrm{D}\Pi}{\mathrm{D}t} = \frac{\mathrm{D}S}{\mathrm{D}t} \left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \frac{\mathrm{D}\Theta}{\mathrm{D}t} \left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi} + \rho(S, \Theta, \Phi) \, \frac{\mathrm{D}\Phi}{\mathrm{D}t}. \tag{30.175}$$

We now create a mechanical energy budget in the form

$$\frac{\mathrm{D}}{\mathrm{D}t} \left[\rho_0 \, \mathscr{K} + \Pi\right] = -[\boldsymbol{v} \cdot \nabla p + \rho \, \boldsymbol{v} \cdot \nabla \Phi] + \dot{S} \left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \dot{\Theta} \left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi} + \rho \, \frac{\mathrm{D}\Phi}{\mathrm{D}t} \tag{30.176a}$$

$$= -[\boldsymbol{v} \cdot \nabla p + \rho \, \boldsymbol{v} \cdot \nabla \Phi] + \dot{S} \left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \dot{\Theta} \left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi} + \rho \, (\partial_t \Phi + \boldsymbol{v} \cdot \nabla \Phi) \tag{30.176b}$$

$$= -\boldsymbol{v} \cdot \nabla p + \rho \, \partial_t \Phi + \dot{S} \left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \dot{\Theta} \left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi}, \tag{30.176c}$$

whose flux-form expression is given by

$$\partial_t \left(\rho_0 \, \mathscr{K} + \Pi\right) + \nabla \cdot [\boldsymbol{v} \cdot (\rho_0 \, \mathscr{K} + \Pi + p)] = \rho \, \partial_t \Phi + \dot{S} \left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \dot{\Theta} \left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi}. \tag{30.177}$$

We thus see that in the absence of irreversible effects, and with a time independent geopotential, we have succeeded in deriving a closed (i.e., flux-form) mechanical energy budget for a Boussinesq ocean, with

$$\rho_0 \, \mathscr{M} = \rho_0 \, \mathscr{K} + \Pi \xrightarrow{\rho = \rho(S,\Theta)} \rho_0 \, \mathscr{K} + \rho \, (\Phi - \Phi_{\mathrm{r}}) \tag{30.178}$$

the appropriate Boussinesq expression for the mechanical energy per volume.

30.8.2 Regionally integrated Boussinesq dynamic enthalpy

Following the treatment for a compressible non-Boussinesq fluid in Section 27.2.4, we here study evolution of the gravitational potential energy integrated over a finite region, $\mathscr{R}$, that is open to material mass transport. Rather than working with the geopotential as done for the non-Boussinesq fluid, we here follow the discussion in Section 30.8.1 by making use of the Boussinesq dynamic enthalpy, thus ensuring a closed mechanical energy budget.

Budget with the equation of state: $\rho = \rho(S, \Theta, \Phi)$

For this purpose we make use the Leibniz-Reynolds transport theorem in the form of equation (21.37) to find

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \Pi \,\mathrm{d}V = \int_{\mathcal{R}} \partial_t \Pi \,\mathrm{d}V + \oint_{\partial\mathcal{R}} \Pi\, \boldsymbol{v}^{(b)} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \frac{\mathrm{D}\Pi}{\mathrm{D}t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \Pi\,(\boldsymbol{v}^{(b)} - \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \quad (30.179)$$

where $\boldsymbol{v}^{(b)}$ is the velocity of a point on the boundary of the domain, $\partial\mathcal{R}$. We expose contributions from irreversible processes leading to material time changes to S and Θ by making use of the identity (30.175)

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \Pi \,\mathrm{d}V = \int_{\mathcal{R}} \left[\frac{\mathrm{D}S}{\mathrm{D}t}\left[\frac{\partial \Pi}{\partial S}\right]_{\Theta,\Phi} + \frac{\mathrm{D}\Theta}{\mathrm{D}t}\left[\frac{\partial \Pi}{\partial \Theta}\right]_{S,\Phi} + \rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}\right] \mathrm{d}V + \oint_{\partial\mathcal{R}} \Pi\,(\boldsymbol{v}^{(b)} - \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \quad (30.180)$$

A constant can be added to the dynamic enthalpy without altering the energetics, which is seen by noting that volume conservation means that (equation (22.65))

$$\frac{\mathrm{d}}{\mathrm{d}t}\int \mathrm{d}V = -\int_{\partial\mathcal{R}} (\boldsymbol{v} - \boldsymbol{v}^{(b)}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \quad (30.181)$$

If the region is a vertical column of fluid with fixed horizontal cross-section, extending from the ocean surface to the ocean bottom, then there is horizontal transport across the vertical boundaries, plus vertical transport of mass across the ocean free surface. For the free surface we make use of the surface kinematic boundary condition (20.73c) to write

$$\int_{z=\eta} (\Pi/\rho)\,\rho\,(\boldsymbol{v}^{(\eta)} - \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{z=\eta} (\Pi/\rho)\,Q_{\mathrm{m}}\,\mathrm{d}A. \quad (30.182)$$

In this equation, Q_{m} is the mass per time per horizontal area of matter crossing the ocean free surface at $z = \eta$ where $Q_{\mathrm{m}} > 0$ for matter entering the ocean domain, and $\mathrm{d}\mathcal{S}$ is the area element on the free surface with $\mathrm{d}A$ its horizontal projection.

Budget with the equation of state: $\rho = \rho(S, \Theta)$

For the special case of an equation of state independent of pressure, $\rho = \rho(S, \Theta)$ (Section 30.6), we have $\Pi = \rho\,(\Phi - \Phi_{\mathrm{r}})$ so that equation (30.180) reduces to

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho\,(\Phi - \Phi_{\mathrm{r}})\,\mathrm{d}V = \int_{\mathcal{R}} \left[(\Phi - \Phi_{\mathrm{r}})\,\frac{\mathrm{D}\rho}{\mathrm{D}t} + \rho\,\frac{\mathrm{D}\Phi}{\mathrm{D}t}\right]\mathrm{d}V + \oint_{\partial\mathcal{R}} [\rho\,(\Phi - \Phi_{\mathrm{r}})\,(\boldsymbol{v}^{(b)} - \boldsymbol{v})] \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \quad (30.183)$$

Note that the reference geopotential, Φ_{r}, drops out since the Boussinesq form of the Leibniz-Reynolds transport theorem (i.e., equation (30.179) with ρ replacing Π) leads to the identity

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{R}} \rho\,\mathrm{d}V = \int_{\mathcal{R}} \frac{\mathrm{D}\rho}{\mathrm{D}t}\,\mathrm{d}V + \oint_{\partial\mathcal{R}} \rho\,(\boldsymbol{v}^{(b)} - \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \quad (30.184)$$

This equation means that the gravitational mass for a region of Boussinesq ocean (left hand side) changes through boundary terms, as for a non-Boussinesq fluid, plus processes that lead to material time changes in S and Θ

$$\rho = \rho(S, \Theta) \Longrightarrow \frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{\partial \rho}{\partial S}\,\frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial \rho}{\partial \Theta}\,\frac{\mathrm{D}\Theta}{\mathrm{D}t}. \quad (30.185)$$

We understand the presence of the $\dot{S}$ and $\dot{\Theta}$ terms by noting that irreversible processes, such as mixing, do not alter volume in a Boussinesq ocean. Hence, if irreversible processes change density of a fluid element, then there must be a corresponding change in the gravitational mass of the element.

30.8.3 Density derivatives

When computing the derivatives of density, it is important to note whether the derivative is computed holding (Θ, S) fixed or holding (x, y) fixed. As seen here, this distinction can be confused for the Boussinesq ocean, especially when the geopotential takes the simple form $\Phi = g\, z$.

Vertical derivative of in situ density for a non-Boussinesq fluid

To motivate the discussion, recall the *in situ* density for a non-Boussinesq fluid is a function of the salinity, S, Conservative Temperature, Θ, and *in situ* pressure, p,

$$\rho = \rho(S, \Theta, p), \tag{30.186}$$

so that its spatial gradient is

$$\nabla\rho = \left[\frac{\partial\rho}{\partial S}\right]_{\Theta,p} \nabla S + \left[\frac{\partial\rho}{\partial\Theta}\right]_{S,p} \nabla\Theta + \left[\frac{\partial\rho}{\partial p}\right]_{S,\Theta} \nabla p = \left[\frac{\partial\rho}{\partial S}\right]_{\Theta,p} \nabla S + \left[\frac{\partial\rho}{\partial\Theta}\right]_{S,p} \nabla\Theta + \frac{1}{c_{\mathrm{s}}^2}\,\nabla p. \tag{30.187}$$

In the final step we introduced the inverse squared sound speed

$$\frac{1}{c_{\mathrm{s}}^2} = \left[\frac{\partial\rho}{\partial p}\right]_{S,\Theta}, \tag{30.188}$$

which is the partial derivative of density holding S and Θ fixed. Equation (30.187) says that the spatial gradient of density on the left hand side is determined by the sum of three terms that arise from spatial gradients of (S, Θ, p), each multiplied by their respective functional derivative of the equation of state for density. The vertical component of this equation arises when measuring vertical stratification, in which case

$$\left[\frac{\partial\rho}{\partial z}\right]_{x,y} = \left[\frac{\partial\rho}{\partial S}\right]_{\Theta,p} \left[\frac{\partial S}{\partial z}\right]_{x,y} + \left[\frac{\partial\rho}{\partial\Theta}\right]_{S,p} \left[\frac{\partial\Theta}{\partial z}\right]_{x,y} + \frac{1}{c_{\mathrm{s}}^2}\left[\frac{\partial p}{\partial z}\right]_{x,y}, \tag{30.189}$$

with $\partial p/\partial z = -\rho\, g$ for a hydrostatic fluid. Note that we exposed the (x, y) labels on the left hand side partial derivative. As seen next, these extra labels are especially important for the case of the Boussinesq ocean.

Vertical derivative of in situ density for a Boussinesq ocean

As seen earlier in this section, the *in situ* density for an energetically consistent Boussinesq ocean has the functional dependence

$$\rho = \rho(S, \Theta, \Phi). \tag{30.190}$$

That is, the geopotential, Φ, replaces pressure in the functional dependence, with the equation of state evaluated with a pressure $p_{\mathrm{eos}} = -\rho_0\,\Phi$. Hence, the spatial gradient of *in situ* density for a Boussinesq ocean is

$$\nabla\rho = \left[\frac{\partial\rho}{\partial S}\right]_{\Theta,\Phi} \nabla S + \left[\frac{\partial\rho}{\partial\Theta}\right]_{S,\Phi} \nabla\Theta + \left[\frac{\partial\rho}{\partial\Phi}\right]_{S,\Theta} \nabla\Phi, \tag{30.191}$$

so that the vertical stratification is measured by

$$\left[\frac{\partial \rho}{\partial z}\right]_{x,y} = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,\Phi} \left[\frac{\partial S}{\partial z}\right]_{x,y} + \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,\Phi} \left[\frac{\partial \Theta}{\partial z}\right]_{x,y} + \left[\frac{\partial \rho}{\partial \Phi}\right]_{S,\Theta} \left[\frac{\partial \Phi}{\partial z}\right]_{x,y}. \tag{30.192a}$$

This relation is analogous to the non-Boussinesq expression (30.189). In particular, the inverse squared sound speed for a Boussinesq ocean is given by

$$\left[\frac{\partial \rho}{\partial \Phi}\right]_{S,\Theta} = -\frac{\rho_0}{c_{\mathrm{s}}^2}. \tag{30.193}$$

Although the prognostic flow is non-divergent for the Boussinesq ocean, the full velocity field is divergent (Section 30.1.9), thus supporting acoustic waves.

Now consider the special (and common) case of a simple geopotential, $\Phi = g\,z$, whereby the Boussinesq sound speed is given by

$$\left[\frac{\partial \rho}{\partial z}\right]_{S,\Theta} = -\frac{\rho_0\, g}{c_{\mathrm{s}}^2}, \tag{30.194}$$

and the vertical stratification derivative is given by

$$\left[\frac{\partial \rho}{\partial z}\right]_{x,y} = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,z} \left[\frac{\partial S}{\partial z}\right]_{x,y} + \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,z} \left[\frac{\partial \Theta}{\partial z}\right]_{x,y} + \left[\frac{\partial \rho}{\partial z}\right]_{S,\Theta}. \tag{30.195}$$

We here see why attachment of subscripts to the partial derivatives is essential to avoid confusion, since

$$\left[\frac{\partial \rho}{\partial z}\right]_{x,y} \neq \left[\frac{\partial \rho}{\partial z}\right]_{S,\Theta}. \tag{30.196}$$

The left hand side vertical derivative is computed holding the horizontal position fixed, as appropriate for computing the vertical stratification, whereas the right hand side vertical derivative is computed with (S, Θ) fixed, as appropriate for computing the sound speed. These two derivatives are conceptually distinct, with equation (30.195) exposing the mathematical distinction.

Horizontal derivative of in situ density for a Boussinesq ocean

The horizontal portion of the gradient (30.191), computed along surfaces of constant geopotential, is given by

$$\nabla_\Phi \rho = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,\Phi} \nabla_\Phi S + \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,\Phi} \nabla_\Phi \Theta. \tag{30.197}$$

Hence, when the geopotential takes the simple form, $\Phi = g\,z$, then we have

$$\nabla_z \rho = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,\Phi} \nabla_z S + \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,\Phi} \nabla_z \Theta. \tag{30.198}$$

In either case, we see that the horizontal density gradient in a Boussinesq ocean is determined by the horizontal gradients of the Conservative Temperature and salinity.

30.8.4 Comments

Decoupling mechanical energy from internal energy

There are further nuances required to unravel energetics of the Boussinesq ocean, with details provided by *Young* (2010). When encountering these details for the first time one may wonder why bother since the non-Boussinesq energetics discussed in Sections 27.4 and 27.7 are, by comparison, very straightforward. However, the difficulty with non-Boussinesq energetics arises from the internal energy. Namely, since many geophysical flows, particularly those in the ocean, have speeds that are tiny compared to molecular speeds (see Section 17.3), the mechanical energy associated with geophysical flow is tiny relative to the internal energy arising from molecular motions. So when studying the total energy budget for a non-Boussinesq fluid, that energy is dominated by the internal energy. As detailed in *Young* (2010), the oceanic Boussinesq approximation allows us to focus on the Boussinesq mechanical energy arising just from the fluid flow, and it does so by decoupling mechanical energy from internal energy.

General form of the geopotential

The treatments in *Young* (2010) and Section 2.4.3 of *Vallis* (2017) focus on the simple form of the geopotential, $\Phi = g\,z$, in which case it appears that density in an energetically consistent Boussinesq ocean can at most have the space and time dependence

$$\rho = \rho[S(\boldsymbol{x},t), \Theta(\boldsymbol{x},t), p = -\rho_0\, g\, z]. \tag{30.199}$$

However, the formalism developed by *Young* (2010) allows for a general geopotential, including those that arise from astronomical tidal forcing and from mass redistributions such as near ice shelves. In these cases we retain a consistent Boussinesq energetics with density of the more general form

$$\rho = \rho[S(\boldsymbol{x},t), \Theta(\boldsymbol{x},t), p = -\rho_0\, \Phi(\boldsymbol{x},t)]. \tag{30.200}$$

Distinct manifestations of irreversible processes

It is notable that the irreversible terms from $\dot{S}$ and $\dot{\Theta}$ that appear in the mechanical energy equations (30.120), (30.176c) and (30.177) are absent from the non-Boussinesq budget in equation (27.49). Instead, for the non-Boussinesq fluid, the irreversible mixing processes manifest through their effects on flow convergence via the mass continuity equation

$$-\nabla \cdot \boldsymbol{v} = \frac{1}{\rho}\,\frac{\mathrm{D}\rho}{\mathrm{D}t}. \tag{30.201}$$

Since the Boussinesq ocean has a zero flow divergence, the role of mixing on the potential energy budget appears elsewhere within the mechanical energy budget.

30.9 Available potential energy

The gravitational potential energy per mass of a fluid element, as measured relative to the $z = 0$ geopotential, is given by $g\,\rho\,z$ (when assuming a simple geopotential). But how much of that potential energy can be transferred to generate kinetic energy? Not all of it since a state of zero potential energy means all of the fluid sits at $z = 0$, which is not generally possible. In Section 30.6 we noted that $-g^{-1}\,b\,\Phi$ is the potential energy per mass relative to the constant density background state. Pursuing this idea one more step, consider a background buoyancy, $b_{\mathrm{ref}}(z)$, that has a non-zero depth dependence but with no horizontal dependence. Without any horizontal buoyancy gradients there are zero horizontal internal pressure gradients so that an

initially static fluid will remain static.[13] Such fluids are said to have zero *baroclinicity*, with a proper treatment of baroclinicity in the context of vorticity given in Section 41.7. As seen in this vorticity discussion, a Boussinesq fluid with zero baroclinicity does not generate vorticity since its pressure gradients are perpendicular to buoyancy gradients, which are vertical for a reference state with $b = b_{\text{ref}}(z)$ (see Section 30.1.2 for the Boussinesq baroclinicity vector). These concepts from vorticity motivate us to compute the potential energy relative to a depth-dependent background buoyancy profile.

Lorenz (1955) suggested that a particularly relevant background buoyancy state is the one obtained by a reversible rearrangement or sorting of the original buoyancy to a state that has zero baroclinicity. A reversible rearrangement means there is no mixing when moving between the original state and the background state. The difference in gravitational potential energy between these two states is termed the *available potential energy* (APE), with the APE measuring the potential energy accessible for generating reversible motion.[14] Figure 30.2 illustrates the basic concept. In the remainder of this section we provide details to support a quantitative understanding of available potential energy. We restrict attention to the perfect Boussinesq ocean with a linear equation of state, and ignore the role of mixing and the rather difficult nuances related with the nonlinear equation of state. We also assume a simple connected domain.

FIGURE 30.2: Isolines of constant buoyancy to illustrate the concept of available potential energy (APE) in a stably stratified Boussinesq ocean. The initial state (left panel) with non-zero baroclinicity is reversibly rearranged to have zero baroclinicity (right panel). The difference in gravitational potential energy between these two states defines the APE in the initial state. As shown in Section 30.9.3, the APE is a non-negative measure of the amount of gravitational potential energy that can, in principle, be reversibly converted to kinetic energy. Due to volume conservation and the absence of irreversible processes, the depth of a buoyancy surface in the background state shown in the right panel equals to the area average depth of the same buoyancy surface in the left panel (see Section 30.9.2).

30.9.1 Analytic continuation of buoyancy surfaces

We use the term *outcrop* to refer to the vanishing of a buoyancy surface at the upper boundary, and *incrop* when it vanishes at the lower boundary. Figure 30.3 illustrates such surfaces. When considering a fluid in a domain with geometric boundaries, and when describing properties of the fluid according to thermodynamic coordinates such as buoyancy, we must decide how to describe these surfaces in regions where they do not exist; i.e., where they are outcropped or incropped. We follow the *Lorenz convention* described in *Lorenz* (1955), *Andrews* (1983), Section 4 of *Young* (2012), and Appendix A of *Ringler et al.* (2017).

[13] External pressure gradients, such as from sea level gradients or applied pressure gradients, are also assumed zero.

[14] Strictly, this is the potential energy available for producing motion *if* the fluid is allowed to relax to a state with zero baroclinicity. Yet as seen in Chapter 32, rotating stratified fluids generally reach a steady state (geostrophic balance) with nonzero baroclinicity (thermal wind). Even so, we ignore this concern by here following the standard treatment of available potential energy.

This goal might appear to be pointless; i.e, if the surface does not exist in a region, then why do we need to specify any of its properties. However, the "analytic continuation" of buoyancy surfaces is very useful when developing their kinematics, with particular use for available potential energy in Section 30.9.3. Such concerns have further applications for studies of water mass transformation arising from boundary buoyancy fluxes (e.g., *Nurser et al.* (1999) as well as Chapter 68). Additionally, the buoyancy frequency along these surfaces is formally infinite since the extended buoyancy surfaces are squeezed into a zero thickness layer. Evidently, analytic continuation of buouyancy layers creates an infinite potential vorticity, which corresponds to the potential vorticity *delta sheets* as discussed by *Bretherton* (1966) and *Schneider et al.* (2003). In the following we limit our attention to domains with flat bottoms and vertical side-walls to minimize the niceties that arise with more general domains.

Buoyancy-area mean height of a buoyancy surface

Let $z = \eta(x, y, \mathcal{B}, t)$ be the vertical position ("height" for brief) of a surface with buoyancy $\mathcal{B}$. We make use of the area mean height when formulating available potential energy. One way to define the area mean is to integrate $\eta(x, y, \mathcal{B}, t)$ over the area of the buoyancy surface and then divide by the area of the buoyancy surface

$$\overline{\eta(\mathcal{B}, t)}^{\text{buoyancy}} = \frac{\int_{\mathcal{B}} \eta(x, y, \mathcal{B}, t)\, \mathrm{d}\mathcal{S}}{\int_{\mathcal{B}} \mathrm{d}\mathcal{S}}, \tag{30.202}$$

where $\int_{\mathcal{B}} \mathrm{d}\mathcal{S}$ is the area integral over the $\mathcal{B}$ buoyancy surface. Yet there are two problems with this area calculation. First, the area of a buoyancy surface is rather complicated to compute in practice, given that it can undulate, incrop, and outcrop. Second, the buoyancy surface area is time dependent thus making the area mean also time dependent.

Domain-area mean height of a buoyancy surface

An alternative method to compute the area mean height is to integrate over the area of the fluid domain

$$\overline{\eta(\mathcal{B})} = \frac{\int \eta(x, y, \mathcal{B}, t)\, \mathrm{d}A}{\int \mathrm{d}A}, \tag{30.203}$$

where

$$A = \int \mathrm{d}A = \int_{\text{fluid domain}} \mathrm{d}x\, \mathrm{d}y \tag{30.204}$$

is the time-independent horizontal area of the fluid domain. Time-independence of the area is a plus. In choosing the full domain area, we must specify the height of a buoyancy surface in those horizontal regions where the surface does not exist; i.e., where the surface outcrops or incrops. By doing so, we prove in Section 30.9.2 that the area mean height is time-independent for all buoyancy surfaces. This is another advantage of this approach. Finally, this area mean height satisfies the monotonicity property

$$\overline{\eta(\mathcal{B}_1)} > \overline{\eta(\mathcal{B}_2)} \qquad \text{if} \qquad \mathcal{B}_1 > \mathcal{B}_2. \tag{30.205}$$

We make use of both the time-independence of the mean height and the monotonicity property when formulating the available potential energy in Section 30.9.3.

FIGURE 30.3: Geometry of buoyancy surfaces in a flat bottom box of perfect Boussinesq ocean with height H and horizontal area $\int \mathrm{d}A = A$. Three representative buoyancy surfaces are shown: one that spans the full domain with $b = \mathcal{B}$, one that incrops at the bottom with $b = \mathcal{B}_{\text{incrop}}$, and one that outcrops at the surface with $b = \mathcal{B}_{\text{outcrop}}$. The vertical height of a buoyancy surface is $z = \eta(x, y, \mathcal{B}, t)$; its area average (which is time independent; see Section 30.9.2) is $\overline{\eta(\mathcal{B})} = A^{-1} \int \eta(x, y, \mathcal{B}, t)\, \mathrm{d}A$; and its corresponding anomalous height is $\eta'(x, y, \mathcal{B}, t) = \eta(x, y, \mathcal{B}, t) - \overline{\eta(\mathcal{B})}$. As a complement, a particular point on the $z = \overline{\eta(\mathcal{B})}$ height surface has buoyancy $b = B(x, y, \overline{\eta(\mathcal{B})}, t)$, which then leads to an anomalous buoyancy $b'(x, y, \overline{\eta(\mathcal{B})}, t) = B(x, y, \overline{\eta(\mathcal{B})}, t) - \mathcal{B}$, where $\overline{B(x, y, \overline{\eta(\mathcal{B})}, t)} = \mathcal{B}$ (see equation (30.209)). To allow the formalism to be transparent across all buoyancy surfaces, we set $\eta(x, y, \mathcal{B}_{\text{outcrop}}, t) = H$ in regions where the surface has outcropped, and $\eta(x, y, \mathcal{B}_{\text{incrop}}, t) = 0$ where the surface has incropped (denoted by the red lines). As a complement, we set $\partial z/\partial b = 1/N^2 = 0$ for regions where the surface has either incropped or outcropped, thus formally imposing an infinitely stratified extension of the incropped and outcropped surfaces across the top and bottom domain boundaries. Through this analytic continuation of the buoyancy surfaces, we are ensured that the area mean height of all buoyancy surfaces forms a monotonic sequence from 0 to H, with $\overline{\eta(\mathcal{B}_1)} > \overline{\eta(\mathcal{B}_2)}$ if $\mathcal{B}_1 > \mathcal{B}_2$. When focused on a single buoyancy surface, we can reduce notational clutter by writing, for example, $\overline{\eta}$ rather than $\overline{\eta(\mathcal{B})}$, as well as $b'(\overline{\eta}) = B(\overline{\eta}) - \mathcal{B}$, and $\eta' = \eta - \overline{\eta}$.

Analytic continuation of surface height at outcrops and incrops

So how do we specify the height in outcrop regions? Let us motivate a specification by considering a buoyancy surface that sits near the top of the domain; i.e., its buoyancy is near the domain maximum, b_{max}. Assume this surface is not horizontal, with the surface $b = \mathcal{B}_{\text{outcrop}}$ in Figure 30.3 an example. Furthermore, let it cover less horizontal area than the full domain area. If we horizontally integrate just over regions where the surface does not outcrop, but still normalize by the total horizontal area of the domain, then the area mean height will be less than certain other buoyancy surfaces whose buoyancy is less and yet whose horizontal area is more. As a result we will not satisfy the monotonicity property (30.205). A way to recover monotonicity is to analytically continue the buoyancy surface along the upper boundary so that its height in the outcropped region is set to $\eta(x_{\text{outcrop}}, y_{\text{outcrop}}, \mathcal{B}_{\text{outcrop}}, t) = H$. Doing so then ensures that the domain-area mean height for buoyancy surfaces will approach H as their buoyancy approaches the maximum buoyancy. We provide an analogous continuation of the surface within the bottom

boundary so that

$$\eta(x,y,\mathcal{B},t) = \left[\begin{array}{ll} H & \text{if } (x,y) \in \text{outcrop region} \\ 0 & \text{if } (x,y) \in \text{incrop region} \\ \eta(x,y,\mathcal{B},t) & \text{otherwise.} \end{array}\right. \tag{30.206}$$

These two continuations of the buoyancy surfaces ensures that the domain-area mean height of all buoyancy surfaces forms a monotonic sequence and that the sequency extends from $0 \leq \overline{\eta(\mathcal{B})} \leq H$.

Analytic continuation of buoyancy stratification at outcrops and incrops

What does the analytic continuation (30.206) imply for buoyancy? As described, we allow all outcropped buoyancy surfaces to continue along the surface at $\eta = H$. All outcropped surfaces are thus squeezed into the infinitesimal upper fluid layer with buoyancy in that layer bounded above by the domain maximum buoyancy, $b_{\max}$. Likewise, for the bottom of the domain we squeeze all incropped buoyancy surfaces into an infinitesimal layer bounded below by $b_{\min}$, the minimum buoyancy in the domain. Consequently, the upper and lower boundaries are formally capped by infinitely stratified shells in which the inverse squared buoyancy frequency vanishes.

30.9.2 The dual relation between height and buoyancy

In deriving an expression for the APE in Section 30.9.3, we will find it useful to have relations between the unsorted and sorted buoyancy fields. We will also make use of the dual relation between the height of a constant buoyancy surface and the buoyancy of a constant height surface. For this purpose we examine certain kinematic properties of buoyancy surfaces in a stably stratified box of a perfect Boussinesq ocean as in Figure 30.3.

Volume beneath a buoyancy surface using height coordinates

Making use of notation from Figure 30.3, the volume of fluid contained beneath an arbitrary buoyancy surface is

$$V(\mathcal{B}) = \int \mathrm{d}A \int_0^{\eta(x,y,\mathcal{B},t)} \mathrm{d}z = \int \eta(x,y,\mathcal{B},t)\,\mathrm{d}A = A\,\overline{\eta(\mathcal{B})}, \tag{30.207}$$

The following properties result from volume conservation in a perfect non-divergent flow in the absence of boundary fluxes (see Chapter 22).

- The volume of fluid beneath an arbitrary buoyancy surface is time-independent, as is the area mean height of this surface. This property allowed us to drop the time argument from $V(\mathcal{B})$ and $\overline{\eta(\mathcal{B})}$ in equation (30.207).
- The area mean height of a buoyancy surface is identical to the height of the surface when it is reversibly rearranged to be horizontal.

To verify these properties, recall that buoyancy surfaces are material in a perfect fluid so that no fluid crosses them even as they fluctuate. It follows that the volume of fluid beneath an arbitrary buoyancy surface is time-independent. Since the horizontal area of the domain is time-independent, equation (30.207) also means that the area averaged height of the buoyancy surface is time-independent. Furthermore, any motion of a buoyancy surface in a perfect fluid is reversible, including motion that flattens the surface. Since its area mean height remains fixed, the area mean equals to the height of the surface when it is flat.

Area mean buoyancy on a constant depth surface

As a further realization of the dual relation between height and buoyancy, note that the area average buoyancy, $b = B(x, y, z, t)$ along a constant height surface is also constant in time

$$\overline{B(z)} = A^{-1} \int B(x, y, z, t) \, \mathrm{d}A = \text{time independent}. \tag{30.208}$$

This property follows since both buoyancy and volume are material constants following a fluid parcel in a perfect Boussinesq ocean. Hence, a fluid parcel carries both its buoyancy and volume unchanged so that the volume integrated buoyancy within any fluid region remains constant. Correspondingly, the area integrated buoyancy along any fixed height surface remains constant. It also follows that the area mean buoyancy at $z = \overline{\eta(\mathcal{B})}$ is $\mathcal{B}$

$$\overline{B[\overline{\eta(\mathcal{B})}]} = A^{-1} \int B(x, y, z = \overline{\eta(\mathcal{B})}, t) \, \mathrm{d}A = \mathcal{B}. \tag{30.209}$$

Volume beneath a buoyancy surface using buoyancy coordinates

Let us return to the volume beneath a buoyancy surface, only now use buoyancy coordinates to write

$$V(\mathcal{B}) = \int \mathrm{d}A \int_0^{\eta(x,y,\mathcal{B},t)} \mathrm{d}z = \int \mathrm{d}A \int_{b(x,y,0,t)}^{\mathcal{B}} \frac{\partial z}{\partial b} \, \mathrm{d}b = \int \mathrm{d}A \int_{b(x,y,0,t)}^{\mathcal{B}} \frac{\mathrm{d}b}{N^2} \tag{30.210}$$

where $b(x, y, 0, t)$ is the buoyancy at the bottom of the domain and

$$N^2 = \frac{\partial b}{\partial z} \tag{30.211}$$

is the squared buoyancy frequency. As noted in Section 30.9.1 and illustrated in Figure 30.3, we analytically continue the buoyancy surfaces into the surface and bottom boundaries so that

$$N^{-2}(x, y, \mathcal{B}) = \left[\begin{array}{ll} = 0 & \text{if } \mathcal{B} > b(x, y, H) \text{ (surface outcrop region)} \\ = 0 & \text{if } \mathcal{B} < b(x, y, 0) \text{ (bottom incrop region)} \\ = N^{-2}(x, y, \mathcal{B}) & \text{if } b(x, y, 0) \le \mathcal{B} \le b(x, y, H). \end{array} \right. \tag{30.212}$$

In this manner we can replace the lower limit in equation (30.210) with a constant buoyancy well below any buoyancy found in the domain, which we write as b_{min}, so that

$$V(\mathcal{B}) = \int \mathrm{d}A \int_{b_{\text{min}}}^{\mathcal{B}} \frac{\mathrm{d}b}{N^2} = \int_{b_{\text{min}}}^{\mathcal{B}} \mathrm{d}b \int \frac{\mathrm{d}A}{N^2}. \tag{30.213}$$

Being able to commute the area and buoyancy integrals proves useful in the following.

30.9.3 Exact expression for APE

In this subsection we develop an expression for the APE of the perfect stably stratified Boussinesq ocean in a box. To start, consider the volume integrated gravitational potential energy per mass of the fluid in Figure 30.3, relative to a constant density background state with $\rho = \rho_0$

$$\mathcal{P} = -\int \mathrm{d}A \int_0^H b \, z \, \mathrm{d}z = -\frac{1}{2} \int \mathrm{d}A \int_0^H b \, \mathrm{d}(z^2). \tag{30.214}$$

Integration by parts leads to the equivalent expression

$$\mathscr{P} = -\frac{1}{2}\int \mathrm{d}A \int_0^H \mathrm{d}(b\,z^2) + \frac{1}{2}\int \mathrm{d}A \int_{b(x,y,0)}^{b(x,y,H)} \eta^2(x,y,b)\,\mathrm{d}b \tag{30.215}$$

$$= -\frac{A\,H^2}{2}\,\overline{b(H)} + \frac{1}{2}\int \mathrm{d}A \int_{b(x,y,0)}^{b(x,y,H)} \eta^2(x,y,b)\,\mathrm{d}b, \tag{30.216}$$

where $\overline{b(H)}$ is the area averaged buoyancy at the top of the fluid domain, $z = H$. As discussed in Section 30.9.1, integration over the finite domain using a buoyancy coordinate leads us to set $\overline{b(H)} = b_{\max}$, the domain maximum buoyancy. Likewise, the second expression in equation (30.216) has its buoyancy integral range extended to $b_{\min}$ and $b_{\max}$. By doing so we can swap the area and buoyancy integrals to render

$$\mathscr{P} = \frac{A}{2}\left[-H^2\,b_{\max} + \int_{b_{\min}}^{b_{\max}} \overline{\eta^2(b)}\,\mathrm{d}b\right], \tag{30.217}$$

where $\overline{\eta^2(b)}$ is the area mean of the squared height of a buoyancy surface. The same calculation for the reference buoyancy, $b_{\mathrm{ref}}(z)$, leads to

$$\mathscr{P}_{\mathrm{ref}} = \frac{A}{2}\left[-H^2\,b_{\max} + \int_{b_{\min}}^{b_{\max}} \overline{\eta(b)}^2\,\mathrm{d}b\right], \tag{30.218}$$

where we noted that the height of a reference buoyancy surface equals to the area mean of the corresponding buoyancy surface

$$\eta(b_{\mathrm{ref}}) = \overline{\eta}(b = b_{\mathrm{ref}}), \tag{30.219}$$

and the reference buoyancy at the surface boundary equals to the maximum buoyancy, $b_{\mathrm{ref}}(H) = b_{\max}$.

Subtracting the gravitational potential energy of the reference/background state from the potential energy of the full state renders an expression for the available potential energy

$$\mathscr{P}_{\mathrm{APE}} = \mathscr{P} - \mathscr{P}_{\mathrm{ref}} = \frac{A}{2}\left[\int_{b_{\min}}^{b_{\max}} [\overline{\eta^2(b)} - \overline{\eta(b)}^2]\,\mathrm{d}b\right] = \int_{b_{\min}}^{b_{\max}} \overline{(\eta')^2}\,\mathrm{d}b \geq 0, \tag{30.220}$$

where (see Figure 30.3)

$$\eta(x,y,b,t) = \overline{\eta(b)} + \eta'(x,y,b,t). \tag{30.221}$$

The positive definite nature of the APE arises since either a positive or negative buoyancy surface undulation gives rise to motion.

Equation (30.220) is an exact expression for the APE of a perfect Boussinesq ocean in a flat bottom and simply connected domain. We encounter the same expression when studying the APE in a shallow water fluid in Section 37.5.6. It is the natural expression when working in buoyancy coordinates, whereby the APE is determined by height variations of constant buoyancy surfaces.

30.9.4 Approximate expression for APE

When working with geopotential coordinates it is useful to obtain an approximate expression for the APE in terms of buoyancy variations on constant height surfaces. That is the subject of this subsection.

Approximate version of APE in terms of buoyancy fluctuations

To develop an approximate expression for the APE we write the height of a buoyancy surface, $\eta(\mathcal{B})$, in the form (see caption to Figure 30.3 if confused by signs)

$$\eta(\mathcal{B}) \approx \overline{\eta(\mathcal{B})} + \left[\frac{\partial z}{\partial b}\right]_{z=\overline{\eta}} [\mathcal{B} - B(\overline{\eta})] = \overline{\eta} - \frac{b'}{N^2} \approx \overline{\eta} - \frac{b'}{N^2_{\text{ref}}}, \tag{30.222}$$

where the final step set $N^2(x, y, \overline{\eta}) \approx N^2_{\text{ref}}(\overline{\eta})$, which is valid to the same order as the approximation. We are thus led to the approximate expression

$$\eta' = \eta - \overline{\eta} \approx -\frac{b'}{N^2_{\text{ref}}} \tag{30.223}$$

so that the APE is given approximately by

$$\mathscr{P}_{\text{APE}} \approx A \left[\int_0^H \frac{\overline{(b')^2}}{2\, N^2_{\text{ref}}}\, \mathrm{d}z\right]. \tag{30.224}$$

This approximate expression is commonly used in practical calculations of APE, particularly when making use of field measurements (e.g., *Bishop et al.* (2020)).

Practical issues related to the sorted buoyancy profile

Figure 30.4 illustrates how to obtain the sorted buoyancy profile from a discretized version of a stably stratified fluid. The buoyancy of each cell is compared to that of all other cells and vertically stacked according to the relative buoyancy. The vertical position of the sorted grid cell is determined by accumulating the volume per horizontal area of the cell, starting from the bottom and moving up.

It is notable that cells with identical buoyancy lead to regions of zero vertical stratification in the sorted buoyancy profile. Such zero stratification regions commonly arise when sorting stratified fluid layers, where the buoyancy is constant within the layers. One is thus led to perform a vertical smoothing of the sorted profile to remove such unstratified regions, particularly if using the profile to define a background buoyancy frequency as required for the approximate APE calculation given by equation (30.224).

Budget for approximatae APE

To develop a budget for the approximate form of APE, start by considering the budget for buoyancy decomposed as

$$b(x, y, z, t) = b_{\text{ref}}(z) + b'(x, y, z, t), \tag{30.225}$$

so that the perfect fluid buoyancy equation takes on the form

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \Longrightarrow \frac{\mathrm{D}b'}{\mathrm{D}t} = -w\, N^2_{\text{ref}}. \tag{30.226}$$

Multiplying by b' leads to

$$\frac{\mathrm{D}[(b')^2/2]}{\mathrm{D}t} = -w\, b'\, N^2_{\text{ref}}, \tag{30.227}$$

FIGURE 30.4: Illustrating how to sort buoyancy to determine the background or reference profile for computing APE. The first panel on the left shows a sample buoyancy field with black lines representing buoyancy isolines. The second panel shows a discretized version of the field, with b_0 a unit of buoyancy and each cell's buoyancy an integer multiple of b_0. For simplicity we assume the horizontal area of the domain is depth independent and that each of the discrete grid cells has the same volume and horizontal area. The third panel shows the result of sorting the discrete buoyancy field, with the most buoyant fluid above the less buoyant fluid. During the sort, the cell's volume remains constant (Boussinesq ocean) and the accumulated volume per horizontal area determines the vertical position of the sorted cell. The final panel shows the sorted profile $b_{\text{ref}}(z)$. Note that regions of zero lateral buoyancy gradient in the unsorted buoyancy field lead to vertically unstratified regions in the sorted buoyancy.

and then dividing by N_{ref}^2 renders

$$\frac{\partial P_{\text{APE}}}{\partial t} + \boldsymbol{v} \cdot \nabla P_{\text{APE}} = -w\, b' \left[1 - \frac{b'}{2} \frac{\partial (1/N_{\text{ref}}^2)}{\partial z} \right], \tag{30.228}$$

where we defined the approximate APE per unit volume

$$P_{\text{APE}} = (1/2)\, [b'/N_{\text{ref}}]^2. \tag{30.229}$$

In the case of a depth-independent reference buoyancy frequency, we see that the APE per unit volume materially evolves with a source $-w\, b'$, which is analogous to the potential energy evolution where the source is $-w\, b$. Now adding equation (30.228) to the kinetic energy equation (30.116) with $\Phi = g\, z$ leads to

$$\frac{\partial (\mathcal{K} + P_{\text{APE}})}{\partial t} + \boldsymbol{v} \cdot \nabla (\mathcal{K} + P_{\text{APE}} + p/\rho_0) = -w \left[g - b_{\text{ref}} - \frac{(b')^2}{2} \frac{\partial (1/N_{\text{ref}}^2)}{\partial z} \right]. \tag{30.230}$$

Note that a global area average on any surface eliminates the $w\,(g - b_{\text{ref}})$ term since

$$\overline{w} = A^{-1} \int w \, \mathrm{d}A = 0, \tag{30.231}$$

which follows from $\nabla \cdot \boldsymbol{v} = 0$ (see Exercise 22.5). Further simplifications arise with depth-independent N_{ref}, with the corresponding space and time spectra studied by *Bühler et al.* (2014).

30.9.5 Comments

Elements of this section follow from Section 3.11.1 of *Vallis* (2017). Available potential energy remains a compelling notion for many aspects of geophysical fluid studies. Unfortunately, for the ocean proves difficult to extend the formalism beyond the perfect fluid Boussinesq system considered here. Particular difficulties arise from the nonlinear equation of state for seawater and the nontrivial ocean geometry with distinct basins and enclosed seas. Further difficulties arise

when considering the non-simply connected nature of the ocean domain.

30.10 Exercises

EXERCISE 30.1: SYMMETRY UNDER A TIME-DEPENDENT TRANSLATION
In this exercise we consider the Euler equation in free space (no boundaries) where we focus only on the acceleration and the pressure gradient force. That is, we ignore any body forces from gravity and planetary rotation so that the Euler equation takes on the form

$$\rho_0 \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\nabla p, \tag{30.232}$$

where we assume a Boussinesq ocean so that $\nabla \cdot \boldsymbol{v} = 0$.

Consider a shift in the reference frame used to describe the flow so that a coordinate position shifts according to

$$\boldsymbol{x} \to \boldsymbol{x} + \boldsymbol{c}(t), \tag{30.233}$$

where the vector $\boldsymbol{c}$ is time dependent but has the same value for all points in space.

(a) Is the shift (30.233) a Galilean transformation? Hint: recall the discussion of Galilean transformation in Section 18.9.

(b) What happens to pressure in the new reference frame? Hint: consider the elliptic problem for pressure as discussed in Section 30.3.1.

(c) Write the equation of motion (30.232) in this new reference frame.

EXERCISE 30.2: STEADY PARALLEL SHEARED FLOW ON A TANGENT PLANE
Consider the non-divergent parallel sheared flow on a tangent plane

$$\boldsymbol{v} = \hat{\boldsymbol{x}}\, u(y), \tag{30.234}$$

so that the flow is steady, zonal, and has a meridional dependence.

(a) Show that this flow is an exact solution to the β-plane inviscid Boussinesq velocity equation.

(b) Express the corresponding pressure gradient in terms of u and other terms.

(c) Show that for an f-plane the stationary velocity can have an arbitrary orientation. Hint: it is sufficient to show that $\boldsymbol{v} = \hat{\boldsymbol{y}}\, v(x)$ is a stationary solution on the f-plane but not on the β-plane.

EXERCISE 30.3: A GENERALIZED BOUSSINESQ APPROXIMATION
In this exercise we derive a mild generalization to the Boussinesq approximation. This generalization facilitates a more accurate decomposition of pressure by introducing a new reference density, $\overline{\rho}(z)$, that is a static function of depth. The new decomposition also leads to a slightly modified buoyancy field.

The derivation starts with the usual decomposition of density using ρ_0 as a space and time constant

$$\rho(\boldsymbol{x}, t) = \rho_0 + \rho'(\boldsymbol{x}, t), \tag{30.235}$$

thus leading to the Boussinesq momentum equation

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho_0^{-1}\,(\nabla p + \hat{\boldsymbol{z}}\,g\,\rho). \tag{30.236}$$

But rather than take the traditional decomposition of the pressure and gravitational terms, we now write

$$\nabla p + \hat{\boldsymbol{z}}\,g\,\rho = \nabla[p - \overline{p}(z) + \overline{p}(z)] + \hat{\boldsymbol{z}}\,g\,[\rho - \overline{\rho}(z) + \overline{\rho}(z)] \tag{30.237a}$$

$$= \nabla[p - \overline{p}(z)] + \hat{\boldsymbol{z}}\,g\,[\rho - \overline{\rho}(z)]. \tag{30.237b}$$

This step introduced the density, $\overline{\rho}(z)$, and the corresponding hydrostatically balanced pressure

$$\frac{\mathrm{d}\overline{p}(z)}{\mathrm{d}z} = -g\,\overline{\rho}(z). \tag{30.238}$$

(a) Show that the pressure is decomposed as

$$p(\boldsymbol{x}, t) = [p(\boldsymbol{x}, t) - \overline{p}(z)] + \overline{p}(z) = \rho_0\,\tilde{\varphi} + \overline{p}(z). \tag{30.239}$$

What is $\tilde{\varphi}$?

(b) Introduce a buoyancy

$$\tilde{b} = -\frac{g\,(\rho - \overline{\rho})}{\rho_0}, \tag{30.240}$$

defined relative to the depth-dependent background density, $\overline{\rho}(z)$, rather than the globally constant density ρ_0. Show that the momentum equation is given by

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\tilde{\varphi} + \hat{\boldsymbol{z}}\,\tilde{b}. \tag{30.241}$$

(c) Show that the baroclinicity vector appearing in the Boussinesq vorticity equation takes the form

$$\tilde{\boldsymbol{B}} = \nabla\tilde{b} \times \hat{\boldsymbol{z}}, \tag{30.242}$$

which is mathematically the same as with the traditional Boussinesq approximation from Section 30.1.2. We have thus succeeded in generalizing the pressure decomposition and buoyancy field, yet without corrupting the familiar Boussinesq vorticity dynamics.

EXERCISE 30.4: KINETIC ENERGY FOR A PERFECT HYDROSTATIC BOUSSINESQ FLUID

Consider a perfect *hydrostatic* Boussinesq ocean. Show that the kinetic energy per mass contained in the horizontal velocity,

$$\mathcal{K}_{\text{horz}} = \frac{\boldsymbol{u} \cdot \boldsymbol{u}}{2}, \tag{30.243}$$

satisfies the exact same equation as $\boldsymbol{v} \cdot \boldsymbol{v}/2$ does for a non-hydrostatic fluid, as given by equation (30.115). Assume the simple form for the geopotential, $\Phi = g\,z$.

EXERCISE 30.5: ENERGETICS FOR A PERFECT BOUSSINESQ OCEAN

In Section 30.6 we developed the energetic balances for a perfect Boussinesq ocean in a closed domain (domain where all boundary fluxes vanish). We here rederive the same energetics but

using the momentum, buoyancy, and continuity equations in the form that exposes buoyancy

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\nabla\varphi + \hat{\boldsymbol{z}}\, b \tag{30.244a}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \tag{30.244b}$$

$$\nabla \cdot \boldsymbol{v} = 0 \tag{30.244c}$$

$$b = b(S, \Theta). \tag{30.244d}$$

Assume the simple form for the geopotential, $\Phi = g\,z$, and assume a closed and static domain (i.e., an Eulerian domain with no boundary contributions). To help physically interpret terms, remember to isolate the total divergence terms and the remainder. Hint: this exercise is a simplification of the material presented in Section 30.7.

(a) Derive the material time evolution equation for the kinetic energy.

(b) Derive the material time evolution equation for $P^{\mathrm{b}} = -g^{-1}\,\Phi\, b = -b\,z$, with $\Phi = g\,z$. Interpret P^{b} and the processes that affect its material time evolution.

(c) Derive the mechanical energy equation written in its flux-form, where we define the mechanical energy per volume as $\rho_0\,(\mathcal{K} + P^{\mathrm{b}})$. Note the presence of ρ_0 multiplying both $\mathcal{K}$ and P^{b}. We thus derive an expression for $\rho_0\,\mathrm{D}(\mathcal{K} + P^{\mathrm{b}})/\mathrm{D}t$, and show that it is not affected by $w\,b$. Discuss.

(d) Integrate the equation for the mechanical energy per mass to derive a global domain budget for mechanical energy. Discuss.

EXERCISE 30.6: KINETIC ENERGY AND THE HYDROSTATIC BOUSSINESQ EQUATIONS

In this exercise we develop some properties of the kinetic energy for the hydrostatic Boussinesq equations listed in Section 30.1.6. We here assume the horizontal frictional acceleration is determined by vertical viscous friction in equation (30.134), and the stress boundary conditions are given by equations (30.137a) and (30.138).

(a) Derive the flux-form expression for the kinetic energy budget.

(b) Why does the kinetic energy only have contributions from the horizontal velocity components?

(c) Discuss the role of vertical viscosity in transporting kinetic energy in the vertical.

(d) Discuss the role of vertical viscosity in dissipating kinetic energy.

(e) Discuss how wind stress and bottom drag impact the globally integrated kinetic energy. Assume bottom drag in the form of equation (30.138).

EXERCISE 30.7: POTENTIAL ENERGY AND THE HYDROSTATIC BOUSSINESQ EQUATIONS

In this exercise we develop some properties of the gravitational potential energy for the hydrostatic Boussinesq equations stated in Section 30.1.6.

(a) Derive the flux-form budget for gravitational potential energy written as $P^{\mathrm{b}} = -g^{-1}\,\Phi\, b$ with $\Phi = g\,z$. Interpret P^{b}.

(b) Discuss the role of the subgrid scale eddy-induced advection in this budget as given by equation (30.127). In particular, discuss its impact on the center of mass of the fluid.

(c) Discuss the role of vertical diffusion in this budget as given by equation (30.127). In particular, discuss its impact on the center of mass of the fluid.

(d) Integrate the gravitational potential energy budget over the global ocean. Discuss how the surface boundary buoyancy flux, Q_{b}, impacts on the global potential energy budget through impacts on the center of mass of the fluid. Ignore any bottom geothermal heating.

EXERCISE 30.8: SQUARED BUOYANCY AND THE OCEAN MODEL EQUATIONS

In this exercise we develop some properties of the squared buoyancy for the hydrostatic Boussinesq equations stated in Section 30.1.6 using the subgrid scale buoyancy flux in equation (30.127).

(a) Write the flux-form budget describing the evolution of b^2, the squared buoyancy. Write the budget using the residual mean velocity defined by the sum

$$\boldsymbol{v}^{\dagger} = \boldsymbol{v} + \boldsymbol{v}^{*}. \tag{30.245}$$

Hint: start from the buoyancy equation written in the form

$$\mathrm{D}b/\mathrm{D}t = -\nabla \cdot \boldsymbol{F}^{\mathrm{b}}, \tag{30.246}$$

with $\boldsymbol{F}^{\mathrm{b}}$ discussed in Section 30.7.1.

(b) Discuss the impacts from vertical diffusion on the b^2 budget.

EXERCISE 30.9: PARAMETERIZED EDDY VELOCITY AND THE OCEAN MODEL EQUATIONS

In this exercise we develop some implications of assuming a specific form for the parameterized eddy velocity for the hydrostatic Boussinesq equations stated in Section 30.1.6. Namely, we consider the specific form for the parameterized eddy-induced velocity proposed by *Gent et al.* (1995)

$$\boldsymbol{u}^{*} = -\partial_z (B\,\boldsymbol{S}) \tag{30.247a}$$

$$w^{*} = \nabla_z \cdot (B\,\boldsymbol{S}) \tag{30.247b}$$

$$\boldsymbol{S} = -\frac{\nabla_z b}{N^2} \tag{30.247c}$$

$$\boldsymbol{v}^{*} \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{at all ocean boundaries.} \tag{30.247d}$$

In this expression, $B > 0$ is an eddy diffusivity. To ensure $\boldsymbol{v}^{*} \cdot \hat{\boldsymbol{n}} = 0$ at all domain boundaries requires that $B = 0$ along these boundaries. The horizontal vector $\boldsymbol{S} = (S^{(x)}, S^{(y)}, 0)$ measures the slope of the buoyancy surfaces relative to the horizontal. We assume the ocean is stably stratified in the vertical, so that $\partial b/\partial z = N^2 > 0$.

(a) Determine the vector streamfunction $\boldsymbol{\Psi}^{*}$ such that

$$\boldsymbol{v}^{*} = \nabla \times \boldsymbol{\Psi}^{*}. \tag{30.248}$$

Choose the gauge with $\hat{\boldsymbol{z}} \cdot \boldsymbol{\Psi}^{*} = 0$.

(b) Show that

$$\int_{-H}^{\eta} \boldsymbol{u}^{*}\, \mathrm{d}z = 0. \tag{30.249}$$

That is, the parameterized horizontal flow has a zero depth integral.

(c) At any chosen meridional position y, the meridional buoyancy transport from advection (resolved plus parameterized) is computed by

$$\mathcal{B}^{(y)}(y,t) = \int_{x_1}^{x_2} \mathrm{d}x \int_{-H}^{\eta} b\,(v + v^*)\,\mathrm{d}z. \tag{30.250}$$

The zonal and vertical integrals are over the full zonal and vertical extent of the ocean domain. Show that the effects from v^* are to reduce the meridional gradients of buoyancy. That is, if buoyancy decreases poleward, then v^* will flux buoyancy poleward to reduce the gradient.

(d) How does the introduction of $\boldsymbol{v}^*$ to the buoyancy equation (30.24c) affect the global integrated *gravitational potential energy*? Discuss.

(e) How does the introduction of $\boldsymbol{v}^*$ to the buoyancy equation (30.24c) affect the global integrated *available potential energy*? Discuss.

Chapter 31

Buoyancy

A large portion of the vertical pressure force acting on a geophysical fluid element is balanced by the gravitational force, with precise balance holding for an exact hydrostatic fluid. If there are unbalanced density-induced pressure forces, then a fluid element experiences a *buoyant* acceleration that causes vertical motion. More precisely, *buoyancy* is the vertical pressure acceleration acting on a fluid element that arises from density inhomogeneities. Correspondingly, buoyancy vanishes in a density homogeneous fluid, even though each fluid element still feels a gravitational force.

Buoyancy is a conceptually useful means to organize vertical forces from gravity in a fluid with varying density, and it does so by offering insights into the role of density inhomogeneities in creating vertical accelerations. Namely, if the vertical pressure forces acting on a fluid element are balanced by gravity, then the fluid element is *neutrally buoyant*. If these forces are unbalanced, then the fluid element has a nonzero vertical buoyancy acceleration.

Our study of buoyancy starts by examining a *test fluid element*, with a test fluid element probing properties of the fluid environment without altering the environment.[1] We refer to the buoyancy of a test fluid element as the *Archimedean buoyancy*, with Archimedean buoyancy providing a natural generalization of the familiar buoyancy acting to keep extended bodies, like a ship, floating in a fluid. Examining the buoyancy of test fluid elements positioned within a fluid leads to the notions of gravitational stability and neutral directions.[2]

Common references to buoyancy in the literature refer to the Archimedean buoyancy. Even so, Archimedean buoyancy is an incomplete rendering of the forces acting in a real fluid element arising from density inhomogeneities. A more complete description requires recognize that a real fluid element affects its surrounding fluid environment. This recognition leads to the concept of *effective buoyancy*, with effective buoyancy accounting for the *static forces* that create vertical accelerations of a fluid element. More precisely, effective buoyancy is the vertical acceleration acting on a fluid element that remains when setting all velocity dependent accelerations to zero. The effective buoyancy has a contribution from Archimedean buoyancy acting on a test fluid element, plus the vertical derivative of a pressure perturbation that depends only on the density field. This extra pressure perturbation force is the *back-reaction* on a fluid element due to the surrounding fluid environment.

[1] As defined in Section 18.3.5, a test fluid element is directly analogous to a point test mass particle that probes a gravitational field and a point test electrical charge that probes an electromagnetic field. Namely, neither the test fluid element, test mass particle, nor test charge alter the force fields that they probe.

[2] Archimedes was a Greek mathematician, inventor, engineer, physicist, and astronomer who lived in Syracuse, Sicily from roughly 287 B.C.E to 212 B.C.E. The Archimedean buoyancy of a test fluid element makes use of perhaps the most ancient of physical concepts in fluid mechanics.

CHAPTER GUIDE

This chapter builds from the study of pressure in Chapters 25, 26, and 29. We also make use of the equations for a Boussinesq fluid derived in Chapter 30, in particular the Poisson equation satisfied by pressure in a non-divergent flow. An understanding of this chapter supports an understanding of how pressure and gravity work within a fluid with density inhomogeneities, thus creating vertical accelerations of fluid elements. Note that we ignore surface tension effects (Section 26.11) in this chapter since we are not concerned with how objects float on the surface of a fluid, but instead focused on how buoyant forces create motion within a fluid.

31.2 Archimedes' Principle for a fluid region

The Archimedean buoyancy acting on a massive body immersed in a static fluid is the vertical acceleration due to the gravitational acceleration of the body *relative* to the gravitational acceleration of the fluid displaced by the body. A body's Archimedean buoyancy is proportional to its density relative to that of the displaced fluid. Hence, there is no Archimedean buoyancy without gravity nor is there a buoyant acceleration without density differences. These statements of *Archimedes' Principle* are a direct consequence of hydrostatics.

Archimedean buoyancy has wide applications for the study of bodies immersed within fluids; e.g. mechanics of marine organisms, ships, submarines, hot air balloons. Our interests concern the buoyancy of the fluid within itself, with this buoyancy fundamentally related to the density field. To extend the notions of Archimedean buoyancy to a fluid, we make use of a *test fluid element* originally defined in Section 18.3.5. A test fluid element is an imaginary probe that does not alter the fluid environment into which it is placed. It serves to map the Archimedean buoyancy of the fluid environment without modifying the fluid environment.

FIGURE 31.1: An arbitrary region of fluid, $\mathscr{R}$, within a density stratified fluid experiences a gravitational force acting down and a buoyant force acting up. The dark gray features represent the solid earth topography.

31.2.1 Hydrostatic pressure force

Consider an arbitrary finite region, $\mathscr{R}$, contained within an exactly hydrostatic fluid such as shown in Figure 31.1. Rather than an outside body, such as a ship or balloon, we are interested in an

arbitrary region of the fluid itself, such as an infinitesimal fluid element or a finite fluid volume. The mass of the fluid region is given by the integral of the fluid density over the region

$$M_{\text{fluid}} = \int_{\mathcal{R}} \rho \, \mathrm{d}V. \tag{31.1}$$

We seek an understanding of the forces acting on this region.

As discussed in Chapters 26 and 29, any surface, even an imaginary surface, within a fluid experiences a contact stress due to interactions between the fluid and the surface. For a fluid at rest in a gravitational field, the only contact stress arises from pressure. Pressure is a compressive stress, acting in the direction determined by minus the outward normal along the surface. Integrating the pressure over the closed boundary, $\partial\mathcal{R}$, leads to the pressure force acting on the region

$$\boldsymbol{F}_{\text{pressure}} = -\oint_{\partial\mathcal{R}} p \, \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{31.2}$$

where p is the pressure, $\hat{\boldsymbol{n}}$ is the outward normal on the boundary, and $\mathrm{d}\mathcal{S}$ is the area element.

Since the region, $\mathcal{R}$, is part of the fluid itself, then we can use Gauss's divergence theorem in the form of equation (2.73) to render the equivalent expression for $\boldsymbol{F}_{\text{pressure}}$ in terms of the volume integral of the pressure gradient

$$\boldsymbol{F}_{\text{pressure}} = -\int_{\mathcal{R}} \nabla p \, \mathrm{d}V. \tag{31.3}$$

Furthermore, since the fluid is at rest, it is in an exact hydrostatic balance so that its pressure only has a dependence on the vertical position within the fluid, $p = p(z)$. The hydrostatic pressure equals to the weight per horizontal area of fluid sitting above any point in the fluid so that its vertical derivative given by

$$\frac{\mathrm{d}p}{\mathrm{d}z} = -\rho \, g. \tag{31.4}$$

Hence, the force acting on the region is

$$\boldsymbol{F}_{\text{pressure}} = -\int_{\mathcal{R}} \nabla p \, \mathrm{d}V = -\int_{\mathcal{R}} \hat{\boldsymbol{z}} \, (\mathrm{d}p/\mathrm{d}z) \, \mathrm{d}V = \hat{\boldsymbol{z}} \, g \int_{\mathcal{R}} \rho \, \mathrm{d}V = \hat{\boldsymbol{z}} \, g \, M_{\text{fluid}}, \tag{31.5}$$

where we assumed a constant gravitational acceleration over $\mathcal{R}$. The hydrostatic pressure acting on the region imparts a vertical upward force equal to the weight of the fluid within the region. This result is a mathematical expression of *Archimedes' Principle* as applied to a fluid region.

Note that the net horizontal force acting over the region vanishes. The reason is that there are no horizontal pressure gradients within the fluid since, by assumption, the fluid is at rest and thus experiences no horizontal acceleration. So although the region $\mathcal{R}$ experiences horizontal compressive pressure forces acting along its boundary, $\partial\mathcal{R}$, these forces balance when integrated over the body, thus leaving a zero net horizontal acceleration. We studied such static force balances in Section 26.5.

31.2.2 Archimedean buoyancy force

Imagine replacing the fluid in the region $\mathcal{R}$ with another material whose density, ρ_{body}, generally differs from that of the displaced fluid, so that its mass is given by

$$M_{\text{body}} = \int_{\mathcal{R}} \rho_{\text{body}} \, \mathrm{d}V. \tag{31.6}$$

If the material has a density less than the displaced fluid, $\rho_{\text{body}} < \rho_{\text{fluid}}$, then we say that $\mathcal{R}$ has a net positive *buoyancy* force relative to the displaced fluid, in which case $\mathcal{R}$ experiences an upward acceleration. The converse holds if $\mathcal{R}$ is filled with matter that is more dense than the displaced fluid, in which case $\mathcal{R}$ sinks downward.

Mathematically we write this buoyancy force as

$$\boldsymbol{F}_{\text{buoy}} = \hat{\boldsymbol{z}}\, g \int_{\mathcal{R}} (\rho_{\text{fluid}} - \rho_{\text{body}})\, \mathrm{d}V = \hat{\boldsymbol{z}}\, g\, (M_{\text{fluid}} - M_{\text{body}}). \tag{31.7}$$

In this manner, we define the Archimedean buoyancy as a *relative force*. The vertical buoyancy force is negative if the weight of the body is larger than that of the fluid it displaces, and conversely if the body has less weight. If the densities are equal, then the body is *neutrally buoyant* and thus experiences no net vertical force; i.e., it floats.

As we observed earlier, a nonzero buoyancy force that leads to vertical acceleration arises from an imbalance between the gravitational body force acting over the region, $\mathcal{R}$, with the pressure contact force acting on the region boundary, $\partial\mathcal{R}$. Furthermore, if $\mathcal{R}$ is a region of fluid itself, then the buoyancy forces arise from non-hydrostatic pressure forces since any vertical acceleration breaks the hydrostatic balance. We further examine these non-hydrostatic pressure forces in Section 31.9.

31.3 Mass density and its flavors

The density of a fluid element is central to determining its buoyancy. The *thermal equation of state*, or *equation of state* to be more brief (Section 24.4.1), provides an expression for the mass density as a function of pressure, temperature, and material tracer concentration (salinity in the ocean and humidity in the atmosphere). In this section we discuss the equation of state as well as the related flavors of mass density used to study stratified fluids.

31.3.1 Equation of state for the atmosphere and ocean

The atmosphere and ocean are commonly approximated as two-component fluids (air and water vapor for the atmosphere; freshwater and salt for ocean). We thus write the *in situ* density as a function

$$\rho = \rho(S, T, p). \tag{31.8}$$

This *equation of state* is a function of the *in situ* temperature, T, the *in situ* pressure, p, and the *in situ* salinity (ocean) or humidity (atmosphere), S.[3] The term *in situ* refers to a property measured locally at a point in the fluid. Such *in situ* properties contrast to *potential* properties, which are based on referencing to a chosen pressure (e.g., potential temperature described in Section 24.3).

Liquids such as seawater have rather complex equations of states obtained from empirical fits to measurements. Part of the complexity arises from the multi-component nature of seawater (salt plus freshwater) as well as the nontrivial inter-molecular forces commonly found in liquids. In contrast, the dry atmosphere can, for many purposes, be well approximated as an ideal gas, which has a rather simple equation of state (see Section 24.4.1). Furthermore, even a moist atmosphere has an equation of state that can be massaged to look like that of an ideal gas (e.g., see Section 18.1 of *Vallis* (2017)). Hence, much of our discussion in this section is biased toward the ocean, where niceties of the equation of state are most important.

[3] For our purposes when discussing the ocean, we set $S = 1000\, C$ with C the salt concentration, with this specification referred to as the *absolute salinity* by *IOC et al.* (2010). C generally has values around 0.035 so that S has values around 35.

31.3.2 Modified temperature variables

As discussed in Section 24.3, the *in situ* temperature of a fluid element changes even if there is no heating applied to the element nor any changes to its material composition. Pressure changes provide the mechanical means for *in situ* temperature to change even with processes that are adiabatic and constant composition. Is it possible to remove such pressure effects and still have a field that describes the "temperature" of a fluid element? That is, can we define a temperature field that is only modified by irreversible processes such as heating and mixing? This question is answered by defining *potential temperature*, θ, as well as potential enthalpy or *Conservative Temperature*, Θ, with details given for potential temperature in Section 24.3 and Conservative Temperature in Section 27.11. For now it is sufficient to note that the mass density can be written as a function salinity, potential temperature, and pressure

$$\rho = \rho(S, \theta, p), \tag{31.9}$$

or as a function of salinity, Conservative Temperature, and pressure

$$\rho = \rho(S, \Theta, p). \tag{31.10}$$

For our purposes throughout this book, it is not important to distinguish between potential temperature and Conservative Temperature.

One comment on notation is key here. Namely, the functions $\rho(S, T, p)$, $\rho(S, \theta, p)$, and $\rho(S, \Theta, p)$ have distinct arguments and yet they all measure the same density. A more mathematically honest nomenclature distinguishes the functions by writing, say,

$$\rho = \mathcal{F}(S, T, p) = \mathcal{G}(S, \theta, p) = \mathcal{H}(S, \Theta, p). \tag{31.11}$$

However, we choose brevity in notation by allowing the functional dependence to signal the distinction. This overloaded notation is standard in the oceanography literature, with care needed to ensure clarity in understanding.[4]

31.3.3 Exact differential and material time changes

When computing the buoyancy of a fluid element, we compare the density of that element with the density of its local surrounding fluid environment. To support that comparison, we here consider how density differs between infinitesimally close spatial positions. Given the functional dependence for the equation of state written in terms of S, θ, p (equation (31.9)), the exact differential of density[5] is given by

$$\mathrm{d}\rho = \left[\frac{\partial \rho}{\partial S}\right] \mathrm{d}S + \left[\frac{\partial \rho}{\partial \theta}\right] \mathrm{d}\theta + \left[\frac{\partial \rho}{\partial p}\right] \mathrm{d}p \equiv \rho\,\beta\,\mathrm{d}S - \rho\,\alpha\,\mathrm{d}\theta + c_{\mathrm{s}}^{-2}\,\mathrm{d}p. \tag{31.12}$$

[4] We made note of this point when introducing scalar fields in Section 1.1.

[5] Recall we introduced exact differentials in Section 2.8. Furthermore, equation (31.12) is the *exterior derivative* of density.

The second equality introduced the following thermodynamic properties of the fluid

$$\beta = \frac{1}{\rho}\left[\frac{\partial \rho}{\partial S}\right]_{\theta,p} \qquad \text{haline contraction coefficient} \tag{31.13}$$

$$\alpha = -\frac{1}{\rho}\left[\frac{\partial \rho}{\partial \theta}\right]_{S,p} \qquad \text{thermal expansion coefficient} \tag{31.14}$$

$$c_{\mathrm{s}}^2 = \left[\frac{\partial p}{\partial \rho}\right]_{S,\theta} \qquad \text{squared sound speed.} \tag{31.15}$$

The haline contraction coefficient, β, is considered for the ocean, where *haline* refers to salinity.[6]

The density differential (31.12) leads to the expression for the material change in the *in situ* density moving along a fluid particle trajectory

$$\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = \beta\,\frac{\mathrm{D}S}{\mathrm{D}t} - \alpha\,\frac{\mathrm{D}\theta}{\mathrm{D}t} + \frac{1}{\rho\,c_{\mathrm{s}}^2}\,\frac{\mathrm{D}p}{\mathrm{D}t}. \tag{31.16}$$

In the absence of mixing, the potential temperature and salinity are materially constant.[7] In this case, the material time evolution of the *in situ* density is affected only through adiabatic processes that lead to material time changes to the pressure

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{1}{c_{\mathrm{s}}^2}\,\frac{\mathrm{D}p}{\mathrm{D}t} \quad \Longleftarrow \quad \text{adiabatic and isohaline changes.} \tag{31.17}$$

31.3.4 Potential density

As discussed in Section 31.3.2, the reversible motion of a perfect fluid element generally occurs with materially constant potential temperature and materially constant tracer concentration. We thus find it convenient to combine the evolution of salinity and potential temperature into the evolution of a single variable. *Potential density* is one such combination, which is defined as the density a fluid element would have if reversibly moved to a chosen reference pressure

$$\varrho = \varrho(S,\theta|p_{\mathrm{ref}}) \equiv \rho(S,\theta,p=p_{\mathrm{ref}}). \tag{31.18}$$

Hence, potential density is found by evaluating the equation of state for *in situ* density with the local value for S and θ, yet with the pressure set to the fixed reference pressure, $p = p_{\mathrm{ref}}$. Potential density is thus parametrically a function of the reference pressure. As for the potential temperature, the reference pressure is often taken at sea level. However, as noted in a few paragraphs below, that choice is neither necessary nor universal.

Material evolution of potential density

With the definition (31.18), the material evolution of potential density is given by

$$\frac{1}{\varrho}\frac{\mathrm{D}\varrho}{\mathrm{D}t} = \beta(S,\theta,p=p_{\mathrm{ref}})\,\frac{\mathrm{D}S}{\mathrm{D}t} - \alpha(S,\theta,p=p_{\mathrm{ref}})\,\frac{\mathrm{D}\theta}{\mathrm{D}t}, \tag{31.19}$$

[6] Note that in many chapters of this book, $\beta = \partial f/\partial y$ is the meridional derivative of the Coriolis parameter. We keep the two usages for β distinct so to avoid confusion.

[7] This statement has nuances that are detailed in *IOC et al.* (2010), and yet they can be ignored for our purposes.

where

$$\beta(S,\theta,p=p_{\rm ref}) = \frac{1}{\varrho(S,\theta,p=p_{\rm ref})}\left[\frac{\partial\rho(S,\theta,p_{\rm ref})}{\partial S}\right]_\theta \qquad \text{haline contraction at } p=p_{\rm ref} \tag{31.20}$$

$$\alpha(S,\theta,p=p_{\rm ref}) = -\frac{1}{\varrho(S,\theta,p=p_{\rm ref})}\left[\frac{\partial\rho(S,\theta,p_{\rm ref})}{\partial \theta}\right]_S \qquad \text{thermal expansion at } p=p_{\rm ref} \tag{31.21}$$

are the haline contraction and thermal expansion coefficients evaluated at the reference pressure $p = p_{\rm ref}$. Since pressure is fixed at the reference value, there is no pressure derivative on the right hand side of equation (31.19). Potential temperature and salinity are materially constant for reversible processes; i.e., adiabatic motion that also maintains constant matter content (e.g., isohaline) for fluid elements. By construction, potential density is also materially constant for reversible processes since both terms on the right hand side of equation (31.19) vanish. This behavior is in contrast to *in situ* density, whose evolution is affected by pressure changes as revealed by equations (31.16) and (31.17).

Reference pressures for ϱ and θ

The reference pressure for the potential density is commonly assumed to be the same as for the potential temperature. This assumption is particularly the norm for the atmosphere, where the reference pressure is generally taken at the sea level. Likewise for the ocean, the potential temperature is generally computed using a standard sea level reference pressure. However, there are many occasions in the ocean to consider potential density with larger reference pressures, such as when considering processes within the ocean interior. Doing so is motivated by the rather strong nonlinear effects associated with the seawater equation of state. In this case, pressure effects prompt one to choose a reference pressure closer to the *in situ* pressure near to the region of analysis. Even though it is common to choose a potential density reference pressure distinct from the surface pressure, the potential temperature reference pressure generally remains at the surface. There is no fundamental problem with the use of distinct reference pressures for ϱ and θ. In particular, all of the above properties of potential density remain unchanged.

31.3.5 Linear equation of state for the ocean

For certain purposes, it is useful to approximate the equation of state used to study ocean fluid mechanics. One common idealization is to compute density as a linear function of potential temperature and salinity

$$\rho = \rho_0\,[1 - \alpha\,(\theta-\theta_0) + \beta\,(S-S_0)], \tag{31.22}$$

where α, β, ρ_0, θ_0, and S_0 are constants. An even further simplification is to set salinity to a constant, so that density is just a linear function of potential temperature. Alternatively, we may choose $\beta = 0$, in which case salinity is a passive tracer that has no impact on density.

31.3.6 Comments on density in a hydrostatic ocean

In an approximate hydrostatic fluid (Section 28.2), we only have access to the hydrostatic pressure so that density is computed as a function of hydrostatic pressure. Furthermore, density is generally a function of pressure whereas hydrostatic pressure is directly determined by the vertical integral of density. This self-referential situation is resolved for the Boussinesq ocean in which energetic consistency requires the seawater equation of state to use the geopotential defined pressure, $p_{\rm eos} = -\rho_0\,\Phi$, as the argument for density (Section 30.8), which takes on the static form, $p_{\rm eos} = -\rho_0\,g\,z$, for a simple geopotential. For the non-Boussinesq hydrostatic ocean, we can make use of pressure

as the vertical coordinate, thus allowing for density to be evaluated at a pressure prescribed by the value of the vertical coordinate.

31.3.7 Further study

Chapter 1 of *Vallis* (2017) provides a pedagogical discussion of the equation of state for an ideal gas atmosphere and for seawater, as well as a discussion of the various flavors of density. See also Section 18.1 of *Vallis* (2017) for the equation of state for an ideal gas with water vapor. The seawater equation of state is detailed by *IOC et al.* (2010), with an overview provided by *McDougall et al.* (2013).

31.4 Archimedean buoyancy of a test fluid element

We now return to the notions of Archimedean buoyancy (in brief, the "buoyancy") of a test fluid element. Again, buoyancy is the gravitational acceleration that acts on a massive body due to the difference between the density of the body and the density of the local surrounding fluid environment. For this section, we consider the massive body to be a test fluid element whose presence does not alter the density field.

31.4.1 Locally referenced Archimedean buoyancy

Consider a local definition of fluid buoyancy according to

$$b_{\text{local}} = -g\,(\rho_{\text{test}} - \rho_{\text{environ}})/\rho_{\text{environ}} = g\,(1 - \rho_{\text{test}}/\rho_{\text{environ}}), \tag{31.23}$$

where ρ_{environ} is the local density of the fluid environment, and ρ_{test} is the density of the test fluid element within that environment. If the fluid element has a density greater than the environment, then it has a negative locally referenced buoyancy, and vice versa.

In probing the buoyancy of the fluid environment, we imagine moving the test fluid element from one point to another. In that movement, the test fluid element might retain all of its original properties, or those properties might be modified during the movement. That is, in determining the buoyancy we determine ρ_{test} by specifying its point of origin and how it is moved (e.g., with or without mixing?). Conventional approaches are specified later in this section. A key notion is that buoyancy as defined by equation (31.23) is a function of the path that the test fluid element takes to reach the environment point. This subjectivity lends ambiguity to the definition of local Archimedean buoyancy. We remove this ambiguity by asking specific questions. One central question we ask is if the test fluid element moves an infinitesimal distance while mixing its temperature and salinity with the environment, then what direction maintains a neutrally buoyant state for the test fluid element? This question forms the basis for defining *neutral directions*, which are the topic of Section 31.5.

Working with locally referenced Archimedean buoyancy requires a redefinition of a reference state when moving from point to point within a fluid. The continuum of reference states allows for a local accounting of the gravitational stability and neutral directions. However, the re-referencing cannot be seamlessly incorporated into the equations of motion since at each point one needs to redefine the reference state. As an alternative means to garner local information about forces associated with density gradients, we examine the nature of the pressure force in our discussion of *effective buoyancy* in Section 31.9.

31.4.2 Globally referenced Archimedean buoyancy

The definition (31.23) accepts that buoyancy is a relative field. Hence, at each fluid point we redefine the environment to compare the density of the test fluid element. However, there are cases in which it is more convenient, and sufficient, to define a globally constant environment with a constant reference density, ρ_{ref}. In this case we consider the global buoyancy as

$$b_{\text{global}} = g\,(1 - \rho/\rho_{\text{ref}}), \tag{31.24}$$

where we compute ρ according to the local environmental density. This definition is particularly useful for idealized cases where the *in situ* density is not a function of pressure. In this case buoyancy is a function only of potential temperature and salinity so that we can make use of potential density to measure buoyancy (as explained below).

Although the numerical value of b_{global} is a function of the reference density, what is more relevant is the buoyancy of one fluid element relative to another

$$\Delta b_{\text{global}} = -g\,(\Delta\rho/\rho_{\text{ref}}). \tag{31.25}$$

The sign of this relative buoyancy does not depend on the reference density, with the sign all that we need to conclude whether one fluid element is more buoyant than another. Furthermore, with a globally constant environmental density, the buoyancy becomes a local function of space. That is, we no longer compare the fluid element density to a changing local density. Instead, we compute the local density and compare it to the reference density. We can thus determine b_{global} at a point through information available just at that point. Correspondingly, we can map b_{global} and determine the relative buoyancy of fluid elements anywhere in the fluid.

31.5 Buoyancy stratification and neutral directions

What are the Archimedean buoyant forces that act on a fluid element? Is the fluid gravitationally stable to small perturbations? We answer these questions by using a test fluid element to probe the local fluid environment without disturbing the environment. We do not consider time changes in this section, instead considering a snapshot of the fluid environment and using test fluid elements to probe the buoyant properties of the environment.

31.5.1 General considerations

As a fluid element moves through its surrouding environment, it is exposed to a suite of physical processes that can modify its thermal, material, and mechanical properties; i.e., its θ, S, and p. Modification of its pressure occurs through contact stresses with other fluid elements (Chapters 26 and 29). Modification of its thermal and material properties occurs through the mixing-induced exchange of heat and matter. The exchange of thermal and material properties occurs in the presence of irreversible processes whereas mechanical exchanges occur either reversibly (pressure exchange) or irreversibly (viscous exchange; Section 26.3).

The *in situ* density of a fluid element generally changes when it moves through the fluid, with the density change determined by how the element interacts with the surrounding environment. We conceive of two complementary interactions for the purpose of examining the local Archimedean buoyancy of the test fluid element.

- UNMIXED TEST FLUID ELEMENT: Displace the test fluid element without changing θ and S yet allowing p to equilibrate with the local environment. We imagine this adiabatic and isohaline displacement to occur by surrounding the test element with a thermally and

materially impermeable elastic sack. In this case there is no mixing of the test element with the environment, yet it mechanically equilibrates its pressure with the surrounding fluid. Hence, the test fluid element's *in situ* density changes through the changing pressure of the local environment.

- MIXED TEST FLUID ELEMENT: Displace the test fluid element with θ, S, and p equilibrating with the local environment. Such equilibration requires a complete mixing of the test fluid element's θ and S with the local environment, as well as the mechanical equilibration of its pressure.

If we displace the unmixed test fluid element to a region where its *in situ* density differs from the local environment, then the fluid element feels a local Archimedean buoyant force. However, there are directions that the test fluid element can move that leave its local Archimedean buoyancy zero; i.e., where the test fluid element retains the same *in situ* density as the local environment and so remains neutrally buoyant. These directions are referred to as *neutral directions*, with a test fluid element displaced along a neutral direction maintaining zero local Archimedean buoyancy. It is as if the test fluid element floats along a neutral direction.

A complementary means to conceive of neutral directions is found by considering the mixed test fluid element that is displaced and equilibrates its θ, S, and p with the local environment. An arbitrary displacement leads to a change in the fluid element's *in situ* density due to changes in θ, S, and p. However, if the test element is displaced along the neutral direction, the mixing-induced changes from θ and S exactly balance (details given below). In this manner, the only change to the *in situ* density arises from changes to the pressure felt by the test fluid element, with these changes identical to those felt by the unmixed test fluid element when moving along a neutral direction.

31.5.2 Comparing *in situ* densities

To make the above ideas mathematically precise, consider an infinitesimal displacement, $\mathrm{d}\boldsymbol{x}$, of a test fluid element and examine how its *in situ* density, $\rho = \rho(S, \theta, p)$, changes under the above two displacements. First consider the mixed fluid element so that it equilibrates θ, S, and p with the local environment. The *in situ* density of the test element at the new location equals to that of the local environment, $\rho(\boldsymbol{x} + \mathrm{d}\boldsymbol{x})$. To leading order, the difference in density between the origin and the displaced position is computed according to the exact differential

$$\begin{aligned}
\mathrm{d}\rho &= \rho(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}) - \rho(\boldsymbol{x}) && (31.26a)\\
&= \rho[S(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}), \theta(\boldsymbol{x} + \mathrm{d}\boldsymbol{x}), p(\boldsymbol{x} + \mathrm{d}\boldsymbol{x})] - \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x})] && (31.26b)\\
&= \mathrm{d}\boldsymbol{x} \cdot \left[\frac{\partial \rho}{\partial \theta}\,\nabla\theta + \frac{\partial \rho}{\partial S}\,\nabla S + \frac{\partial \rho}{\partial p}\,\nabla p\right] && (31.26c)\\
&= \rho\,\mathrm{d}\boldsymbol{x} \cdot \left[-\alpha\,\nabla\theta + \beta\,\nabla S + \frac{1}{\rho\,c_{\mathrm{s}}^2}\,\nabla p\right]. && (31.26d)
\end{aligned}$$

For the unmixed test fluid element there is no exchange (mixing) of θ and S with the surrounding environment. Hence, the test element's density changes just from pressure changes

$$\begin{aligned}
(\mathrm{d}\rho)_{(\text{no mix})} &= \rho(\boldsymbol{x} + \mathrm{d}\boldsymbol{x})_{(\text{no mix})} - \rho(\boldsymbol{x}) && (31.27a)\\
&= \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x} + \mathrm{d}\boldsymbol{x})] - \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x})] && (31.27b)\\
&= \rho\,\mathrm{d}\boldsymbol{x} \cdot \left[\frac{1}{\rho\,c_{\mathrm{s}}^2}\,\nabla p\right]. && (31.27c)
\end{aligned}$$

Comparing the densities of the two displaced test fluid elements renders

$$\rho(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})-\rho(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})_{(\text{no mix})}=[\rho(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})-\rho(\boldsymbol{x})]-[\rho(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})_{(\text{no mix})}-\rho(\boldsymbol{x})] \tag{31.28a}$$

$$=\rho[S(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}),\theta(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}),p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})]-\rho[S(\boldsymbol{x}),\theta(\boldsymbol{x}),p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] \tag{31.28b}$$

$$=\rho\,\mathrm{d}\boldsymbol{x}\cdot[-\alpha\,\nabla\theta+\beta\,\nabla S]\,. \tag{31.28c}$$

We discuss this result in the following.

31.5.3 Neutral directions and the neutrality condition

As noted in Figure 31.2, if the density of the displaced and unmixed test fluid element is the same as the local environment, then the particular displacement defines a neutral direction. From equation (31.28c) we see a displacement along a neutral direction satisfies

$$\mathrm{d}\boldsymbol{x}_{\text{neutral}}\cdot[-\alpha\,\nabla\theta+\beta\,\nabla S]=\mathrm{d}\boldsymbol{x}_{\text{neutral}}\cdot\hat{\boldsymbol{\gamma}}\,|-\alpha\,\nabla\theta+\beta\,\nabla S|=0, \tag{31.29}$$

where we introduced the *dianeutral direction*

$$\hat{\boldsymbol{\gamma}}=\frac{-\alpha\,\nabla\theta+\beta\,\nabla S}{|-\alpha\,\nabla\theta+\beta\,\nabla S|}, \tag{31.30}$$

which points in the direction of increasing density.[8] Infinitesimal displacements, $\mathrm{d}\boldsymbol{x}_{\text{neutral}}$, that are orthogonal to the dianeutral direction, $\hat{\boldsymbol{\gamma}}$, occur along a neutral direction

$$\mathrm{d}\boldsymbol{x}_{\text{neutral}}\cdot\hat{\boldsymbol{\gamma}}=0\Longrightarrow\text{displacement along a neutral direction.} \tag{31.31}$$

These displacements of the unmixed test fluid element lead to no difference in the *in situ* density of the local environment and the fluid element. Hence, neutral displacements retain a vanishing local Archimedean buoyancy for the unmixed test fluid element. In contrast, displacements in the dianeutral direction alter the local buoyancy.

Let us write the neutral displacement in the form

$$\mathrm{d}\boldsymbol{x}_{\text{neutral}}=\hat{\boldsymbol{t}}_{\text{neutral}}\,\mathrm{d}s, \tag{31.32}$$

where $\mathrm{d}s$ is the arc-length along the displacement and $\hat{\boldsymbol{t}}_{\text{neutral}}$ is the unit vector pointing along the neutral displacement. We can thus write equation (31.29) as

$$\alpha\,\hat{\boldsymbol{t}}_{\text{neutral}}\cdot\nabla\theta=\beta\,\hat{\boldsymbol{t}}_{\text{neutral}}\cdot\nabla S, \tag{31.33}$$

which we refer to as the *neutrality condition*. The neutrality condition means that the α and β weighted derivatives of θ and S are exactly balanced when aligned along a neutral direction. So when considering neutral directions from the perspective of the mixed test fluid element, the mixing-induced changes in θ precisely compensate mixing-induced changes in S as per the neutrality condition (31.33). As a result, the *in situ* density of the mixed test fluid element changes only via changes to the pressure (since θ and S changes are compensated), which is precisely how the unmixed test fluid element changes its *in situ* density.

[8] Equation (4) in *McDougall et al.* (2014) makes use of the opposite convention so that their dianeutral direction points towards decreasing density. We instead follow the water mass transformation convention as in equation (68.38), so that $\hat{\boldsymbol{\gamma}}$ points in the direction of increasing density.

$$\rho[S(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), \theta(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] = \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] \Longrightarrow \text{neutral direction}$$

$$\alpha\, \hat{\boldsymbol{t}}_{\text{neutral}} \cdot \nabla\theta = \beta\, \hat{\boldsymbol{t}}_{\text{neutral}} \cdot \nabla S \Longrightarrow \text{neutrality condition}$$

FIGURE 31.2: Schematic of the complementary thought experiments used to determine neutral directions. For the right pathway we imagine a test fluid element that is thermally and materially closed but is mechanically open. Hence, as the test fluid element is displaced from its original location, $\boldsymbol{x}$, to a new position, $\boldsymbol{x}+\mathrm{d}\boldsymbol{x}$, it equilibrates to the local pressure but retains the θ and S of the origin. If the *in situ* density of the fluid element is displaced along a direction where it maintains the same density as the local environment, then the locally defined Archimedean buoyancy vanishes and this displacement is aligned along a neutral direction. The complement perspective is shown by the left pathway whereby we follow the mixed test fluid element. If the mixing-induced changes in θ precisely compensate mixing-induced changes in S, according to the neutrality condition (31.33), then the *in situ* density changes for this test fluid element arise only from pressure changes, just like for the ummixed test element on the right pathway.

31.5.4 Buoyancy frequency and gravitational stability

Thus far we have considered a general displacement, $\mathrm{d}\boldsymbol{x}$, of two test fluid elements, and determined conditions for this displacement to keep the locally defined Archimedean buoyancy at zero. Here we specialize to the case of a vertical displacement (Figure 31.3) in which the difference between the environmental density and the unmixed test element's density is

$$\rho(z+\mathrm{d}z) - \rho(z+\mathrm{d}z)_{(\text{no mix})} = \rho\, \mathrm{d}z\, (-\alpha\, \partial_z\theta + \beta\, \partial_z S). \tag{31.34}$$

Now consider a vertically upward displacement so that $\mathrm{d}z > 0$. If the surrounding environment has a lower density than the adiabatic and isohaline displaced test fluid element, $\rho(z+\mathrm{d}z) < \rho(z+\mathrm{d}z)_{(\text{no mix})}$, then the test element will feel a buoyancy force returning it to the original depth. The restorative buoyancy force per volume is written

$$g\, [\rho(z+\mathrm{d}z) - \rho(z+\mathrm{d}z)_{(\text{no mix})}] = g\, \rho\, \mathrm{d}z\, (-\alpha\, \partial_z\theta + \beta\, \partial_z S) \equiv -N^2\, \rho\, \mathrm{d}z, \tag{31.35}$$

where we defined the squared buoyancy frequency

$$N^2 = g\, (\alpha\, \partial_z\theta - \beta\, \partial_z S). \tag{31.36}$$

Stable vertical motion results from a background density profile with $N^2 > 0$. An unstable profile occurs when $N^2 < 0$, in which case motion of the test fluid element results in an exponential growth associated with a *gravitational instability*. That is, when the fluid column is vertically stratified with $N^2 < 0$, an initially tiny vertical displacement of a test element will lead to an even larger displacement, thus causing the perturbation to grow unbounded as the gravitational instability grows. We illustrate these cases in Figure 31.4 for the case of linear density profiles.

$\rho[S(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), \theta(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] < \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] \Longrightarrow$ **gravitationally stable**

$\rho[S(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), \theta(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] > \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] \Longrightarrow$ **gravitationally unstable**

$\rho[S(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), \theta(\boldsymbol{x}+\mathrm{d}\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] = \rho[S(\boldsymbol{x}), \theta(\boldsymbol{x}), p(\boldsymbol{x}+\mathrm{d}\boldsymbol{x})] \Longrightarrow$ **gravitationally neutral**

FIGURE 31.3: Schematic of the calculation used to examine whether a fluid column is gravitationally stable under vertical displacement of a test fluid element, here realized by specializing the general displacement in Figure 31.2. A test fluid element is displaced from its original location at a position $\boldsymbol{x}$ to a position $\boldsymbol{x}+\mathrm{d}\boldsymbol{x}$, with $\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{z}}\,\mathrm{d}z$ and $\mathrm{d}z > 0$ in this figure. We compare the density of the displaced unmixed test fluid element with the local environment to determine whether the density stratification of the fluid environment is gravitationally stable, unstable, or neutral.

31.5.5 Locally referenced potential density

Equation (31.36) defines the squared buoyancy frequency in terms of the vertical temperature and salinity gradients. This expression is identical to the vertical gradient of the potential density (31.18), when the reference pressure for density is taken local to the point where the buoyancy frequency is computed. That is, the vertical gradient of the *locally referenced potential density* provides a measure of the vertical stratification

$$N^2 = -g\left[\frac{1}{\varrho}\frac{\partial \varrho}{\partial z}\right]_{p_{\mathrm{ref}}=p} = g\left[\alpha\,\frac{\partial \theta}{\partial z} - \beta\,\frac{\partial S}{\partial z}\right]. \tag{31.37}$$

At a point in the fluid, the locally referenced potential density equals to the *in situ* density. However, when probing nearby points by displacing test fluid elements, and thus taking spatial variations into account, the two densities have distinct gradients. Namely, the gradient of the *in situ* density is affected by pressure gradients, whereas spatial gradients of the locally referenced potential density do not feel pressure effects.

31.5.6 Gravitational stability of an ideal gas atmosphere

We introduced the adiabatic lapse rate in Section 24.2 as a measure of how temperature varies as a function of pressure or depth. For an ideal gas atmosphere (Section 24.4), the squared buoyancy frequency can be written (Exercise 31.2)

$$N^2 = \frac{g}{\theta}\,\frac{\partial \theta}{\partial z}. \tag{31.38}$$

FIGURE 31.4: Sample vertical "soundings" of density in the atmosphere or density profiles in the ocean, with the density assumed to be a linear function of z. If the density decreases upward, the squared buoyancy frequency is positive, $N^2 > 0$, and the fluid is gravitationally stable. If the density does not change when moving vertically, then the fluid is said to be neutrally buoyant with $N^2 = 0$. If the density increases moving upward, then the fluid is gravitationally unstable, with this instability signaled by $N^2 < 0$.

The potential temperature for an ideal gas is given by equation (24.92)

$$\theta = T \left[\frac{p_{\text{ref}}}{p} \right]^{\varphi} \tag{31.39}$$

where

$$\varphi = R^{\text{M}} / c_p \tag{31.40}$$

is a dimensionless constant for a simple ideal gas. Consequently, the squared buoyancy frequency takes the form

$$g^{-1} N^2 = \frac{\partial \ln \theta}{\partial z} = \frac{\partial \ln T}{\partial z} - \varphi \frac{\partial \ln p}{\partial z}. \tag{31.41}$$

For a hydrostatic fluid with a constant gravitational acceleration, the vertical derivative of pressure is given by (Section 28.2)

$$\frac{\partial p}{\partial z} = -\rho\, g, \tag{31.42}$$

so that pressure at a point in the fluid equals to the weight per area above that point. Using this result leads to the squared buoyancy frequency

$$g^{-1} N^2 = \frac{\partial \ln T}{\partial z} + \frac{\varphi\, g\, \rho}{p} = \frac{1}{T} \frac{\partial T}{\partial z} + \frac{g}{c_p T}, \tag{31.43}$$

where we used the ideal gas relation $p = \rho T R^{\text{M}}$ for the final step.

A vanishing buoyancy frequency, or equivalently a vanishing vertical derivative of potential temperature, occurs when the vertical temperature gradient equals to the dry adiabatic lapse rate

$$N^2 = 0 \Longleftrightarrow \frac{\partial T}{\partial z} = \Gamma_d, \tag{31.44}$$

FIGURE 31.5: Three vertical profiles of *in situ* temperature in a dry ideal gas atmosphere. The neutrally stable profile has $T_{\text{neutral}} = T_0 + z\,\Gamma_d$, where $\Gamma_d = -g/c_p \approx -9.8$ K/(1000 m). A vertically unstable profile (heavy over light) has $T_{\text{unstable}} = T_0 + z\,\Gamma_{\text{unstable}}$ where $\Gamma_{\text{unstable}} < \Gamma_d = -g/c_p$. In contrast, the gravitationally stable atmosphere has $T_{\text{stable}} = T_0 + z\,\Gamma_{\text{stable}}$ where $\Gamma_{\text{stable}} > \Gamma_d = -g/c_p$.

where (see equation (24.74))

$$\Gamma_d = -\frac{g}{c_p} \approx -9.8 \text{ K/(1000 m)}. \tag{31.45}$$

That is, if the *in situ* temperature decreases upon ascent more quickly than the dry adiabatic lapse rate, then the vertical column is gravitationally unstable. In effect, the column becomes top heavy and subject to overturning. We summarize this stability criteria as

$$\text{stable} \qquad N^2 > 0 \Longleftrightarrow -\frac{\partial T}{\partial z} < \frac{g}{c_p} \tag{31.46}$$

$$\text{unstable} \qquad N^2 < 0 \Longleftrightarrow -\frac{\partial T}{\partial z} > \frac{g}{c_p}, \tag{31.47}$$

with Figure 31.5 providing an illustration for three linear temperature profiles.

31.5.7 Constant buoyancy frequency in idealized studies

In many idealized studies, pressure effects are ignored in the density, so that the squared buoyancy frequency is computed as the vertical derivative

$$N^2 = -\frac{g}{\rho}\frac{\partial \rho}{\partial z} \tag{31.48}$$

We thus see that if the density has the exponential structure

$$\rho(z) = \rho_0\, \mathrm{e}^{-z/H}, \tag{31.49}$$

then the squared buoyancy frequency is

$$N^2 = g/H. \tag{31.50}$$

For a Boussinesq ocean (Chapter 30), one typically computes the squared buoyancy frequency as

$$N^2_{\text{Bous}} = -\frac{g}{\rho_0}\frac{\partial \rho}{\partial z} \tag{31.51}$$

so that the constant buoyancy frequency (31.50) arises from the linear density profile

$$\rho = \rho_0 \, (1 - z/H). \tag{31.52}$$

Evidently, the Boussinesq density profile (31.52) is an approximation to the non-Boussinesq profile (31.49) in the case of very large H. When studying thermodynamics we derived the atmospheric scale height in equation (24.85), in which $H \approx 10$ km, which is within the troposphere. In contrast, the ocean scale depth is about an order of magnitude larger given the nearly incompressible nature of the ocean fluid, so that the scale depth for the ocean is well beneath the ocean bottom. This is yet another reason that the Boussinesq ocean is a useful approximation for many purposes of ocean mechanics.

31.5.8 Comments and further study

Neutral directions were introduced to oceanography by *McDougall* (1987a,b), and they are the basis for how oceanographers think about buoyancy stratification. *McDougall et al.* (2014) offer another presentation of why neutral directions are relevant for the ocean, taking into account measurements of dianeutral mixing. Our discussion of neutral directions was inspired by the concise presentation in Section 2.7.2 of *Olbers et al.* (2012).

We did not present a dynamical argument for why physical processes favor neutral displacements. Any argument would require dynamical principles, such as the equations of motion and associated energetic constraints. There is presently no dynamical argument for why the ocean prefers neutral displacements over arbitrary non-neutral displacements. However, robust empirical measures support the relevance of neutral directions for orienting tracer mixing within the ocean interior. More discussion of these points is given by *McDougall et al.* (2014), with mathematical implications presented in Chapter 66.

Our study of vertical gravitational stability follows Section 3.6 of *Gill* (1982) as well as Section 2.10 of *Vallis* (2017). In an actual fluid, the movement of any fluid, even a tiny fluid element, modifies the surrounding fluid so that a perfect test fluid element is a fiction. We return to this point in Section 31.9 when studying effective buoyancy.

31.6 Neutral helicity[9]

In our study of neutral directions in Section 31.5 we introduced the notion of a neutral displacement. We here consider a remarkable property of neutral displacements and the dianeutral direction, with this property first identified by *McDougall and Jackett* (1988).

31.6.1 Mathematical preliminaries

Consider a continuous vector field, $\boldsymbol{N}(\boldsymbol{x})$, and write its normalized version as

$$\hat{\boldsymbol{n}} = \boldsymbol{N}/|\boldsymbol{N}|. \tag{31.53}$$

[9]This section greatly benefited from input by Geoffrey Stanley.

Let this vector field define a smooth two-dimensional surface, $\mathcal{S}$, so that wherever $\boldsymbol{N}$ is evaluated on $\mathcal{S}$ then it is perpendicular to $\mathcal{S}$ (see Figure 31.6 for an example). In general there is a continuum of such surfaces, yet we are here only interested in one of them. To be specific, assuming $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}}$ is single-signed, let $\mathcal{S}$ be defined by the accumulation of points $\boldsymbol{x}_{\mathcal{S}} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} + \psi(x,y)\,\hat{\boldsymbol{z}}$, where $\psi(x,y)$ provides the vertical position of the surface as a continuous function of horizontal position.[10] In this case, $\boldsymbol{N} = \hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\partial_x\psi - \hat{\boldsymbol{y}}\,\partial_y\psi$ when evaluated on $\mathcal{S}$, so that $\boldsymbol{N} = \hat{\boldsymbol{x}}$ when the surface is flat. In the following, we say that these sorts of surfaces are *well-defined* since they are both smooth and everywhere have an outward normal vector.

Consider an arbitrary closed region, Ω, that lives on the surface, $\Omega \in \mathcal{S}$. Let $\hat{\boldsymbol{t}}$ be a unit tangent vector to the boundary of Ω and that is oriented counterclockwise around the boundary, $\partial\Omega$, as defined relative to $\boldsymbol{N}$ (see Figure 31.6). Since $\boldsymbol{N} \cdot \hat{\boldsymbol{t}} = 0$ by construction, we can integrate this identity around $\partial\Omega$ to have

$$\oint_{\partial\Omega} \boldsymbol{N} \cdot \hat{\boldsymbol{t}}\,\mathrm{d}s = 0 \Longrightarrow \int_{\Omega} (\nabla \times \boldsymbol{N}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0, \tag{31.54}$$

where Stokes' theorem renders the second identity. Since the region, Ω, is arbitrary, the area integral in equation (31.54) vanishes only if the integrand is identically zero for each point on $\mathcal{S}$. We thus conclude:

$$\text{well-defined surface } \mathcal{S} \Longrightarrow \mathcal{H} \equiv \boldsymbol{N} \cdot (\nabla \times \boldsymbol{N}) = 0. \tag{31.55}$$

The contrapositive also holds so that[11]

$$\mathcal{H} \neq 0 \Longrightarrow \text{ill-defined surface } \mathcal{S}. \tag{31.56}$$

FIGURE 31.6: A smooth and orientable two-dimensional surface, $\mathcal{S}$, which we refer to as a "well-defined surface". At each point on $\mathcal{S}$ we can unambiguously define an outward normal, $+\hat{\boldsymbol{n}}$, and an inward normal, $-\hat{\boldsymbol{n}}$. Furthermore, we can consider an arbitrary simply connected closed region, Ω, with boundary $\partial\Omega$. The boundary is oriented by a unit tangent vector, $\hat{\boldsymbol{t}}$, that is perpendicular to the unit normal, $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0$, and is oriented counterclockwise around $\partial\Omega$ according to $\hat{\boldsymbol{n}}$.

[10] We considered such surfaces in Section 20.4.2 when studying kinematic boundary conditions for flow encountering a material surface.

[11] A contrapositive is a proposition or theorem formed by contradicting both the subject and predicate or both the hypothesis and conclusion of a given proposition or theorem. More succintly, the proposition "if A then B" has the contrapositive "if not-B then not-A". Likewise, the proposition has the converse "if B then A", and it has the inverse "if not-A then not-B".

31.6.2 Neutral helicity is the reason neutral surfaces are ill-defined

Now apply the above general results to the question of whether a surface with its outward normal parallel to the dianeutral direction, $\hat{\boldsymbol{\gamma}}$,

$$\boldsymbol{N} = -\alpha\,\nabla\theta + \beta\,\nabla S = \hat{\boldsymbol{\gamma}}|-\alpha\,\nabla\theta + \beta\,\nabla S| \tag{31.57}$$

is a well-defined surface. We refer to this surface as a *neutral surface*, since at each point its local normal is $\hat{\boldsymbol{\gamma}}$. From the discussion in Section 31.6.1 we know that neutral surfaces are well defined only if the *neutral helicity* vanishes, where the neutral helicity is

$$\mathscr{H}_{\text{neutral}} = \boldsymbol{N}\cdot(\nabla\times\boldsymbol{N}) = (-\alpha\,\nabla\theta + \beta\,\nabla S)\cdot[\nabla\,\times\,(-\alpha\,\nabla\theta + \beta\,\nabla S)], \tag{31.58}$$

which can be written

$$\begin{aligned}
\mathscr{H}_{\text{neutral}} &= (-\alpha\,\nabla\theta + \beta\,\nabla S)\cdot[\nabla\,\times\,(-\alpha\,\nabla\theta + \beta\,\nabla S)] && (31.59\text{a})\\
&= -\alpha\,\nabla\theta\cdot(\nabla\,\times\,\beta\,\nabla S) - \beta\,\nabla S\cdot(\nabla\,\times\,\alpha\,\nabla\theta) && (31.59\text{b})\\
&= -\alpha\,\nabla\theta\cdot(\nabla\beta\,\times\,\nabla S) - \beta\,\nabla S\cdot(\nabla\alpha\,\times\,\nabla\theta). && (31.59\text{c})
\end{aligned}$$

Further expanding the spatial gradients of α and β

$$\begin{aligned}
\nabla\alpha &= \partial_\theta\alpha\,\nabla\theta + \partial_S\alpha\,\nabla S + \partial_p\alpha\,\nabla p && (31.60\text{a})\\
\nabla\beta &= \partial_\theta\beta\,\nabla\theta + \partial_S\beta\,\nabla S + \partial_p\beta\,\nabla p, && (31.60\text{b})
\end{aligned}$$

then leads to

$$\begin{aligned}
-\alpha\,\nabla\theta\cdot(\nabla\beta\,\times\,\nabla S) &= -\alpha\,\nabla\theta\cdot(\partial_p\beta\,\nabla p\times\nabla S) = -\alpha\,\partial_p\beta\,\nabla p\cdot(\nabla S\times\nabla\theta) && (31.61\text{a})\\
-\beta\,\nabla S\cdot(\nabla\alpha\,\times\,\nabla\theta) &= -\beta\,\nabla S\cdot(\partial_p\alpha\,\nabla p\times\nabla\theta) = \beta\,\partial_p\alpha\,\nabla p\cdot(\nabla S\times\nabla\theta) && (31.61\text{b})
\end{aligned}$$

which brings neutral helicity to the form

$$\mathscr{H}_{\text{neutral}} = \nabla p\cdot(\nabla S\,\times\,\nabla\theta)\,(\beta\,\partial_p\alpha - \alpha\,\partial_p\beta). \tag{31.62}$$

Introducing the thermobaricity parameter[12]

$$\mathscr{T} = \beta\,\partial_p(\alpha/\beta) = \beta^{-1}\,(\beta\,\partial_p\alpha - \alpha\,\partial_p\beta) \tag{31.63}$$

renders the tidy result

$$\mathscr{H}_{\text{neutral}} = \beta\,\mathscr{T}\,\nabla p\cdot(\nabla S\,\times\,\nabla\theta). \tag{31.64}$$

A nonzero neutral helicity (31.64) is fundamentally related to a nonzero thermobaricity parameter $\mathscr{T}$. It is also associated with the non-zero volume for a parallelopiped in (θ, S, p) space[13]

$$\nabla p\cdot(\nabla S\,\times\,\nabla\theta) = \nabla\theta\cdot(\nabla p\,\times\,\nabla S) = \nabla S\cdot(\nabla\theta\,\times\,\nabla p), \tag{31.65}$$

with this volume a function of the (S, θ, p) arrangement.

Returning to the question of whether a neutral surface is well-defined, we see that with $\mathscr{H}_{\text{neutral}} \neq 0$ then neutral surfaces are ill-defined. What does this result mean in practice? Consider a stably stratified ocean where $\hat{\boldsymbol{\gamma}}\cdot\hat{\boldsymbol{z}} \neq 0$ everywhere. Even for this ocean we are unable to find any finite smooth surface, $\mathscr{S}_{\text{neutral}}$, whose outward normal is given by $\hat{\boldsymbol{\gamma}}$. That is, we cannot find

[12] We further discuss the thermobaricity parameter in Section 67.3.

[13] See Section 1.5 for how three vectors define a volume in the space of the vectors.

a single function, $\psi(x, y)$, where $\boldsymbol{N} = \hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\partial_x\psi - \hat{\boldsymbol{y}}\,\partial_y\psi$ everywhere on $\mathcal{S}_{\text{neutral}}$.

31.6.3 Comments and further study

Figure 31.6 provides an example smooth surface; i.e., a canonical well-defined surface. What does an ill-defined surface look like? *McDougall and Jackett* (1988) answered by noting that neutral paths possess a helical structure, with each closed loop in (S, θ) space displaced vertically in pressure. Besides being rather novel mathematically, this helical structure provides a source for irreversible (dianeutral) transformation of seawater. *Klocker and McDougall* (2010a,b) estimated the effects of this transformation on large-scale ocean overturning circulation. They found the effects from neutral helicity to be comparable to those from mixing, especially in the Southern Ocean.

Bennett (2019) discussed the geometry of neutral paths and made a connection to a theorem of Carathéodory developed in the context of thermodynamics. Additionally, *Stanley* (2019) showed that S and θ (or ρ and p) on a neutral surface are functionally related but in a way that varies geographically. Stanley's topological analysis determined how different single-valued S-θ relations in different geographic regions mesh together to form a globally continuous S-θ relation. *Stanley et al.* (2021) then provided a corresponding method for determining approximate neutral surfaces. Such approximate neutral surfaces are globally well-defined, but with a local normal direction that is closely aligned with the dianeutral direction, $\hat{\boldsymbol{\gamma}}$.

31.7 Pressure forces and vertical motion

As introduced in Section 28.2 and further detailed in Section 30.2, an approximate hydrostatic fluid is one in which the vertical pressure gradient locally balances the gravitational acceleration, with the horizontal gradient of hydrostatic pressure contributing to horizontal accelerations. Although vertical motion can occur in the approximately hydrostatic fluid, that motion is diagnosed rather than prognosed since the vertical momentum equation is reduced to local hydrostatic balance. For example, a diagnostic evaluation of the vertical velocity in a Boussinesq ocean is performed through vertically integrating the continuity equation, $\partial_z w = -\nabla_z \cdot \boldsymbol{u}$, along with the specification of w at one point within the vertical column.

As we see in equation (31.75c) derived below, the vertical derivative of the non-hydrostatic pressure is the only inviscid force contributing to a vertical acceleration. So even if the fluid satisfies the assumptions of approximate hydrostatic balance, it is the non-hydrostatic pressure force that enables vertical accelerations. That is, for the approximately hydrostatic fluid, the local hydrostatic balance holds, $\partial p/\partial z = -\rho\, g$, and yet there is a nonzero vertical acceleration, $\mathrm{D}w/\mathrm{D}t \neq 0$. This situation is directly analogous to the Boussinesq ocean as derived in Section 30.1. For the Boussinesq ocean, we have a non-divergent flow field, $\nabla \cdot \boldsymbol{v} = 0$, and yet the fluid itself is compressible so that density has space and time variations, $\mathrm{D}\rho/\mathrm{D}t \neq 0$.

We are concerned in this section with how pressure and gravity contribute to motion, and offer two methods to organize their accelerations starting from the momentum equation with the geopotential, $\Phi = g\, z$,

$$\rho\, \mathrm{D}\boldsymbol{v}/\mathrm{D}t + 2\,\boldsymbol{\Omega} \times \rho\, \boldsymbol{v} = -\nabla p - g\, \rho\, \hat{\boldsymbol{z}} + \rho\, \boldsymbol{F}. \tag{31.66}$$

Analysis involving both methods serve complementary roles in understanding the nature of vertical accelerations.

31.7.1 Dynamically active and passive pressures

We here follow the formulation of the Boussinesq ocean equations from Section 30.1.1 to organize the pressure and gravity accelerations. For that purpose, introduce a constant reference density, ρ_0, along with a corresponding hydrostatically balanced reference pressure

$$p(\boldsymbol{x}, t) = p'(\boldsymbol{x}, t) + p_0(z) \quad \text{with} \quad \mathrm{d}p_0/\mathrm{d}z = -\rho_0\, g. \tag{31.67}$$

By decomposing pressure as $p = p_0 + p'$, we expose the dynamically active portion of the pressure field, p', by removing the dynamically irrelevant pressure, p_0, from the momentum equation. Note that the dynamical pressure, p', generally has both hydrostatic and non-hydrostatic contributions.

The decomposition (31.67) brings the pressure and gravity contributions on the right hand side of equation (31.66) into the form

$$\nabla p + \rho\, g\, \hat{\boldsymbol{z}} = \nabla p' - \rho_0\, b\, \hat{\boldsymbol{z}}. \tag{31.68}$$

In this equation we introduced the globally referenced Archimedean buoyancy computed relative to the globally constant reference density, ρ_0,

$$b = -g\,(\rho - \rho_0)/\rho_0 = -g\,\rho'/\rho_0, \tag{31.69}$$

where

$$\rho' = \rho - \rho_0 \tag{31.70}$$

is the density deviation relative to the reference density.

31.7.2 Hydrostatic and non-hydrostatic pressures

The second decomposition of the pressure and gravity forces in equation (31.66) is based on splitting into a local hydrostatic pressure, p_{h}, and a non-hydrostatic pressure, p_{nh},

$$p = p_{\mathrm{h}} + p_{\mathrm{nh}} \quad \text{with} \quad \partial p_{\mathrm{h}}/\partial z = -\rho\, g. \tag{31.71}$$

This decomposition is particularly useful when concerned with deviations from a local hydrostatic balance, which is central to the current analysis. However, it does not remove the global hydrostatic background pressure (i.e., the dynamically irrelevant $p_0(z)$ pressure), which can be seen by the identity

$$\partial p_{\mathrm{h}}/\partial z = \mathrm{d}p_0(z)/\mathrm{d}z - \rho'\, g = \mathrm{d}p_0(z)/\mathrm{d}z + \rho_0\, b. \tag{31.72}$$

With the pressure decomposition (31.71), the pressure and gravity contributions to the equation of motion take on the form

$$\begin{aligned}
\nabla p + \rho\, g\, \hat{\boldsymbol{z}} &= \nabla(p_{\mathrm{h}} + p_{\mathrm{nh}}) + \rho\, g\, \hat{\boldsymbol{z}} && (31.73\mathrm{a})\\
&= \nabla_z(p_{\mathrm{h}} + p_{\mathrm{nh}}) + (\partial_z p_{\mathrm{nh}} + \partial_z p_{\mathrm{h}} + \rho\, g)\, \hat{\boldsymbol{z}} && (31.73\mathrm{b})\\
&= \nabla_z p + \hat{\boldsymbol{z}}\, \partial_z p_{\mathrm{nh}} && (31.73\mathrm{c})\\
&= \nabla p_{\mathrm{nh}} + \nabla_z p_{\mathrm{h}}. && (31.73\mathrm{d})
\end{aligned}$$

31.7.3 Boussinesq ocean momentum equation

To further study how pressure and gravity lead to vertical motion, we find it convenient to assume a Boussinesq ocean so that the momentum equation (31.66) takes the form of equation (30.65)

$$\rho_0 \, \mathrm{D}\boldsymbol{v}/\mathrm{D}t + 2\,\boldsymbol{\Omega} \times \rho_0 \, \boldsymbol{v} = -\nabla p - \rho \, g \, \hat{\boldsymbol{z}} + \rho_0 \, \boldsymbol{F} \tag{31.74a}$$

$$= -\nabla p' + \rho_0 \, b \, \hat{\boldsymbol{z}} + \rho_0 \, \boldsymbol{F} \tag{31.74b}$$

$$= -\nabla p_{\mathrm{nh}} - \nabla_z p_{\mathrm{h}} + \rho_0 \, \boldsymbol{F}. \tag{31.74c}$$

We focus on the vertical velocity equation in studying processes leading to vertical accelerations of a fluid element (i.e., the vertical Lagrangian acceleration)

$$\rho_0 \, \mathrm{D}w/\mathrm{D}t + \hat{\boldsymbol{z}} \cdot (2\,\boldsymbol{\Omega} \times \rho_0 \, \boldsymbol{v}) = -\partial_z p - \rho \, g + \rho_0 \, \boldsymbol{F} \cdot \hat{\boldsymbol{z}} \tag{31.75a}$$

$$= -\partial_z p' + \rho_0 \, b + \rho_0 \, \boldsymbol{F} \cdot \hat{\boldsymbol{z}} \tag{31.75b}$$

$$= -\partial_z p_{\mathrm{nh}} + \rho_0 \, \boldsymbol{F} \cdot \hat{\boldsymbol{z}}, \tag{31.75c}$$

Equation (31.75b) reveals that the vertical Lagrangian acceleration has contributions from vertical gradients in the dynamical pressure, p', plus the globally referenced Archimedean buoyancy, b. From equation (31.75c) we see that the vertical Lagrangian acceleration has an inviscid contribution that arises solely from vertical derivatives in the non-hydrostatic pressure, p_{nh}. Note that when making either the tangent plane approximation (Section 25.5) or the Traditional approximation (Section 28.1.3), the Coriolis acceleration is absent from the vertical momentum equation since the rotating reference frame has an angular velocity oriented according to the local vertical, $\boldsymbol{\Omega} = \Omega \, \hat{\boldsymbol{z}}$.

31.8 Motion of a test fluid element

In this section we study the motion of a test fluid element with nonzero Archimedean buoyancy and in the absence of mixing. We assume a tangent plane so that the Coriolis acceleration does not appear in the vertical momentum equation. Also, to avoid questions about local versus global buoyancy, and the associated questions about neutral directions, we assume the fluid environment has a constant density, ρ.

In pursuing this analysis it is important to realize the nature of the corresponding thought experiments. Namely, we place a test fluid element somewhere in a prescribed fluid environment and examine how the forces affect its motion. Importantly, we assume the environment is unaffected by the test fluid element, so that the contact forces remain fixed and prescribed. That is, the pressure and frictional forces are unaffected by the test fluid element. This assumption is mechanically inconsistent since all fluid elements affect their surroundings. Even so, results from the analysis are borne out for situations where we can safely ignore the environmental perturbations of real fluid elements. The analysis also forms a suitable starting point for the physically self-consistent, yet analytically more challenging, study of effective buoyancy in Section 31.9.

31.8.1 Equations of motion

The equation of motion for a fluid element is given by

$$\rho \, \mathrm{D}\boldsymbol{v}/\mathrm{D}t + 2\,\Omega \, \hat{\boldsymbol{z}} \times \rho \, \boldsymbol{v} = -\nabla p - g \, \rho \, \hat{\boldsymbol{z}} + \rho \, \boldsymbol{F}, \tag{31.76}$$

whereas the equation of motion for the test fluid element is

$$\rho^{\text{tfe}}\,\dot{\boldsymbol{v}}^{\text{tfe}} + 2\,\Omega\,\hat{\boldsymbol{z}} \times \rho^{\text{tfe}}\,\boldsymbol{v}^{\text{tfe}} = -\nabla p - g\,\rho^{\text{tfe}}\,\hat{\boldsymbol{z}} + \rho^{\text{tfe}}\,\boldsymbol{F}, \tag{31.77}$$

where ρ^{tfe} is the density of the test fluid element, $\boldsymbol{v}^{\text{tfe}}$ is its velocity, and $\dot{\boldsymbol{v}}^{\text{tfe}}$ is its acceleration.[14] As per our assumption stated earlier, both the pressure gradient and friction vector are the same for the fluid element and the test fluid element.

31.8.2 Exact hydrostatic environment

As our first example, consider a test fluid element in a fluid that is in exact hydrostatic equilibrium, so that there is no fluid motion. We thus examine vertical motion of the test fluid element, with the vertical component of equation (31.77) yielding

$$\rho^{\text{tfe}}\,\dot{w}^{\text{tfe}} = -\mathrm{d}p/\mathrm{d}z - g\,\rho^{\text{tfe}}. \tag{31.78}$$

The assumed hydrostatic background pressure gradient satisfies $\mathrm{d}p/\mathrm{d}z = -\rho\,g$, so that the test fluid element accelerates vertically according to

$$\rho^{\text{tfe}}\,\dot{w}^{\text{tfe}} = b\,\rho, \tag{31.79}$$

where we introduced the Archimedean buoyancy for the test fluid element, computed relative to the environmental fluid,

$$b = -g\,(\rho^{\text{tfe}} - \rho)/\rho. \tag{31.80}$$

Evidently, the test fluid element accelerates upward if it is lighter than the environment ($b > 0$), downward if heavier ($b < 0$), and remains stationary if neutrally buoyant ($b = 0$). This result accords with our understanding of Archimedean buoyancy from Section 31.2.

31.8.3 Accelerating yet non-rotating environment

In Section 11.3 we studied particle mechanics as viewed from an accelerated reference frame that is not rotating, such as for motion viewed in an accelerating train moving along a straight track. Here we place a tank of fluid (e.g., a tank of water) on a train car that experiences acceleration $\boldsymbol{A}^{\text{tank}}$, such as depicted in Figure 31.7. Following equation (11.48), the equation of motion for the fluid in the tank is

$$\rho\,\mathrm{D}\boldsymbol{v}/\mathrm{D}t = -\nabla p - \rho\,(g\,\hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}) + \rho\,\boldsymbol{F}. \tag{31.81}$$

We refer to $-\boldsymbol{A}^{\text{tank}}$ as the *non-inertial acceleration* that arises from the tank acceleration, and with $-\rho\,\boldsymbol{A}^{\text{tank}}$ the *non-inertial force* per volume acting on the fluid.[15] As a result of the non-inertial force, fluid piles up on the back side of the tank and is depleted from the front.

The difference in fluid depth within the tank leads to a horizontal pressure gradient, with higher pressure at the back of the tank and lower in the front. There is no fluid motion (relative to the tank) if there is a balance between the horizontal pressure gradient and the tank acceleration, as well as a balance between the vertical pressure gradient and gravity,

$$-(\nabla p)^{\text{equilib}} = \rho\,g\,(\hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}/g). \tag{31.82}$$

[14] We write the acceleration as $\dot{\boldsymbol{v}}^{\text{tfe}}$ rather than $\mathrm{D}\boldsymbol{v}^{\text{tfe}}/\mathrm{D}t$ since we are concerned with the motion of just a single test fluid element.

[15] The minus sign accords with being pushed backward into a seat when a vehicle accelerates forward.

FIGURE 31.7: Left panel: A tank of homogeneous water on a train accelerating along a horizontal straight track, thus resulting in a pile up of the water at the back of the tank and depletion in the front. The water reaches a static equilibrium ($\boldsymbol{v} = 0$) when the pressure gradient acceleration balances both the gravitational acceleration and the train acceleration, $-(\nabla p)^{\text{equilib}} = \rho\, g\, (\hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}/g)$. Right panel: Fore vector diagram for a positively buoyant test fluid element, with contributions from vertical buoyant acceleration and horizontal pressure gradient acceleration. The net acceleration on the test element acts at an angle to the vertical that is determined by the gravitational and train acceleration, making a slope, $\tan\alpha = |\boldsymbol{A}^{\text{tank}}|/g$, with the vertical. Notably, the positively buoyant test fluid element is accelerated vertically upward and horizontally in the *same* direction as the train's acceleration, whereas a negatively buoyant test fluid element is accelerated vertically downward and horizontally in the *opposite* direction as the acceleration. This thought experiment is readily verified by a helium balloon tied to the floor of an accelerating car, or a pendulum tied to the ceiling of the car.

We can consider this result as exact hydrostatic balance but with a modified gravitational acceleration.[16]

Motion of the test fluid element satisfies the equation

$$\rho^{\text{tfe}}\, \dot{\boldsymbol{v}}^{\text{tfe}} = -\nabla p - \rho^{\text{tfe}}\, (g\, \hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}) + \rho^{\text{tfe}}\, \boldsymbol{F}. \tag{31.83}$$

Now consider the test fluid element that feels the equilibrated pressure gradient according to equation (31.82), in which case

$$\rho^{\text{tfe}}\, \dot{\boldsymbol{v}}^{\text{tfe}} = (\rho - \rho^{\text{tfe}})\, (g\, \hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}) = b\, \rho\, (\hat{\boldsymbol{z}} + \boldsymbol{A}^{\text{tank}}/g) = -(b/g)\, (\nabla p)^{\text{equilib}}. \tag{31.84}$$

Note that there is no frictional acceleration when there is no fluid motion, thus allowing us to set $\boldsymbol{F} = 0$. Evidently, the test fluid element accelerates along a line that is perpendicular to surfaces of constant pressure, thus making an angle with the vertical given by

$$\tan\alpha = |\boldsymbol{A}^{\text{tank}}|/g. \tag{31.85}$$

Acceleration of a positively buoyant test fluid element is sloped in the same direction as the accelerating train, with this result readily verified by attaching a helium balloon to the floor of a train or car. Acceleration of the negatively buoyant test fluid element is sloped in the opposite direction as the accelerating train. This result for the pendulum accords with the discussion in Section 11.3.3, in which a pendulum at rest in the accelerated train slopes opposite to the acceleration.

31.8.4 Rotating tank

In Section 28.4 we studied the motion of a homogeneous fluid in a rotating tank, whose equation of motion in the rotating reference frame is given by equation (28.87)

$$\rho\, \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\Omega\, \hat{\boldsymbol{z}} \times \rho\, \boldsymbol{v} = -\nabla \left[p + g\, z\, \rho - \Omega^2\, \rho\, (x^2 + y^2)/2\right] + \rho\, \boldsymbol{F}. \tag{31.86}$$

[16]The Principle of Equivalence from general relativity says we cannot distinguish between the acceleration of a reference frame and the acceleration from gravity. The result (31.82) supports this equivalence.

The analogous equation for the test fluid element, again written in the rotating reference frame, is given by

$$\rho^{\text{tfe}}\,\dot{\boldsymbol{v}}^{\text{tfe}} + 2\,\Omega\,\hat{\boldsymbol{z}} \times \rho^{\text{tfe}}\,\boldsymbol{v}^{\text{tfe}} = -\nabla\left[p + g\,z\,\rho^{\text{tfe}} - \Omega^2\,\rho^{\text{tfe}}\,(x^2+y^2)/2\right] + \rho^{\text{tfe}}\,\boldsymbol{F}, \tag{31.87}$$

where we evaluate the position, $\boldsymbol{x} = \hat{\boldsymbol{x}}\,x + \hat{\boldsymbol{y}}\,y + \hat{\boldsymbol{z}}\,z$, according to the position of the test fluid element. At mechanical equilibrium, the fluid rotates as a rigid-body ($\boldsymbol{v} = 0$) with a parabolic free surface where the free surface is higher at the outer rim of the tank and lowest at the center. Furthermore, as the motion is rigid-body, the viscous friction vanishes. We thus find that the pressure gradient in the rigid-body rotating equilibrium satisfies

$$-(\nabla p)^{\text{equilb}} = \rho\,\nabla[g\,z - \Omega^2\,(x^2+y^2)/2] = g\,\rho\,[\hat{\boldsymbol{z}} - \Omega^2\,(x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}})/g] \equiv -\rho\,\boldsymbol{g}^{\text{rotate}}, \tag{31.88}$$

where the final equality defined the gravitational vector, $\boldsymbol{g}^{\text{rotate}}$, arising from the sum of the geopotential (central earth gravity plus planetary centrifugal) plus the centrifugal acceleration from the rotating tank. When placed in this mechanically equilibrated fluid environment, the test fluid element equation of motion (31.87) becomes

$$\rho^{\text{tfe}}\,\dot{\boldsymbol{v}}^{\text{tfe}} + 2\,\Omega\,\hat{\boldsymbol{z}} \times \rho^{\text{tfe}}\,\boldsymbol{v}^{\text{tfe}} = b\,\rho\,[\hat{\boldsymbol{z}} - \Omega^2\,(\hat{\boldsymbol{x}}\,x + \hat{\boldsymbol{y}}\,y)/g] = -(\rho - \rho^{\text{tfe}})\,\boldsymbol{g}^{\text{rotate}}. \tag{31.89}$$

Evidently, a positively buoyant test fluid element accelerates upward and toward the center of the tank. Furthermore, as it moves horizontally toward the tank center, the test fluid element picks up a Coriolis acceleration that deflects it to the right for counter-clockwise rotating tanks.

For the test fluid element, the ratio of the magnitudes of its Coriolis acceleration to the centrifugal acceleration is

$$\frac{\text{Coriolis}}{\text{centrifugal}} = \frac{2\,\rho^{\text{tfe}}}{\rho}\,\frac{g}{b}\,\frac{|\boldsymbol{u}^{\text{tfe}}|}{\Omega\sqrt{x^2+y^2}} = \frac{2\,\rho^{\text{tfe}}}{\rho - \rho^{\text{tfe}}}\,\frac{|\boldsymbol{u}^{\text{tfe}}|}{\Omega\sqrt{x^2+y^2}}. \tag{31.90}$$

Heavy test fluid elements, with small buoyancy, move toward the outer edge of the tank due to dominance of the centrifugal acceleration, whereas lighter test fluid elements concentrate toward the center. We can further reduce the influence of the Coriolis acceleration by changing the geometry to that of a long test tube to thus reduce $|\boldsymbol{u}^{\text{tfe}}|$, with this geometry is used for *centrifuges*.

Is there is a dynamically consistent motion in which the test fluid element has exactly zero horizontal material acceleration, $\dot{\boldsymbol{u}}^{\text{tfe}} = 0$? For this motion to occur requires a balance between the Coriolis and centrifugal accelerations

$$2\,\Omega\,\rho^{\text{tfe}}\,(\hat{\boldsymbol{z}} \times \boldsymbol{u}^{\text{tfe}}) = -(b\,\rho\,\Omega^2/g)\,(\hat{\boldsymbol{x}}\,x + \hat{\boldsymbol{y}}\,y) \Longrightarrow \boldsymbol{u}^{\text{tfe}} = [b\,\rho/(2\,g\,\rho^{\text{tfe}})]\,(\boldsymbol{\Omega} \times \boldsymbol{x}). \tag{31.91}$$

However, this velocity field does not, in fact, have a zero acceleration since

$$\dot{\boldsymbol{u}}^{\text{tfe}} = [b\,\rho/(2\,g\,\rho^{\text{tfe}})]\,(\boldsymbol{\Omega} \times \boldsymbol{u}^{\text{tfe}}) \neq 0. \tag{31.92}$$

We conclude that there is no self-consistent free motion with $\dot{\boldsymbol{u}}^{\text{tfe}} = 0$, much like the case of the test fluid element moving in the accelerating train studied in Section 31.8.3.

31.9 Effective buoyancy and vertical accelerations

In this section, we extend the discussion of Archimedean buoyancy by focusing on the vertical forces acting on a real fluid element, or more generally a finite sized fluid region, rather than on a test fluid element. To do so requires us to study, in some detail, the various forces appearing in

the momentum equation. As a means to conceptually organize these forces, we introduce *static forces*, which are those forces not associated with fluid motion, plus *motional forces*, which are forces not associated with density inhomogeneities. Motional forces are specific to details of the velocity field, whereas static forces are deduced just from knowledge of the density field.

Effective buoyancy arises from the static forces acting on a fluid element. Although the effective buoyancy is in part comprised of Archimedean buoyancy, there are distinctions that arise through interactions between the fluid element and its surrounding environment. These interactions depend on the shape of the fluid region. As shown in this section (see in particular Figure 31.8), effective buoyancy explains why fluid regions of different geometric shape can have different effective buoyancy, even while they have the same Archimedean buoyancy.

To facilitate the analysis in this section, we consider a Boussinesq ocean, with the analysis also directly relevant to an anelastic atmosphere as considered by *Jeevanjee and Romps* (2015b). As explored in Section 30.3, pressure in a Boussinesq ocean constrains the velocity field to remain non-divergent. Furthermore, Boussinesq ocean pressure satisfies an elliptic boundary value problem (Poisson equation from Section 3.4). This boundary value problem is linear for the pressure field. Linearity is exploited for conceptual purposes by decomposing the pressure sources into physically distinct processes and studying the associated pressure field. The task for this section is to derive the Poisson equations according to the various pressure sources, and then to discuss the physics of their associated vertical accelerations.

31.9.1 Poisson equations for $p' = p'_{\text{buoy}} + p'_{\text{flow}}$

The two decompositions of pressure described in Sections 31.7.1 and 31.7.2, as reflected in the Boussinesq velocity equations from Section 31.7.3, render two sets of corresponding Poisson equations for pressure. We here focus on the decomposition (31.74b), where the pressure and gravity accelerations appear in terms of the Archimedean buoyancy plus perturbation pressure. We defer until Section 31.9.3 an examination of the alternative decomposition into the local hydrostatic and non-hydrostatic pressures given by equation (31.74c).

Boundary value problem for the perturbation pressure, p'

We start by considering the Boussinesq momentum equation (31.74b)

$$\rho_0 \left(\partial_t + \boldsymbol{v} \cdot \nabla\right) \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \rho_0\, \boldsymbol{v} = -\nabla p' + \rho_0\, b\, \hat{\boldsymbol{z}} + \rho_0\, \boldsymbol{F}. \tag{31.93}$$

As detailed in Section 30.3.1, the time tendency is eliminated by computing the divergence of this equation to render the Poisson equation for the perturbation pressure

$$-\nabla^2 p' = \rho_0\, \nabla \cdot \boldsymbol{G}' = \rho_0\, \nabla \cdot [(\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} - b\, \hat{\boldsymbol{z}} - \boldsymbol{F}], \tag{31.94}$$

where we introduced the vector,

$$\boldsymbol{G}' = (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} - b\, \hat{\boldsymbol{z}} - \boldsymbol{F}, \tag{31.95}$$

whose divergence renders a source for the pressure field. We find it convenient to carry around a minus sign on the Laplacian operator since a positive source, $\rho_0\, \nabla \cdot \boldsymbol{G}' > 0$, leads to a locally positive pressure signal (see Section 30.3.1 for more details on this point).

We require boundary conditions to fully specify the pressure, and for simplicity we assume material boundaries. In this case, the analysis considered in Section 30.3.2 renders the Neumann boundary condition

$$\hat{\boldsymbol{n}} \cdot \nabla p' = -\rho_0\, \hat{\boldsymbol{n}} \cdot \boldsymbol{G}', \tag{31.96}$$

where $\hat{\boldsymbol{n}}$ is the outward normal along the boundary. We further simplify the analysis by assuming flat and rigid top and bottom boundaries along with horizontal boundaries that are either doubly periodic or infinite. Hence, along the top boundary, where $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, the pressure satisfies the Neumann boundary condition

$$\partial_z p' = -\rho_0\, \hat{\boldsymbol{z}} \cdot \boldsymbol{G}' = \rho_0\, (b + \boldsymbol{F} \cdot \hat{\boldsymbol{z}}) \quad \text{top boundary.} \tag{31.97}$$

To reach this result we noted that

$$\hat{\boldsymbol{z}} \cdot [(\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v}] = (\boldsymbol{v} \cdot \nabla)\, (\hat{\boldsymbol{z}} \cdot \boldsymbol{v}) = 0, \tag{31.98}$$

since $\hat{\boldsymbol{z}} \cdot \boldsymbol{v} = w = 0$ along a rigid and material flat surface. The analogous result holds along the bottom boundary where $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{z}}$ so that

$$\partial_z p' = \rho_0\, \hat{\boldsymbol{z}} \cdot \boldsymbol{G}' = -\rho_0\, (b + \boldsymbol{F} \cdot \hat{\boldsymbol{z}}) \quad \text{bottom boundary.} \tag{31.99}$$

Buoyancy induced and flow induced pressures

The Laplacian operator is linear, with linearity affording the freedom to decompose the source in the Poisson equation (31.94), $\rho_0\, \nabla \cdot \boldsymbol{G}'$, into physically distinct processes and then studyinig the pressures resulting from these processes. For this purpose we choose the following decomposition

$$-\nabla^2 p' \equiv -\nabla^2 (p'_{\text{buoy}} + p'_{\text{flow}}) \tag{31.100a}$$

$$-\nabla^2 p'_{\text{buoy}} = -\rho_0\, \partial_z b \tag{31.100b}$$

$$-\nabla^2 p'_{\text{flow}} = \rho_0\, \nabla \cdot [(\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + 2\, \boldsymbol{\Omega} \times \boldsymbol{v} - \boldsymbol{F}]. \tag{31.100c}$$

The source term for the buoyancy pressure, p'_{buoy}, only involves the vertical derivative of the Archimedean buoyancy. Hence, there is no direct contribution from fluid motion on p'_{buoy}, with fluid motion only affecting p'_{buoy} indirectly through effects on $\partial_z b$. The converse holds for the pressure perturbation, p'_{flow}, which is sourced by fluid motion that gives rise to accelerations from self-advection, Coriolis, and friction. Hence, there is no direct impact from Archimedean buoyancy on p'_{flow}. The Neumann boundary conditions for these two pressures follows from the boundary conditions (31.97) and (31.99). For example, along the top boundary we have

$$\partial_z p'_{\text{buoy}} = \rho_0\, b \quad \text{and} \quad \partial_z p'_{\text{flow}} = \rho_0\, \hat{\boldsymbol{z}} \cdot \boldsymbol{F} \qquad \text{top boundary conditions,} \tag{31.101}$$

with the same conditions holding along the bottom yet with a minus sign on the right hand side.

31.9.2 Accelerations from effective buoyancy and fluid motion

Having established the Poisson equations for the variety of pressures in Section 31.9.1, we now examine contributions to the vertical Lagrangian acceleration as given by equations (31.75b) and (31.75c). Emulating the decomposition used for pressure, we here decompose the vertical acceleration into conceptually distinct contributions from buoyancy and from fluid flow.

Vertical acceleration from effective buoyancy

Effective buoyancy is the first contribution to vertical Lagrangian acceleration, which is the vertical acceleration arising solely from the instantaneous mass/density field. Operationally, we deduce the effective buoyancy by instantaneously setting velocity to zero everywhere in the expression

for the vertical acceleration

$$b_{\text{eff}} \equiv \left.\frac{\mathrm{D}w}{\mathrm{D}t}\right|_{\boldsymbol{v}=0} . \tag{31.102}$$

Two conclusions follow directly from the operational definition of b_{eff}. First, as viscous friction only arises when there is relative fluid motions that lead to strains (Section 26.8.6), viscous friction does not contribute to the effective buoyancy. Next, we observe that any direct role for pressure in b_{eff} arises solely from the buoyancy pressure, p'_{buoy}. We make this conclusion since the Poisson equation (31.103) for the buoyancy pressure has a source that only depends on the instantaneous Archimedean buoyancy field, whereas it ignores all contributions from fluid flow. This dependence is precisely that defined for b_{eff}.

From the definition (31.102) we make use of equations (31.75b) and (31.75c) to unpack the variety of contributions to effective buoyancy

$$\rho_0\, b_{\text{eff}} = \rho_0\, b - \left.\partial_z p'\right|_{\boldsymbol{v}=0} = -\left.\partial_z p_{\text{nh}}\right|_{\boldsymbol{v}=0} . \tag{31.103}$$

The first equality identifies the difference between the effective buoyancy and the Archimedean buoyancy

$$\rho_0\,(b_{\text{eff}} - b) = -\partial_z p'_{\text{buoy}}, \tag{31.104}$$

in which we set

$$\left.\partial_z p'\right|_{\boldsymbol{v}=0} = \partial_z p_{\text{buoy}} \tag{31.105}$$

as per the discussion below equation (31.102). So equation (31.104) states that in the presence of a vertical gradient in the buoyancy pressure, then the Archimedean buoyancy is an incomplete description of the vertical acceleration associated with the density field.

Equation (31.103) also reveals that the effective buoyancy is associated with that portion of the vertical gradient in the non-hydrostatic pressure that remains when $\boldsymbol{v} = 0$

$$\rho_0\, b_{\text{eff}} = -\left.\partial_z p_{\text{nh}}\right|_{\boldsymbol{v}=0} . \tag{31.106}$$

This equation provides a generalization of the local hydrostatic balance, $\rho_0\, b = \partial_z(p_{\text{h}} - p_0)$ (equation (31.72)), so that we have the correspondence

$$\underbrace{\rho_0\, b = \partial_z(p_{\text{h}} - p_0)}_{\text{hydrostatic}} \longleftrightarrow \underbrace{\rho_0\, b_{\text{eff}} = -\left.\partial_z p_{\text{nh}}\right|_{\boldsymbol{v}=0}}_{\text{non-hydrostatic}} . \tag{31.107}$$

Vertical acceleration from fluid flow

If one introduces an Archimedean buoyancy anomaly in a static fluid, then the initial vertical acceleration acting on the anomaly is given by its effective buoyancy, with this result following from the definition of effective buoyancy in equation (31.102). However, as the anomaly evolves, fluid motion is generated, at which point effective buoyancy is an incomplete measure of vertical acceleration. So in the presence of fluid motion we must also consider another term referred to as the *flow induced or motional vertical acceleration*. Operationally, we deduce the motional vertical acceleration by setting the density to a constant within the expression for the vertical acceleration

$$A_{\text{flow}} \equiv \left.\frac{\mathrm{D}w}{\mathrm{D}t}\right|_{\rho=\rho_0} . \tag{31.108}$$

As for the effective buoyancy in equation (31.102), the right hand side of equation (31.108) is evaluated using the full flow field at an instant, but with the accelerations evaluated with constant

density at that instance. Since the Archimedean buoyancy vanishes when density has the uniform value, we know that

$$\rho_0\, A_{\text{flow}} = -\,\partial_z p'\big|_{\rho=\rho_0} + \rho_0\, \boldsymbol{F}\cdot\hat{\boldsymbol{z}} = -\,\partial_z p_{\text{nh}}\big|_{\rho=\rho_0} + \rho_0\, \boldsymbol{F}\cdot\hat{\boldsymbol{z}}. \tag{31.109}$$

Consequently, when the density field is uniform, $\rho = \rho_0$, then the vertical gradient of p' and p_{nh} are identical

$$\partial_z p'\big|_{\rho=\rho_0} = \partial_z p_{\text{nh}}\big|_{\rho=\rho_0}\,. \tag{31.110}$$

Furthermore, we identify the vertical gradient in $\partial_z p'|_{\rho=\rho_0}$ with the vertical gradient in the flow induced pressure, p'_{flow}, that satisfies the Poisson equation (31.100c). We thus have the identities

$$\partial_z p'\big|_{\rho=\rho_0} = \partial_z p'_{\text{flow}} = \partial_z p_{\text{nh}}\big|_{\rho=\rho_0}\,. \tag{31.111}$$

31.9.3 Boundary value problems for the accelerations

Following from the discussion in Section 31.9.2, we here derive the boundary value problems for the effective buoyancy and the flow induced acceleration.

Poisson equations for b_{eff} and A_{flow}

From equation (31.104) for the effective buoyancy and from the Poisson equation (31.100b) for the buoyancy pressure, we arrive at the Poisson equation for the effective buoyancy

$$\rho_0\, b_{\text{eff}} = \rho_0\, b - \partial_z p'_{\text{buoy}} \quad\text{and}\quad -\nabla^2 p'_{\text{buoy}} = -\rho_0\, \partial_z b \Longrightarrow -\nabla^2 b_{\text{eff}} = -\nabla_z^2 b. \tag{31.112}$$

Hence, the source for the effective buoyancy is the horizontal Laplacian of the Archimedean buoyancy. Correspondingly, the source for the difference, $b_{\text{eff}} - b$, is the vertical curvature of the Archimedean buoyancy

$$-\nabla^2(b_{\text{eff}} - b) = \partial_{zz} b. \tag{31.113}$$

We similarly derive the Poisson equation for the motional acceleration by making use of its operational definition (31.109) as well as the Poisson equation (31.100c) for the flow pressure

$$\begin{aligned}\rho_0\, A_{\text{flow}} = -\partial_z p'_{\text{flow}} + \rho_0\, \boldsymbol{F}\cdot\hat{\boldsymbol{z}} \quad\text{and}\quad -\nabla^2 p'_{\text{flow}} &= \rho_0\, \nabla\cdot[(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} - \boldsymbol{F}]\\ \Longrightarrow -\nabla^2 A_{\text{flow}} &= -\partial_z \nabla\cdot[(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v} - \boldsymbol{F}] - \nabla^2(\boldsymbol{F}\cdot\hat{\boldsymbol{z}}).\end{aligned} \tag{31.114}$$

Boundary conditions

To completely specify the decomposition of vertical acceleration requires boundary conditions for the effective buoyancy, b_{eff}, and the motional acceleration, A_{flow}. Following our discussion of the Poisson equations in Section 31.9.1, we here only consider rigid and flat material upper and lower boundaries with no boundaries for the horizontal domain (either periodic or infinite horizontal domain). At the upper and lower boundaries we have $\mathrm{D}w/\mathrm{D}t = 0$, and this boundary condition holds whether $\boldsymbol{v} = 0$ or $\rho = \rho_0$, so that

$$b_{\text{eff}} = 0 \quad\text{and}\quad A_{\text{flow}} = 0 \quad\text{on rigid and flat boundaries.} \tag{31.115}$$

We are thus ensured that the net vertical acceleration is indeed the sum

$$\frac{\mathrm{D}w}{\mathrm{D}t} = A_{\text{flow}} + b_{\text{eff}}. \tag{31.116}$$

Poisson equation for the local non-hydrostatic pressure

We can also arrive at the above results by considering the momentum equation (31.74c) written using the decomposition of pressure into is local non-hydrostatic and local hydrostatic components

$$\rho_0 \left(\partial_t + \boldsymbol{v} \cdot \nabla\right) \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \rho_0\, \boldsymbol{v} = -\nabla p_{\rm nh} - \nabla_z p_{\rm h} + \rho_0\, \boldsymbol{F}. \tag{31.117}$$

A divergence of this equation leads to the Poisson equation for the non-hydrostatic pressure

$$-\nabla^2 p_{\rm nh} = \nabla_z^2 p_{\rm h} + \rho_0\, \nabla \cdot [(\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} - \boldsymbol{F}]. \tag{31.118}$$

Taking a vertical derivative and use of the hydrostatic relation leads to the Poisson equation for the vertical derivative of the non-hydrostatic pressure

$$-\nabla^2 (\partial_z p_{\rm nh}) = -g\, \nabla_z^2 \rho + \rho_0\, \partial_z \nabla \cdot [(\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} - \boldsymbol{F}]. \tag{31.119}$$

Setting $\boldsymbol{v} = 0$ in equation (31.118) renders the Poisson equation

$$-(\nabla^2 p_{\rm nh})_{\boldsymbol{v}=0} = \nabla_z^2 p_{\rm h}. \tag{31.120}$$

This equation says that the static portion of the non-hydrostatic pressure is sourced by the horizontal Laplacian of the hydrostatic pressure. Equivalently, the convergence of $(\nabla p_{\rm nh})_{\boldsymbol{v}=0}$ is balanced by the divergence of the horizontal hydrostatic presure gradient, $\nabla_z p_{\rm h}$. Furthermore, setting $\boldsymbol{v} = 0$ in equation (31.119) yields the Poisson equation for the effective buoyancy

$$-\rho_0 \nabla^2 b_{\rm eff} = g \nabla_z^2 \rho \Longleftrightarrow \nabla^2 b_{\rm eff} = \nabla_z^2 b, \tag{31.121}$$

which accords with equation (31.112).

31.9.4 Relative scales for effective and Archimedean buoyancies

One way to emphasize the distinction between the effective buoyancy equation (31.121) and that for the Archimedean buoyancy is to compare their two elliptic equations

$$-\rho_0 \nabla^2 b = g\, \nabla^2 \rho \quad \text{and} \quad -\rho_0 \nabla^2 b_{\rm eff} = g\, \nabla_z^2 \rho, \tag{31.122}$$

with the first equality following trivially by definition of Archimedean buoyancy, $b = -(g/\rho_0)\,(\rho - \rho_0)$. The different Laplacian operators acting on the source terms for $b_{\rm eff}$ and b it crucial. Namely, it means that these two buoyancy fields scale differently.

As an example of the distinct scaling for $b_{\rm eff}$ and b, consider a cylindrically shaped Archimedean buoyancy anomaly (Figure 31.8) of scale B and with diameter D and height H. Given this information we seek a corresponding scale for the effective buoyancy, $B_{\rm eff}$. Using the relation (31.121), and the cylindrical-polar coordinate version of the Laplacian operator (equation (10.83b)), we have

$$\nabla^2 b_{\rm eff} = \frac{1}{r}\, \frac{\partial}{\partial r} \left[r\, \frac{\partial b_{\rm eff}}{\partial r} \right] + \frac{1}{r^2}\, \frac{\partial^2 b_{\rm eff}}{\partial \vartheta^2} + \frac{\partial^2 b_{\rm eff}}{\partial z^2} \quad \text{and} \quad \nabla_z^2 b = \frac{1}{r}\, \frac{\partial}{\partial r} \left[r\, \frac{\partial b}{\partial r} \right] + \frac{1}{r^2}\, \frac{\partial^2 b}{\partial \vartheta^2}, \tag{31.123}$$

where r is the radial distance from the cylinder axis, z the vertical coordinate along the cylinder axis, and ϑ the polar coordinate. We thus find the scalings

$$\nabla^2 b_{\rm eff} \sim B_{\rm eff}\, (D^{-2} + H^{-2}) \quad \text{and} \quad \nabla_z^2 b \sim B\, D^{-2}, \tag{31.124}$$

so that for a given Archimedean buoyancy anomaly scale, B, we find an associated effective buoyancy scale

$$B_{\text{eff}} = \frac{B}{1 + D^2/H^2}. \tag{31.125}$$

Evidently, the effective buoyancy scale is smaller than the Archimedean buoyancy scale. The effective buoyancy scale is smaller due to the pressure contribution that slows down any buoyant fluid element, with this pressure induced environmental back-reaction missing from the Archimedean buoyancy. Also observe that the effective buoyancy decreases when the ratio D/H increases. As a result, wide and flat "pancake" shaped buoyancy anomalies rise slower (with $B > 0$) than narrow "rocket shaped" anomalies. This result follows since a pancake anomaly must push aside more surrounding fluid as it moves vertically, whereas the narrow rocket shaped anomaly is more streamlined and thus more readily rises or falls.

FIGURE 31.8: An Archimedean buoyancy anomaly of scale B here configured in the shape of a cylinder with diameter D and height H. Also shown are the vertical, z, and radial, r, axes for cyclindrical-polar coordinates from Section 10.3. In equation (31.125) we find the effective buoyancy for this anomaly scales as $B_{\text{eff}} = B/(1+D^2/H^2)$, so that the effective buoyancy has a smaller magnitude than the Archimedean buoyancy. Also note that the magnitude of the effective buoyancy decreases as the diameter increases. This behavior reflects the need for a wide and flat buoyancy anomaly to push aside more surrounding fluid as it moves vertically, whereas a narrow and tall anomaly is more streamlined and so has less resistance to vertical motion.

As a buoyant fluid element moves vertically, it must displace the surrounding environmental fluid. The pressure contribution to the effective buoyancy accounts for the back-reaction of the environmental fluid on the buoyant fluid element. Since the Archimedean buoyancy ignores the back-reaction, it generally over estimates the magnitude of the vertical acceleration. By accounting for the pressure forces acting on the element from the surrounding fluid, the effective buoyancy offers a more accurate measure of the static vertical forces arising from density inhomogeneities.

31.9.5 Thought experiments for effective buoyancy

We here present some thought experiments for the purpose of developing an understanding of effective buoyancy. The thought experiments are somewhat trivial physically and yet they require us to confront basic assumptions, which is generally a useful exercise.

Horizontally unstratified density

Consider a horizontally unstratified density, $\rho = \rho(z)$, on a horizontally periodic domain with the fluid in hydrostatic equilibrium. By construction, the Archimedean buoyancy, $b = -g\,(\rho - \rho_0)/\rho_0$, exactly balances the vertical pressure gradient, $\mathrm{d}(p - p_0)/\mathrm{d}z = b\,\rho_0$. In the absence of horizontal density gradients, the effective buoyancy is everywhere a harmonic function since $\nabla^2 b_{\text{eff}} = 0$. With vanishing Dirichlet boundary conditions at the rigid bottom and top of the domain, $z = 0, H$, then $b_{\text{eff}} = 0$ everywhere, signaling the absence of any vertical acceleration.

It is notable that this result holds for an arbitrary vertical profile of density, even if the density is gravitationally unstable (Section 31.5). The assumed horizontal symmetry is the key point. This assumption precludes any vertical motion since no fluid element at a single horizontal position can be vertically displaced without breaking the assumption of horizontal symmetry. The only way to maintain volume conservation ($\nabla \cdot \boldsymbol{v} = 0$) with vertical motion is for some fluid to move up while other fluid moves down, and for that to happen requires breaking horizontal symmetry. Once a tiny seed of horizontal asymmetry is presented to the fluid, effective buoyancy is sourced by $\nabla_z^2 \rho \neq 0$, which in turn allows the gravitational instability to grow.

Vertically unstratified density

Now consider a vertically unstratified density field, $\rho = \rho(x, y)$, so that the Archimedean buoyancy has no depth dependence. This vertically "neutrally buoyant" case commonly means that a fluid element can move vertically without feeling any buoyancy forces. Indeed, such is the case when referring to Archimedean buoyancy. What about effective buoyancy?

If density is a linear function of horizontal position then the effective buoyancy is a harmonic function so that $b_{\text{eff}} = 0$. If density is a nonlinear function of the horizontal then the effective buoyancy is nonzero. Yet is there vertical motion? Again we must confront the boundary conditions to answer this question. Here, the rigid top and bottom boundaries preclude movement of fluid across these boundaries by imparting a boundary pressure acting throughout the fluid to counteract the effective buoyancy. As a result, the fluid remains static. If instead we allow for a free surface, then the effective buoyancy would cause vertical motion that then leads to horizontal convergences, thus leading to further motion. Alternatively, if we allow for depth dependence of the density, then fluid can move laterally as well as vertically.

Localized source of Archimedean buoyancy

Although useful to garner some understanding of effective buoyancy, the previous examples are not realistic. More realistic applications are concerned with Archimedean buoyancy sources localized in both the horizontal and vertical directions. In this case the nonzero buoyancy source, $\nabla_z^2 \rho \neq 0$, along with the boundary conditions lead to a nontrivial structure for the effective buoyancy as found by solving the Poisson equation. Studies listed below offer examples, both analytical and numerical, to further an understanding of how effective buoyancy offers a more complete description of vertical acceleration than Archimedean buoyancy.

31.9.6 Comments and further study

Studies from *Davies-Jones* (2003b), *Doswell and Markowski* (2004), *Jeevanjee and Romps* (2015a), *Jeevanjee and Romps* (2015b), and *Tarshish et al.* (2018), point to the use of the effective buoyancy and the limitations of Archimedean buoyancy when studying buoyancy dominated motion, such as the early stages of a buoyant thermal in the atmosphere. Much of the material in this

section was gleaned from these papers, particularly from *Jeevanjee and Romps* (2015a,b). Chapter 2 of *Markowski and Richardson* (2010) provides a pedagogical foundation for understanding pressure forces leading to vertical motion.

The structure of b_{eff} is distinct from the Archimedean buoyancy, b, with *Jeevanjee and Romps* (2015a) and *Tarshish et al.* (2018) providing examples where b and b_{eff} can even have opposite signs. Furthermore, *Tarshish et al.* (2018) made use of an analogy between the Poisson equation for b_{eff} and the Poisson equation for certain magnetostatics problems. The analogy allowed them to derive analytical expressions for b_{eff} from spherical and elliptical Archimedean buoyancy sources.

31.10 Exercises

EXERCISE 31.1: EXAMPLES OF BUOYANCY PERIOD

Using approximate but realistic values for the observed stratification, determine the buoyancy period ($T_{\text{b}} = 2\pi/N$) for

- mid-latitude troposphere
- stratosphere
- ocean thermocline
- ocean abyss.

Express the period in units of minutes, and provide references for where you obtained the observed stratification. Hint: for both the atmosphere and ocean, it is sufficient to assume stratification is dominated by potential temperature.

EXERCISE 31.2: BUOYANCY FREQUENCY FOR AN IDEAL GAS

Derive equation (31.38) for the squared buoyancy frequency of an ideal gas. Hint: first derive the expression for the potential density and then take its vertical derivative as per equation (31.37).

EXERCISE 31.3: VERTICAL INTEGRAL OF N^2

The expression for squared buoyancy frequency

$$N^2 = -g \left[\frac{\partial \ln \varrho}{\partial z} \right]_{p_{\text{ref}}=p} \tag{31.126}$$

makes is tempting to consider its vertical integral according to

$$-g^{-1} \int_{-H}^{\eta} N^2 \, \mathrm{d}z \stackrel{?}{=} [\ln \varrho]_{\eta} - [\ln \varrho]_{-H} \, . \tag{31.127}$$

Discuss what is wrong with this equation. Under what conditions is it correct?

EXERCISE 31.4: WATER LEVEL OF A BOAT WITH AND WITHOUT A STONE

Consider a boat of mass M_{b} floating in constant density water, ρ_{w}, contained in a tank with vertical sidewalls and cross-sectional area A. Place a stone of mass M_{s} and density $\rho_{\text{s}} > \rho_{\text{w}}$ in the boat and measure the water level on the tank wall, h_1. Then throw the stone into the water. What is the new water level, h_2, as a function of h_1 and the other properties listed above? Does the water level rise or fall along the sides of the tank as a result of throwing the stone over the side? Hint: Watch this Physics Girl video.

EXERCISE 31.5: ICEBERG FLIPPING INSTABILITY (a) Consider an iceberg with constant density ρ_{berg} that is floating in ocean water with constant density ρ_{ocn}. Let the iceberg have a square solid shape with vertical thickness H and horizontal length $L \gg H$. What fraction of the iceberg sits above the ocean surface?

(b) Consider an iceberg with non-uniform density, $\rho_{\text{berg}}(z)$, where $0 \leq z \leq H$ measures the position along the vertical axis of the iceberg. A non-uniform density might occur for cases where rocks are frozen into the ice. Depending on the density profile, the iceberg can be unstable to horizontal forces that cause the iceberg to flip over, particularly if L decreases to be on the order of H. Develop the stability criteria for this "flipping instability" using Archimedes' principle and the mechanics of angular momentum and torques.

Chapter 32

GEOSTROPHY AND THERMAL WIND

Large-scale and low frequency flows in the atmosphere and ocean are stongly affected by planetary rotation. The inviscid balance for such flows is termed *geostrophy*, in which the planetary Coriolis acceleration balances the pressure gradient acceleration. In this chapter, we introduce salient features of geostrophically balanced flow and the associated *thermal wind balance*. These two diagnostic relations involve no time derivatives, and so cannot be used to predict the fluid flow evolution. However, they provide a very powerful framework for interpreting large-scale and low frequency flow in the atmosphere and ocean.

After studying the basic elements of rotating flow, we study the distinctive nature of isopycnal form stresses associated with geostrophically balanced eddy motions. Such form stresses are a key feature of the earth's planetary energy balance, whereby positive buoyancy in the tropics is, in part, transported meridionally through the action of geostrophic eddies.

READER'S GUIDE TO THIS CHAPTER

This chapter assumes an understanding of the primitive equations from Chapter 28 and the Coriolis acceleration from Chapters 13 and 14. The material in this chapter is fundamental to understanding the nature and mechanisms of large-scale flow in the atmosphere and ocean, so that we make great use of this chapter in the remainder of this book. Throughout the discussion we are not explicitly concerned with sphericity, thus enabling the use of Cartesian vector calculus.

32.1 Loose threads

- Max Nikurashin's work on topographic form stress in the Southern Ocean, and the lack of a direct connection to interfacial form stress. Unsure if this material is better here or in Chapter 29.

32.2 Primitive equations

Throughout this chapter we make use of the inviscid hydrostatic primitive equations derived in Section 28.1

$$\partial \boldsymbol{u}/\partial t + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{u} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\rho^{-1}\,\nabla_z p \tag{32.1a}$$

$$\partial p/\partial z = -g\,\rho \tag{32.1b}$$

$$\mathrm{D}\rho/\mathrm{D}t = -\rho\,\nabla\cdot\boldsymbol{v}, \tag{32.1c}$$

where the velocity vector is written using Cartesian coordinates

$$\boldsymbol{v} = \boldsymbol{u} + \hat{\boldsymbol{z}}\,w = \hat{\boldsymbol{x}}\,u + \hat{\boldsymbol{y}}\,v + \hat{\boldsymbol{z}}\,w, \tag{32.2}$$

and the horizontal gradient operator is

$$\nabla_z = \hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y. \tag{32.3}$$

For some of the scale analysis in this chapter we assume a Boussinesq ocean (Section 30.1), in which case the mass continuity equation (32.1c) becomes the non-divergent condition on the velocity

$$\nabla\cdot\boldsymbol{v} = 0. \tag{32.4}$$

Furthermore, ρ in the Boussinesq horizontal momentum equation (32.1a) is converted to a constant reference density, ρ_0, and yet it retains its full form when appearing in the hydrostatic equation since it is there multiplied by the gravitational acceleration.

32.3 The Rossby number

Large-scale geophysical fluid flows are strongly influenced by the earth's rotation. Indeed, the earth can be considered a rapidly rotating planet for much of the observed large-scale motion of the ocean and atmosphere. There are two points to emphasize in this regard. First, much

of the ocean and atmosphere motion is close to rigid-body rotation, in which weather patterns and ocean circulation are best viewed in the terrestrial reference frame on the rotating earth (a non-inertial reference frame) rather than from an inertial reference frame. Second, length scales directly experienced by humans are generally far too small to take a direct notice of the planetary rotation. This point is quantified by considering the *Rossby number*, which includes a horizontal length scale, a velocity scale, and angular rotation speed.

32.3.1 Scaling for the Rossby number

The Rossby number measures the ratio of the horizontal material acceleration (acceleration of a fluid particle) to the Coriolis acceleration. The material acceleration has two contributions: one from local time tendencies and one from advection. We expose typical characteristic scales for the horizontal acceleration of a fluid particle by writing

$$\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{u} \sim \frac{U}{T} + \frac{U^2}{L} + \frac{WU}{H}, \tag{32.5}$$

where U, W are typical horizontal and vertical velocity scales, L, H are typical horizontal and vertical length scales, and T is a typical time scale (recall a similar scale analysis for the hydrostatic balance in Section 28.2). Likewise, the Coriolis acceleration scales as

$$f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} \sim f_0\, U, \tag{32.6}$$

where f_0 is the scale for the Coriolis parameter. From the continuity equation for non-divergent flow ($\nabla \cdot \boldsymbol{v} = 0$) we see that the vertical and horizontal velocity scales are related by[1]

$$W/H \sim U/L \Longrightarrow W \sim U\,(H/L). \tag{32.7}$$

We are interested in flows where the ratio of the vertical to horizontal length scales, referred to as the *aspect ratio*, is small

$$\alpha_{\text{aspect}} = H/L \ll 1, \tag{32.8}$$

as per the hydrostatic approximation discussed in Section 28.2. Consequently, the vertical velocity scale is much less than the horizontal

$$W \ll U. \tag{32.9}$$

32.3.2 Ratio of material acceleration to Coriolis acceleration

Taking the ratio of the advection scale to the Coriolis scale leads to our first expression for the Rossby number

$$\text{Ro} = \frac{U^2/L}{f_0\, U} = \frac{U}{f_0\, L}. \tag{32.10}$$

Due to the latitudinal variation of the Coriolis parameter, the Rossby number is generally smaller in magnitude near the poles than in the tropics. This functional dependence is modified by noting that the length and velocity scales are not constant.

[1] For divergent flows we can replace W with the scale for motion across hydrostatic pressure surfaces.

32.3.3 Ratio of local time tendency to Coriolis acceleration

A complementary way to understand the Rossby number is to consider it as the ratio of the local time tendency for the horizontal velocity to the Coriolis acceleration

$$\mathrm{Ro} = \frac{U/T}{U f_0} = \frac{1/T}{f_0}. \tag{32.11}$$

Hence, the Rossby number is small for motions that have a frequency, T^{-1}, that is small compared to the *inertial frequency*, f_0. In both ways of writing the Rossby number, we associate small Ro with regimes of flow where the earth's rotation plays a crucial role in the dynamics. With small Rossby number, both the local time derivative and the advective acceleration are smaller than the Coriolis acceleration.

32.3.4 Rossby number for a kitchen sink

Consider flow in a kitchen sink (left panel of Figure 32.1). Here, the length scale is $L = 1$ m (sink size) and the velocity scale is $U = 0.01 - 0.1$ m s^{-1}, thus giving a typical time scale for sink motion of $L/U \approx 10$ s $- 100$ s. Hence, at 30° latitude, where $f = 2\Omega \sin\phi = \Omega$, the Rossby number for fluid motion in a sink is

$$\mathrm{Ro}_{\mathrm{sink}} \approx 10^2 - 10^3. \tag{32.12}$$

The effects from planetary rotation are tiny on these length scales, so that the Coriolis force is negligible for kitchen sink fluid dynamics. Correspondingly, it is extremely difficult to experimentally determine a correlation between the hemisphere (northern or southern) to the rotational direction of water leaving a sink drain.

FIGURE 32.1: Estimating the Rossby number for flow in a kitchen sink (left panel) and rings spawned from the Gulf Stream (right panel). The kitchen sink has velocity scales on the order of $U \sim 0.01 - 0.1$ m s^{-1} whereas Gulf Stream rings have velocity scales on the order $U \sim 0.1 - 1.0$ m s^{-1}. Their length scales are much more distinct, with the scale for a sink $L \sim 1$ m whereas for the Gulf Stream rings $L \sim 10^5$ m. Taking the Coriolis parameter at 30° leads to $\mathrm{Ro}_{\mathrm{sink}} \sim 10^2 - 10^3$ and $\mathrm{Ro}_{\mathrm{ring}} \sim 10^{-2} - 10^{-1}$. The planetary Coriolis acceleration is central to Gulf Stream ring dynamics whereas it is utterly negligible for the kitchen sink.

32.3.5 Rossby number for a Gulf Stream ring

For a Gulf Stream ring (right panel of Figure 32.1), the typical length scale is $L = 10^5$ m and velocity scale is $U = 0.1 - 1.0$ m s^{-1}, thus leading to a time scale $L/U \approx 10^5 - 10^6$ s. At 30° latitude the Rossby number is

$$\mathrm{Ro}_{\mathrm{ring}} \approx 10^{-2} - 10^{-1}. \tag{32.13}$$

Flow features of such large length scales can feel the planetary rotation so that the Coriolis acceleration is central to dynamics of Gulf Stream rings, as reflected in the small magnitude of

the associated Rossby number.

32.4 Geostrophic balance

Under the influence of horizontal pressure forces, a fluid accelerates down the pressure gradient (movement from high pressure to low pressure). In the presence of rotation, a nonzero horizontal velocity couples to the earth's rotation via the Coriolis parameter, f, thus giving rise to a nonzero horizontally oriented Coriolis acceleration $-f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}$. The Coriolis acceleration acts perpendicular to the fluid motion

$$\boldsymbol{u} \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{u}) = 0, \tag{32.14}$$

and as such it affects the fluid motion but does not alter kinetic energy; i.e., it does zero work on the fluid.[2] In the northern hemisphere where $f > 0$, the Coriolis acceleration acts to the right of the parcel motion. It follows that if the Coriolis and pressure gradient accelerations are balanced, then a fluid particle moves counter-clockwise around low pressure centers and clockwise around high pressure centers. In the southern hemisphere, where $f < 0$, the Coriolis acceleration acts in the opposite direction so that geostrophically balanced flow is oppositely oriented in the southern hemisphere relative to the north. In Figure 32.2 we offer a heuristic model to help understand the orientation of flow where the Coriolis acceleration balances the pressure gradient acceleration.

FIGURE 32.2: Geostrophy is a diagnostic relation where the pressure gradient acceleration balances the Coriolis acceleration so that the net acceleration acting on a fluid element is zero. Here we depict a particle on a rotating and frictionless hill (analogous to a high pressure center) as a conceptual model to help understand geostrophic balance. As the particle moves downhill (or down the pressure gradient) it picks up a rightward component to its trajectory as a result of the Coriolis acceleration that couples to motion. Equilibrium arises when the downhill acceleration (pressure gradient acceleration) balances the oppositely directed Coriolis acceleration.

32.4.1 What is geostrophic balance?

When the pressure acceleration balances the Coriolis acceleration, fluid motion is said to be in *geostrophic* balance. Geostrophically balanced flows in the atmosphere and ocean follow isobars (lines of constant pressure). Recall from Chapter 13 that point particles also experience a Coriolis acceleration when viewed in a rotating reference frame, as we noted in Figure 32.2. However, geostrophic balance is not afforded to particles since particles do not experience a pressure force that can balance the Coriolis force. Hence, the geostrophic balance is a distinctly fluid mechanical phenomena.

[2] These characteristics of the Coriolis acceleration are directly analogous to the Lorentz force in electrodynamics (*Jackson*, 1975).

32.4.2 Geostrophic relation in geopotential coordinates

When the Rossby number is small and friction is negligible, the leading order dynamical balance in the horizontal momentum equation (32.1a) is between the Coriolis acceleration and horizontal pressure gradient acceleration

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\rho^{-1}\,\nabla_z p, \tag{32.15}$$

which leads to the expression for the geostrophic velocity[3]

$$\boldsymbol{u}_{\mathrm{g}} = \frac{\hat{\boldsymbol{z}} \times \nabla p}{f\rho} \Longrightarrow u_{\mathrm{g}} = -\frac{1}{f\rho}\,\frac{\partial p}{\partial y} \qquad \text{and} \qquad v_{\mathrm{g}} = \frac{1}{f\rho}\,\frac{\partial p}{\partial x}. \tag{32.16}$$

Note that the equator is special since the Coriolis parameter, $f = 2\,\Omega\,\sin\phi$, vanishes, thus precluding the relevance of geostrophy near the equator.

Equation (32.16) for the geostrophic velocity can be written as

$$\rho\,f\,\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla_z p, \tag{32.17}$$

which suggests we interpret pressure as a streamfunction for $\rho\,f\,\boldsymbol{u}_{\mathrm{g}}$. For the particular case of a Boussinesq ocean on an f-plane, in which we set ρ to the reference density ρ_0 and f is a constant, then we can write

$$\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla_z[p/(\rho_0\,f)]. \tag{32.18}$$

In this case $p/(\rho_0\,f)$ is referred to as the *geostrophic streamfunction* for the f-plane Boussinesq geostrophic flow.

32.4.3 Cyclonic and anti-cyclonic flow orientation

FIGURE 32.3: Geostrophic motion around low and high pressure centers in the northern hemisphere and southern hemisphere ($f = 2\,\Omega\sin\phi > 0$ in the north and $f < 0$ in the south). Upper panel: the counter-clockwise motion around the low pressure center in the northern hemisphere is in the same sense as the planetary rotation, and is thus termed cyclonic. Cyclonic motion around a low pressure in the southern hemisphere occurs in a clockwise direction, again corresponding to the planetary rotation direction as viewed from the south. Geostrophic motion around a high pressure center is counter to the planetary rotation in both hemispheres, and is thus termed anti-cyclonic.

When oriented in the same sense as the earth's rotation (i.e., same sign of the Coriolis parameter) rotational motion is said to be in a *cyclonic* sense. Oppositely oriented motion is *anti-cyclonic*. For example, geostrophic motion around a low pressure center in the northern hemisphere is counter-clockwise (Figure 32.3). Using the right hand rule, this motion represents a positively

[3] We can write either ∇ or ∇_z in equation (32.16). The reason is that the $\hat{\boldsymbol{z}}\times$ operator selects only the horizontal portion of the gradient.

oriented rotation. Hence, with $f > 0$ in the north, counter-clockwise motion is cyclonic. In the southern hemisphere, geostrophic motion around a low pressure center is clockwise, which is a negatively oriented rotational motion (again, recall the right hand rule). In the south where $f < 0$, clockwise motion around a low pressure center represents cyclonic motion (Figure 32.3).

32.4.4 Density gradients and thermal wind balance

Horizontal momentum is affected by horizontal pressure gradient forces. Furthermore, the hydrostatic balance says that the vertical derivative of the horizontal pressure gradient is determined by horizontal density gradients

$$\frac{\partial(\nabla_z p)}{\partial z} = -g\nabla_z \rho. \tag{32.19}$$

Hence, in the presence of horizontal density gradients, the horizontal pressure gradient forces are depth dependent. Correspondingly, the horizontal velocity field experiences a depth dependent pressure force.

FIGURE 32.4: Horizontal density gradients support a vertical dependence to the horizontal gradient of the hydrostatic pressure via $\partial(\nabla_z p)/\partial z = -g\nabla_z \rho$. This figure depicts a vertically stable stratification of density ($\partial\rho/\partial z < 0$), along with pressure that decreases upward as per the hydrostatic balance ($\partial p/\partial z = -\rho\, g < 0$). Density is assumed to have a constant zonal gradient with $\partial\rho/\partial x < 0$, which leads to an increase in the zonal pressure gradient with height, $\partial(\partial p/\partial x)/\partial z > 0$. Depending on the thickness of the fluid column, the horizontal pressure gradient can change sign when moving up in the column, as shown here. Compare this figure to Figure 28.6, which discusses how to compute horizontal pressure gradients in a hydrostatic fluid.

We illustrate this depth dependence in Figure 32.4 with a depth independent horizontal density gradient, $\partial\rho/\partial x = \text{constant} < 0$. This density gradient leads to a depth dependent horizontal gradient in the hydrostatic pressure. This figure also illustrates how the sign of the horizontal pressure gradient can change when moving in the vertical, depending on the value of the gradient at depth. It also illustrates how horizontal density gradients that are mis-aligned with pressure gradients lead to a nonzero baroclinicity vector

$$\boldsymbol{B} = \frac{\nabla\rho \times \nabla p}{\rho^2}. \tag{32.20}$$

As shown in Section 41.4, a nonzero baroclinicity (i.e., a mis-alignment of the density and pressure surfaces) imparts a "torque" on fluid elements that acts as a source for vorticity.

Depth dependence to the horizontal pressure gradient leads to a vertical shear in the horizontal geostrophic velocity

$$\frac{\partial(\rho\, f\, \boldsymbol{u}_{\mathrm{g}})}{\partial z} = \hat{\boldsymbol{z}} \times \nabla(\partial p/\partial z) = -g\, \hat{\boldsymbol{z}} \times \nabla\rho. \tag{32.21}$$

This connection between horizontal density gradients and vertical shears in the geostrophic velocity is known as the *thermal wind balance*, which we return to in Section 32.5.6.

32.4.5 Geostrophic relation in pressure coordinates

The hydrostatic balance

$$\partial p/\partial z = -\rho\, g \tag{32.22}$$

can be used to eliminate density from the geostrophic balance (32.15) to render

$$f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = \frac{g \nabla_z p}{\partial p/\partial z}. \tag{32.23}$$

The right hand side is minus the lateral gradient of the geopotential, $\Phi = g\, z$, as computed along surfaces of constant pressure[4]

$$f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\nabla_p\, \Phi \Longrightarrow f\, \boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla_p \Phi. \tag{32.24}$$

This is a useful expression of geostrophy for the compressible atmosphere.

32.4.6 Further study

Visualizations from rotating tank experiments offer a useful complement to the mathematical expressions presented here. For example, start around the 10 minute mark in this video from Prof. Fultz.

32.5 Planetary geostrophic mechanics

We here introduce the planetary geostrophic (PG) equations, which have found great use in describing elements of the large-scale laminar ocean circulation. We state the equations and discuss their physical implications, deferring a systematic derivation for later. In particular, the shallow water planetary geostrophic equations are derived in Section 44.4 and the continuously stratified planetary geostrophic equations are derived in Section 45.2.

32.5.1 Planetary geostrophic equations

The governing equations for planetary geostrophy are based on the hydrostatic Boussinesq equations stated in Section 30.1.7, with the assumption of a steady state linear and frictional/-geostrophic balance for the horizontal momentum

$$\rho_0\, f\, (\hat{\boldsymbol{z}} \times \boldsymbol{u}) = -\nabla p - \rho\, g\, \hat{\boldsymbol{z}} + \partial \boldsymbol{\tau}/\partial z \tag{32.25a}$$

$$\nabla_z \cdot \boldsymbol{u} + \partial w/\partial z = 0 \tag{32.25b}$$

$$\mathrm{D}b/\mathrm{D}t = \dot{b}. \tag{32.25c}$$

The stress, $\boldsymbol{\tau}$, acts just in the horizontal directions so that the vertical component of the momentum equation (32.25a) is the hydrostatic balance

$$\partial p/\partial z = -\rho\, g. \tag{32.26}$$

[4]See Section 59.12.2 for details of computing derivatives using generalized vertical coordinates. In particular, the formalism in that section reveals that $(\partial p/\partial x)_{y,z}/(\partial p/\partial z)_{x,y} = -(\partial z/\partial x)_{y,p} = -g^{-1}\, (\partial \Phi/\partial x)_{x,p}$, and likewise for the meridional derivative.

We now list some of the key physical attributes captured by these equations.

Velocity is determined by buoyancy

The only time derivative appearing in the planetary geostrophic equations appears in the buoyancy equation (32.25c). All other equations are diagnostic. As the buoyancy evolves, the hydrostatic pressure changes and so too does the geostrophic velocity. Hence, the velocity is determined by the buoyancy field.

Planetary geostrophy admits no turbulence

The momentum equation is linear since planetary geostrophy drops the nonlinear advection of momentum. Turbulence relies on the nonlinear momentum advection. Hence, there is no turbulence in the planetary geostrophic fluid. Instead, planetary geostrophy is used to describe laminar ocean circulation at the large-scales.

Vertical transfer of horizontal momentum and subgrid scale parameterizations

We introduced a horizontal stress vector (dimensions of force per area) into the momentum equation

$$\boldsymbol{\tau} = (\tau^x, \tau^y, 0). \tag{32.27}$$

This stress is associated with vertical transfer of horizontal momentum in the ocean interior through vertical viscosity, as well as vertical transport of momentum from the atmosphere to the ocean. The stress is enhanced by waves and turbulent features such as mesoscale eddies. However, such transient processes are not represented by planetary geostrophy. Hence, they must be parameterized, which generally leads to an enhanced vertical viscosity relative to that from molecular viscosity.

In general, all models, either analytical or numerical, that are focused on planetary scale circulations do not resolve the scales over which molecular viscosity dominates the frictional dissipation. Consequently, it is necessary to provide rational *subgrid-scale (SGS) parameterizations* for the variety of physical processes that are unresolved by the model. We have more to say about the parameterization of vertical transfer of horizontal momentum in Section 66.3.5.

32.5.2 Planetary geostrophic vorticity equation

The vertical component of relative vorticity is

$$\zeta = \partial v/\partial x - \partial u/\partial y, \tag{32.28}$$

with a thorough discussion of vorticity given in Chapter 41. Here, we form the relative vorticity budget for the planetary geostrophic system by taking the curl of the momentum equation.

Curl of the PG momentum equation

Taking the curl of the momentum equation (32.25a), and rearranging terms, leads to the planetary geostrophic vorticity equation

$$-\rho_0 \, f \, \frac{\partial \boldsymbol{u}}{\partial z} + \hat{\boldsymbol{z}} \, \rho_0 \, \nabla \cdot (f \, \boldsymbol{u}) = -g \, \nabla \times (\hat{\boldsymbol{z}} \, \rho) + \frac{\partial (\nabla \times \boldsymbol{\tau})}{\partial z}. \tag{32.29}$$

Note that $\nabla \cdot (f\,\boldsymbol{u}) = \nabla_z \cdot (f\,\boldsymbol{u})$ since $\boldsymbol{u}$ is the horizontal velocity vector. Introducing the Archimedean buoyancy (Section 30.1.2)

$$b = -g\,(\rho - \rho_0)/\rho_0 \tag{32.30}$$

leads to

$$-f\,\frac{\partial \boldsymbol{u}}{\partial z} + \hat{\boldsymbol{z}}\,\nabla_z \cdot (f\,\boldsymbol{u}) = \nabla \times (\hat{\boldsymbol{z}}\,b) + \frac{1}{\rho_0}\frac{\partial(\nabla \times \boldsymbol{\tau})}{\partial z}. \tag{32.31}$$

Relative vorticity is absent from the PG vorticity equation

It is notable that there is no appearance of the relative vorticity, $\zeta = \partial_x v - \partial_y u$, in the planetary geostrophic vorticity equation (32.25a). The reason is that we dropped the material time derivative of velocity when forming the planetary geostrophic momentum equation (32.25a). By doing so, we eliminate ζ from the vorticity equation. Planetary geostrophy is valid for those cases where

$$|\zeta| \ll |f|, \tag{32.32}$$

which means the absolute vorticity (sum of planetary vorticity plus relative vorticity) is dominated by the planetary vorticity. We encounter more complete versions of the vorticity equation in Chapter 41 where we do not make the planetary geostrophic assumption.

Rather than taking the curl of the planetary geostrophic momentum equation, we could have also derived the vorticity equation (32.31) by taking planetary geostrophic scaling in the full vorticity equation. We choose here the path through the planetary geostrophic momentum equation since we have yet to discuss the full vorticity equation (Chapter 41).

32.5.3 Taylor-Proudman and vertical stiffening

Consider the vorticity equation (32.31) on an f-plane with zero friction, in which the horizontal geostrophic motion is horizontally non-divergent

$$\nabla_z \cdot \boldsymbol{u} = 0 \qquad f\text{-plane geostrophy.} \tag{32.33}$$

Use of continuity (equation (32.25b)) means there is no vertical stretching of a vertical material line element (Section 19.4.3)

$$\partial w/\partial z = 0. \tag{32.34}$$

As shown in Chapter 41, a vortex tube exhibits the same kinematics as a material line element described in Section 19.3. Hence, $\partial w/\partial z = 0$ means there is no vertical stretching of a vortex tube in the planetary geostrophic fluid. This result has important implications that we now describe.

Flat bottom boundary and columnar motion

If there is a solid flat bottom to the domain, then the vertical velocity vanishes at that surface. With $\partial_z w = 0$ in the interior as well, then w vanishes throughout the domain. Hence, the fluid has zero vertical velocity, and motion occurs on horizontal planes perpendicular to the rotation axis; i.e., the flow is two-dimensional. We furthermore assume zero horizontal buoyancy gradients, so that the vorticity equation (32.31) implies that the horizontal velocity has zero vertical shear

$$\partial \boldsymbol{u}/\partial z = 0 \qquad f\text{-plane and homogeneous density.} \tag{32.35}$$

This result is known as the *Taylor-Proudman effect*, with Figure 32.5 providing an illustration.

FIGURE 32.5: The Taylor-Proudman effect, summarized by equation (32.35), says that horizontal flow is depth-independent when it occurs in a homogeneous and rapidly rotating fluid over a flat bottom (where $w = 0$). Hence, when flow encounters an obstacle anywhere in the column, such as the red ring shown here at the bottom, then flow throughout the full depth coherently moves around the obstacle. The result is a vertically stiffened motion known as *Taylor columns.*

Relevance to the ocean and atmosphere

In the ocean and atmosphere, the assumptions leading to the Taylor-Proudman effect are rarely satisfied due to the presence of stratification (i.e., vertical density variations), and a sloping solid earth bottom. Nonetheless, there is a tendency for vertical velocities to be quite small due to the effects of rotation; even smaller than the non-divergent flow scaling $W/H \sim U/L$ would indicate (see Section 32.3.1). Additionally, for unstratified or linearly stratified fluids, there is a tendency for geostrophic turbulence to cascade energy into the *gravest vertical mode*; i.e., the largest vertical scale. This largest vertical scale mode is termed the *barotropic* mode, and motion of this mode is predominantly horizontal and depth independent. Smaller vertical scales of variation are captured by an infinite hierarchy of *baroclinic* modes. The process of moving energy to the barotropic mode is referred to as *barotropization.*

32.5.4 Meridional motion in response to vortex stretching and stress curls

The vertical component to the vorticity balance (32.31) leads to

$$\nabla_z \cdot (f\,\boldsymbol{u}) = \frac{1}{\rho_0}\frac{\hat{\boldsymbol{z}} \cdot \partial\,(\nabla \times \boldsymbol{\tau})}{\partial z} \tag{32.36}$$

which can be written

$$\beta\, v = -f\,\nabla_z \cdot \boldsymbol{u} + \frac{1}{\rho_0}\frac{\hat{\boldsymbol{z}} \cdot \partial\,(\nabla \times \boldsymbol{\tau})}{\partial z} \tag{32.37}$$

where

$$\beta = \partial f / \partial y \tag{32.38}$$

is the gradient of planetary vorticity. The continuity equation (32.25b) can be used to remove the horizontal divergence, which yields the vorticity balance

$$\beta\, v = f\,\frac{\partial w}{\partial z} + \frac{1}{\rho_0}\frac{\hat{\boldsymbol{z}} \cdot \partial\,(\nabla \times \boldsymbol{\tau})}{\partial z}. \tag{32.39}$$

The left hand side is the meridional advection of planetary vorticity, with $\beta > 0$ over the globe. The first term on the right hand side arises from vortex stretching by planetary vorticity; i.e., planetary induction or the β-effect discussed in Section 41.6.2. The second term is the vertical

divergence of the curl of the frictional stress.

Reading the vorticity equation (32.39) from right to left indicates that any process leading to a vorticity source via vortex stretching or vertically dependent frictional stress curls must be balanced by meridional motion. That is, the fluid responds to vortex stretching and vertically dependent stress curls by moving meridionally through the planet's vorticity field. In the frictional planetary geostrophic theory, meridional movement is the only means for fluid to respond to vorticity input since the fluid's vorticity is set by planetary vorticity (recall that for this theory, the relative vorticity is far smaller in magnitude than planetary vorticity). Reading equation (32.39) from left to right reveals that any meridional motion itself must be balanced by vortex stretching/squashing plus stress curls. For example, in the absence of the frictional stress term, then poleward flow is balanced by stretching of a fluid column, whereas equatorial flow is balanced by squashing a column. We provide a detailed study the depth integrated form of the vorticity equation (32.39) in Section 45.4, where we see how the depth integrated meridional flow is affected by stretching impacted by boundary torques. To get an initial taste for that study, we consider the Sverdrup balance in Section 32.5.5.

32.5.5 Sverdrup balance

Depth integrating the vorticity balance (32.39) over the full depth of an ocean column leads to

$$\beta\, V = f\,[(w(\eta) - w(\eta_{\mathrm{b}})] + \hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_{\mathrm{b}})]/\rho_0, \tag{32.40}$$

where

$$V = \int_{\eta_{\mathrm{b}}}^{\eta} v \,\mathrm{d}z \tag{32.41}$$

is the depth integrated meridional velocity. For the large-scale we generally assume the surface vertical velocity is small, with $w(\eta) = 0$ when making the *rigid lid approximation*. Further assuming a flat bottom allows us to drop the vertical velocity at the ocean bottom, $w(\eta_{\mathrm{b}}) = 0$. Additionally, the surface turbulent stress is often far larger than the bottom turbulent stress. These assumptions then lead to the *Sverdrup balance*, which is a balance between the depth integrated meridional motion and the curl of the surface turbulent stress

$$\rho_0\, \beta\, V_{\mathrm{Sverdrup}} = \hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{\tau}(\eta) \qquad \text{Sverdrup balance.} \tag{32.42}$$

As further discussed in Section 41.9.4, the most problematic aspect of this balance concerns the assumption of vanishing $w(\eta_{\mathrm{b}})$, with $w(\eta_{\mathrm{b}})$ generally non-negligible in regions with sloping bottom boundaries and sizable bottom flows. Even so, this is a very good place to start when studying the connection between wind stress curls and meridional transport. We also discuss a variant of this balance, known as the *geostrophic Sverdrup balance*, in Section 45.5.

32.5.6 Features of thermal wind balanced flows

Horizontal components to the inviscid vorticity equation (equation (32.31) with $\boldsymbol{\tau}$ set to zero) form the thermal wind balance

$$f\, \partial \boldsymbol{u}/\partial z = -\nabla \times (\hat{\boldsymbol{z}}\, b) = \hat{\boldsymbol{z}} \times \nabla b, \tag{32.43}$$

which takes on the component form

$$f\, \partial u/\partial z = -\partial b/\partial y \quad \text{and} \quad f\, \partial v/\partial z = \partial b/\partial x. \tag{32.44}$$

As seen already in Section 32.4.4, these relations can also be derived directly by taking the vertical derivative of the horizontal momentum equation (32.25a) and then using the horizontal gradient of the hydrostatic balance (32.26). In either case, the thermal wind balance (32.43) says that the horizontal geostrophic velocity possesses a vertical shear where the buoyancy field has a horizontal gradient. Buoyancy with a horizontal gradient is termed *baroclinic* since it leads to a nonzero baroclinicity vector that provides a source for vorticity (discussed in Section 41.7.2). Correspondingly, it is only the baroclinic (depth dependent) piece of geostrophic velocity that is related to horizontal buoyancy gradients. The depth-independent flow is not constrained by horizontal buoyancy gradients.

Thermal wind, the atmospheric jet stream and the Antarctic Circumpolar Current

Due to the increased solar radiation reaching the equator relative to the poles, the zonal averaged temperature generally reduces when moving poleward. This poleward reduction in temperature corresponds to a poleward reduction in buoyancy. Also, for a stably stratified fluid, density increases with depth so that buoyancy decreases. Figure 32.6 illustrates this situation.

FIGURE 32.6: Schematic of the density and hydrostatic pressure fields and the associated thermal wind balanced flow in the northern hemisphere ($f > 0$) with north to the right and east out of the page. We show surfaces of constant density (solid lines) and constant pressure (isobars; dashed lines). Density increases poleward ($\partial\rho/\partial y > 0$) so that, according to the discussion surrounding Figure 32.4, the meridional pressure gradient decreases when moving upward, $\partial(\partial p/\partial y)/\partial z = -g\,\partial_y \rho < 0$. We illustrate isobars with an equatorward directed downgradient pressure force at lower elevations ($-\partial p/\partial y < 0$) and poleward directed pressure force at higher elevations ($-\partial p/\partial y > 0$). The zonal geostrophic wind is in geostrophic balance with these pressure gradients, with a westward zonal flow at lower elevations (easterly winds) and eastward flow at higher elevations (westerly winds). This flow configuration creates an eastward vertical shear of the zonal geostrophic winds, $\partial u_{\mathrm{g}}/\partial z > 0$.

A zonal average around a zonally symmetric globe, such as in the Antarctic Circumpolar Current, eliminates zonal derivatives and so renders the zonally averaged thermal wind relation

$$f\,\frac{\partial \overline{u}}{\partial z} = \frac{g}{\rho_0}\,\frac{\partial \overline{\rho}}{\partial y} = -\frac{\partial \overline{b}}{\partial y} > 0, \tag{32.45}$$

where $\overline{(\ )}$ is the zonal mean operator. In the northern hemisphere, $\partial_y \overline{b} < 0$, so that the zonal

averaged thermal wind shear is positive, $\partial_z \overline{u} > 0$. For example, a westerly zonal wind (blowing to the east) strengthens with height (easterly thermal wind shear). In the Southern Hemisphere, $f < 0$ with poleward decreasing buoyancy, $\partial_y \overline{b} > 0$, means there is also an eastward thermal wind shear. Note that movement towards the poles, where $|f|$ increases, leads to a smaller thermal wind shear given the same buoyancy gradient.

Diagnosing geostrophic velocity from the buoyancy field

Vertical integration of the thermal wind relation (32.43) between two constant depth surfaces leads to

$$\boldsymbol{u}(z) = \boldsymbol{u}(z_{\text{ref}}) - f^{-1} \nabla \times \hat{\boldsymbol{z}} \int_{z_{\text{ref}}}^{z} b \, \mathrm{d}z. \tag{32.46}$$

Hence, knowledge of the buoyancy field (e.g., through hydrographic measurements of temperature and salinity in the ocean), along with knowledge of the geostrophic velocity at a single depth, allows for determination of the full geostrophic velocity in terms of density. Unfortunately, specification of the unknown reference velocity is unavailable just from hydrographic measurements. This is the origin of the *depth of no motion* problem in oceanography.

32.5.7 Thermal wind balance for the atmosphere

The large-scale atmosphere is compressible and approximately in hydrostatic balance. The expression for geostrophic balance (32.24) in pressure coordinates is a suitable starting point to derive thermal wind for the atmosphere. For this purpose, we take the pressure derivative, $\partial/\partial p$, of (32.24) to render

$$f \frac{\partial \boldsymbol{u}}{\partial p} = \hat{\boldsymbol{z}} \times \nabla_p \left[\frac{\partial \Phi}{\partial p} \right], \tag{32.47}$$

with $\Phi = g\, z$ the geopotential. The hydrostatic relation $\partial p/\partial z = -\rho\, g$ takes the form

$$\frac{\partial p}{\partial \Phi} = -\rho \Rightarrow \frac{\partial \Phi}{\partial p} = -1/\rho \tag{32.48}$$

in which case

$$f \frac{\partial \boldsymbol{u}}{\partial p} = -\hat{\boldsymbol{z}} \times \nabla_p (1/\rho). \tag{32.49}$$

Ideal gas atmosphere

The specific volume takes the following form for an ideal gas atmosphere (see Section 24.4.1)

$$\rho^{-1} = R^{\mathrm{M}}\, T/p. \tag{32.50}$$

Since the horizontal derivative in the thermal wind relation (32.49) is along pressure surfaces, we have

$$f \frac{\partial \boldsymbol{u}}{\partial p} = -\frac{R^{\mathrm{M}}}{p} \left[\hat{\boldsymbol{z}} \times \nabla_p T \right]. \tag{32.51}$$

This expression gives rise to the name "thermal wind", with vertical shears of the horizontal velocity generated by horizontal temperature gradients along isobars.

As for the ocean in equation (32.46), we vertically integrate the thermal wind expression

(32.51), here between two pressure levels

$$\boldsymbol{u}(p_{\rm A}) - \boldsymbol{u}(p_{\rm B}) = f^{-1}\, R^{\rm M}\, \hat{\boldsymbol{z}} \times \nabla_p \left[\int_{p_{\rm A}}^{p_{\rm B}} \frac{T\, {\rm d}p}{p} \right], \tag{32.52}$$

where $p_{\rm A} < p_{\rm B}$, so that $p_{\rm A}$ is at a higher altitude than $p_{\rm B}$. We define the thermal wind shear as the difference between the wind aloft (higher altitude and lower pressure) from that at a lower altitude (greater pressure)

$$\boldsymbol{u}_T = \boldsymbol{u}(p_{\rm A}) - \boldsymbol{u}(p_{\rm B}) \qquad \text{with } p_{\rm A} < p_{\rm B} \tag{32.53}$$

so that

$$\boldsymbol{u}_T = \frac{R^{\rm M}}{f}\, \hat{\boldsymbol{z}} \times \nabla_p \overline{T}^{\ln {\rm p}}, \tag{32.54}$$

where we introduced the log-pressure weighted temperature between the two pressure surfaces

$$\overline{T}^{\ln {\rm p}} = \int_{p_{\rm A}}^{p_{\rm B}} \frac{T\, {\rm d}p}{p}. \tag{32.55}$$

The relation (32.54) means that on the f-plane, $R^{\rm M}/f$ times the log-pressure weighted temperature serves as a streamfunction for the thermal wind shear. Reconsider the previous example where the polar regions are colder than tropics, so that in the northern hemisphere on pressure surfaces, $\partial \overline{T}^{\ln {\rm p}}/\partial y < 0$. Hence, the zonal westerly winds increase in magnitude with height. We depict this situation in Figure 32.7. Furthermore, the thermal wind shear points to the east. For a more general flow in the northern hemisphere, cold air sits on the left side of the thermal wind shear and warm air on the right. The opposite orientation holds for the southern hemisphere where the Coriolis parameter is negative, $f < 0$

FIGURE 32.7: Thermal wind shear in the northern hemisphere ($f > 0$) middle latitude atmosphere, whereby cold/dense air sits to the north and warm/light air to the south. The zonal geostrophic winds increase to the east when rising in elevation, $\partial u_{\rm g}/\partial z > 0$. We say that the zonal winds have an eastward thermal wind shear. In general, a geostrophic wind in the northern hemisphere atmosphere has cold/dense air to the left when facing downwind, whereas the opposite orientation holds for the southern hemisphere where $f < 0$.

Barotropic flow

Return to the thermal wind equation (32.49)

$$f\, \frac{\partial \boldsymbol{u}}{\partial p} = -\hat{\boldsymbol{z}} \times \nabla_p (1/\rho) = \frac{\hat{\boldsymbol{z}} \times \nabla_p \rho}{\rho^2}. \tag{32.56}$$

For the special case of density a function just of the pressure, $\rho = \rho(p)$, then $\nabla_p \rho = 0$. This situation defines a *barotropic* flow, which is characterized here by a horizontal geostrophic velocity with zero vertical variations. Note that we are here only concerned with the geostrophic flow. A density related to pressure through $\rho = \rho(p)$ can still support vertical variations of the ageostrophic flow.

We further discuss barotropic flow in Section 41.2 as part of our study of vorticity. As detailed in that discussion, the general definition of a barotropic flow is one whereby the *baroclinicity* vector vanishes, $\boldsymbol{B} = \nabla p \times \nabla(1/\rho) = 0$. The functional relation $\rho = \rho(p)$ (equivalently $p = p(\rho)$) is a sufficient condition for vanishing baroclinicity. As seen in Section 41.4, for a barotropic flow there is no generation of vorticity through the torques created when density isosurfaces deviate from pressure isosurfaces (isobars).

32.5.8 Thermal wind balance for the ocean

We here expose a few details for how to work with thermal wind in the ocean. To start, consider the most general form of thermal wind according to equation (32.21)

$$f\,\frac{\partial(\rho\,\boldsymbol{u}_{\mathrm{g}})}{\partial z} = -g\,\hat{\boldsymbol{z}} \times \nabla\rho. \tag{32.57}$$

Treatment of the *in situ* density depends on whether we consider a Boussinesq ocean, as done for most of this section, versus a non-Boussinesq ocean.

Thermal wind for a Boussinesq ocean

For a Boussinesq ocean, the *in situ* density on the left hand side of equation (32.57) is set to the constant reference density, ρ_0, in which case the thermal wind relation is given by

$$f\,\rho_0\,\frac{\partial \boldsymbol{u}_{\mathrm{g}}}{\partial z} = -g\,\hat{\boldsymbol{z}} \times \nabla\rho. \tag{32.58}$$

Following from the discussion of Boussinesq energetics in Section 30.8.4, we know that the *in situ* density in a Boussinesq ocean takes the functional form of equation (30.200)

$$\rho = \rho[S(\boldsymbol{x},t), \Theta(\boldsymbol{x},t), p = -\rho_0\,\Phi(\boldsymbol{x},t)]. \tag{32.59}$$

For geostrophic flows we are generally only concerned with the simple geopotential, $\Phi(\boldsymbol{x},t) = g\,z$, which defines the local vertical direction, $\hat{\boldsymbol{z}}$. Hence, $\hat{\boldsymbol{z}} \times \nabla\rho$ picks out horizontal derivatives of the *in situ* density along surfaces of constant geopotential

$$g\,\hat{\boldsymbol{z}} \times \nabla\rho = g\,\hat{\boldsymbol{z}} \times \nabla_z\rho. \tag{32.60}$$

We can thus express the horizontal *in situ* density gradient as

$$\nabla_z\rho = \left[\frac{\partial\rho}{\partial S}\right]_{\Theta,\Phi} \nabla_z S + \left[\frac{\partial\rho}{\partial\Theta}\right]_{S,\Phi} \nabla_z\Theta = \rho_0\,(\beta\,\nabla_z S - \alpha\,\nabla_z\Theta), \tag{32.61}$$

where we introduced the Boussinesq form of the haline contraction and thermal expansion coefficients

$$\beta = \frac{1}{\rho_0}\left[\frac{\partial\rho}{\partial S}\right]_{\Theta,\Phi} \qquad \text{and} \qquad \alpha = -\frac{1}{\rho_0}\left[\frac{\partial\rho}{\partial\Theta}\right]_{S,\Phi}. \tag{32.62}$$

These results lead to the oceanic Boussinesq form of the thermal wind relation

$$f\,\frac{\partial \boldsymbol{u}_{\rm g}}{\partial z} = -g\,\hat{\boldsymbol{z}} \times (\beta\,\nabla_z S - \alpha\,\nabla_z \Theta), \tag{32.63}$$

which decomposes the thermal wind shear into a contribution from horizontal gradients in S and from Θ. In some treatments, the right hand side contribution is referred to as the horizontal gradient of the locally referenced potential density (see Section 31.5.5). Correspondingly, one generally finds that vertical sections of the potential density (referenced to a pressure near to that where computing thermal wind) provide a useful means to determine the magnitude and direction of the thermal wind shears; more useful than sections of *in situ* density.

Thermal wind for a non-Boussinesq hydrostatic ocean

Formulation of the thermal wind equation for a non-Boussinesq ocean follows quite closely to a Boussinesq, only now we start from the expression (32.49) for a compressible hydrostatic fluid using pressure as a vertical coordinate

$$\rho^2\,f\,\frac{\partial \boldsymbol{u}}{\partial p} = \hat{\boldsymbol{z}} \times \nabla_p \rho. \tag{32.64}$$

For a non-Boussinesq ocean, we make use of the pressure dependence of the density so that

$$\rho = \rho[S(\boldsymbol{x},t), \Theta(\boldsymbol{x},t), p(\boldsymbol{x},t)]. \tag{32.65}$$

The gradient operator is here computed along surfaces of constant pressure so that

$$\nabla_p \rho = \left[\frac{\partial \rho}{\partial S}\right]_{\Theta,p} \nabla_p S + \left[\frac{\partial \rho}{\partial \Theta}\right]_{S,p} \nabla_p \Theta = \rho\,(\beta\,\nabla_p S - \alpha\,\nabla_p \Theta), \tag{32.66}$$

where we introduced the non-Boussinesq form of the haline contraction and thermal expansion coefficients

$$\beta = \frac{1}{\rho}\left[\frac{\partial \rho}{\partial S}\right]_{\Theta,p} \qquad \text{and} \qquad \alpha = -\frac{1}{\rho}\left[\frac{\partial \rho}{\partial \Theta}\right]_{S,p}. \tag{32.67}$$

In this manner we can write the thermal wind relation (32.64) as

$$\rho\,f\,\frac{\partial \boldsymbol{u}}{\partial p} = \hat{\boldsymbol{z}} \times (\beta\,\nabla_p S - \alpha\,\nabla_p \Theta). \tag{32.68}$$

This expression is directly analogous to the Boussinesq form given by equation (32.63). Indeed, we can go one step further by using the chain rule and the hydrostatic relation to write

$$\frac{\partial \boldsymbol{u}}{\partial p} = \frac{\partial \boldsymbol{u}}{\partial z}\,\frac{\partial z}{\partial p} = -(\rho\,g)^{-1}\,\frac{\partial \boldsymbol{u}}{\partial z}, \tag{32.69}$$

in which case the non-Boussinesq thermal wind takes on the form

$$f\,\frac{\partial \boldsymbol{u}}{\partial z} = -g\,\hat{\boldsymbol{z}} \times (\beta\,\nabla_p S - \alpha\,\nabla_p \Theta). \tag{32.70}$$

Now, the key distinction from the Boussinesq form (32.63) is the appearance of a constant pressure derivative, ∇_p, for the non-Boussinesq case, in contrast to the constant geopotential derivative, ∇_z, appearing in the Boussinesq case. Additionally, the non-Boussinesq case uses the slightly

distinct form of α and β given by equation (32.67) rather than the Boussinesq form in equation (32.62).

32.5.9 Further study

Much of the material in this section forms the basis for laminar theories of the large-scale ocean circulation. We further pursue these theories in Chapter 45 where we take a deeper dive into the study of planetary geostrophy. Further discussion of phenomenology is given in Chapter 7 of *Marshall and Plumb* (2008), and with Chapters 19-22 of *Vallis* (2017) as well as *Samelson* (2011) presenting ocean circulation theory making use of fundamental concepts from geophysical fluid dynamics. A compelling discussion of the cascade of energy from the baroclinic modes to barotropic mode is offered by *Smith and Vallis* (2001). *Gill* (1982) provides a discussion of the depth of no motion problem in dynamic oceanography.

Rotating tank laboratory experiments offer a powerful means to explore the variety of rotating fluid mechanics relevant to the atmosphere and oceans. The following resources exemplify the Taylor-Proudman effect (32.35) and the associated vertical stiffening of rotating fluids.

- One means to test Taylor-Proudman is to insert a dye into a rapidly rotating tank of unstratified water. After a few rotation periods the dye forms vertical sheets known as *Taylor curtains* whose center is along the rotation axis. The fluid is said to have a *vertical stiffness* due to the effects of rotation. Vertical stiffening in turn means that flow over a small obstacle is deflected throughout the column rather than just near the bump. This situation is depicted in Figure 32.5 and more vividly illustrated in this video from the UCLA SpinLab.

- Near the 20 minute mark of this video, also from UCLA, we see how vortices in a rotating fluid maintain their coherency much more than in a non-rotating fluid.

- Another laboratory test shown in this video from Prof. Fultz shows that a buoyant object (a ping pong ball) placed into a rotating tank rises much slower than in a non-rotating tank. The reason for the slower rise is that the ball must push up against the vertically stiffened fluid column when rotating, thus slowing its rise relative to when in a non-rotating fluid. Later in the same video, near the 16 minute mark, we see Taylor curtains in rotating fluids.

32.6 Isopycnal form stress from geostrophic eddies

As introduced in Section 29.1, form stress is the horizontal stress arising from pressure acting on a sloped surface. The mathematical expression for the form stress acting on the top side of a surface is given by equation (29.6)

$$\mathbf{\Sigma}^{\text{form}} = p\,\nabla\eta, \tag{32.71}$$

with the opposite sign for the form stress on the bottom side of the surface. Here, $z = \eta(x, y, t)$ is the depth of the surface (see Figure 29.3 or Figure 32.8). The net horizontal force from form stress is the area integral over the surface.

In this section we examine the zonal mean zonal form stress acting on an isopycnal surface (Section 32.6.1) and on an isopycnal layer (Section 32.6.2), each for an adiabatic, Boussinesq, hydrostatic fluid in geostrophic balance and within a zonally periodic channel of length L. As we show, the zonal mean zonal form stress arising from geostrophically balanced fluctuations provide an eastward acceleration to the fluid. At the same time, these *geostrophic eddies* transport buoyancy and thickness/volume meridionally. Although the channel geometry is rather simple,

it has applications to the middle latitude atmospheric circulation as well as for ocean circulation, particularly in the Southern Ocean where there is circumpolar channel-like flow within the Antarctic Circumpolar Current. Furthermore, the discussion exposes key elements of eddy-mean flow interactions, sharing points with the leading order generalized Lagrangian mean of Section 65.3 and the quasi-Stokes transport discussed in Section 66.3.

FIGURE 32.8: Schematic of the zonal form stress, Σ_x^{form}, acting on a surface whose zonal mean vertical position is $z = \overline{\eta}(y,t)$ and whose vertical position relative to the zonal mean is $z = \overline{\eta}(y,t) + \eta'(x,y,t)$.

32.6.1 Zonal mean zonal form stress on an isopycnal surface

We are here interested in the form stress acting on an isopycnal surface. Before specializing to an isopycnal, we decompose the form stress according to the zonal mean depth and its deviation from zonal mean (see Figure 32.8). Thereafter, specialization to an isopycnal surface in an adiabatic fluid connects the zonal mean form stress to the meridional eddy flux of buoyancy.

Zonal form stress on an arbitrary surface in a channel

The zonal mean vertical position of the surface is written

$$\overline{\eta}(y,t) = \frac{1}{L}\int_0^L \eta(x,y,t)\,\mathrm{d}x \tag{32.72}$$

and its corresponding zonal fluctuation is

$$\eta' = \eta - \overline{\eta}. \tag{32.73}$$

The zonal component of the form stress is thus given by

$$p\,\partial_x\eta = p(x,\overline{\eta}+\eta')\,\partial_x(\overline{\eta}+\eta') \tag{32.74a}$$
$$= p(x,\overline{\eta}+\eta')\,\partial_x\eta' \tag{32.74b}$$
$$\approx [p(x,\overline{\eta}) + \partial_z p(x,\overline{\eta})\,\eta']\,\partial_x\eta' \tag{32.74c}$$
$$= p(x,\overline{\eta})\,\partial_x\eta' + \mathcal{O}(\eta')^2. \tag{32.74d}$$

Hence, to second order in fluctuations, η', the zonal form stress acting on the surface equals to $p(x,\overline{\eta})\,\partial_x\eta'$, where it is important to note that pressure is evaluated at the zonal mean depth, $z = \overline{\eta}$.

To within the same accuracy, the zonal integral of the zonal form stress is given by

$$\int_0^L \Sigma_x^{\text{form}}\,\mathrm{d}x \approx \int_0^L p(\overline{\eta})\,(\partial\eta'/\partial x)\,\mathrm{d}x = -\int_0^L \eta'\,[\partial p(\overline{\eta})/\partial x]\,\mathrm{d}x, \tag{32.75}$$

where the final equality follows from zonal periodicity. Now assume the zonal pressure gradient

at $\overline{\eta}$ is balanced by a meridional geostrophic velocity

$$\partial p(\overline{\eta})/\partial x = f\rho_0\, v(\overline{\eta}), \tag{32.76}$$

where

$$v(\overline{\eta}) = \overline{v}(\overline{\eta}) + v'(\overline{\eta}) \tag{32.77}$$

so that

$$\int_0^L \Sigma_x^{\text{form}}\, \mathrm{d}x = -\rho_0\, f \int_0^L \eta'\, v'\, \mathrm{d}x, \tag{32.78}$$

where we noted that the Coriolis parameter is independent of zonal position. Hence, there is a nonzero zonal mean zonal form stress when there is a nonzero zonal correlation between fluctuations in the meridional velocity and the depth of the surface

$$\overline{\Sigma}_x^{\text{form}} = -\rho_0\, f\, \overline{v'\,\eta'}. \tag{32.79}$$

Zonal mean zonal form stress acting on an isopycnal surface

To further unpack the correlation appearing in equation (32.79), specialize to the case of an isopycnal surface in an adiabatic fluid. As shown in our discussion of generalized Lagrangian mean averaging in Sections 65.3.6 and 65.5.7, vertical fluctuations in the position of the isopycnal surfaces, relative to the zonal mean $\overline{\eta}$, are related to zonal fluctuations in the density

$$\eta' \approx -\frac{\rho'}{\partial\overline{\rho}/\partial z} = -\frac{b'}{N^2}, \tag{32.80}$$

where we introduced the squared buoyancy frequency of the zonal mean state as well as the fluctuating buoyancy

$$N^2 = -\frac{g}{\rho_0}\frac{\partial\overline{\rho}}{\partial z} \qquad \text{and} \qquad b' = -\frac{g\,\rho'}{\rho_0}. \tag{32.81}$$

The zonally averaged zonal form stress thus takes the form

$$\overline{\Sigma}_x^{\text{form}} = \frac{\rho_0\, f}{N^2}\, \overline{v'\, b'}. \tag{32.82}$$

Again, the assumptions rendering the result (32.82) are (i) zonal periodicity, (ii) adiabatic and Boussinesq fluid, (iii) geostrophically balanced flow. Under these assumptions, the zonal mean zonal form stress acting on an isopycnal surface is proportional to the zonal correlation between fluctuations in the meridional velocity and the buoyancy. It is a general property of unstable *quasi-geostrophic eddies* in the atmosphere and ocean to transport positive buoyancy (e.g., warm air/water) poleward and negative buoyancy (e.g., cold air/water) equatorward, thus ameliorating the equator-to-pole buoyancy difference setup by solar radiation that preferentially warms the tropics. More generally, as shown in Section 58.9, unstable quasi-geostrophic disturbances, such as those associated with *baroclinic instability*, transport buoyancy down the horizontal buoyancy gradient. Evidently, with buoyancy decreasing poleward, such disturbances transport buoyancy poleward. In turn, this property of geostrophic eddies leads to a positive zonal mean zonal form stress

$$\overline{\Sigma}_x^{\text{form}} > 0. \tag{32.83}$$

Hence, in addition to transporting buoyancy poleward, geostrophic eddies provide a positive zonal mean force through zonal integrated form stress that accelerates the fluid in the eastward direction. These two properties of geostrophic eddies (poleward flux of positive buoyancy anomalies along

with an eastward acceleration from form stress) are fundamental to the middle latitude atmospheric circulation as well as for ocean circulation, particularly within the channel-like Antarctic Circumpolar Current.

32.6.2 Zonal mean zonal form stress acting on an isopycnal layer

We offer yet another means to understand the zonal mean zonal form stress by here examining the form stress acting on a constant density layer of adiabatic Boussinesq fluid such as shown in Figure 32.9. This layered/isopycnal analysis anticipates some of the development considered for the stacked shallow water model in Chapters 36 and 37 as well as for isopycnal models in Section 62.2.

The net form stress acting on the upper and lower layer interfaces in Figure 32.9 is given by

$$\begin{aligned}
\mathbf{\Sigma}^{\text{layer form}} &= p_1 \nabla \eta_1 - p_2 \nabla \eta_2 && (32.84a)\\
&= p(\eta + h/2)\, \nabla(\eta + h/2) - p(\eta - h/2)\, \nabla(\eta - h/2) && (32.84b)\\
&\approx [p(\eta) - \rho\, g\, h/2]\, \nabla(\eta + h/2) - [p(\eta) + \rho\, g\, h/2]\, \nabla(\eta - h/2) && (32.84c)\\
&= p\, \nabla h - \rho\, g\, h\, \nabla \eta && (32.84d)\\
&= \nabla(p\, h) - h\, \nabla(p + \rho\, g\, \eta) && (32.84e)\\
&= \nabla(p\, h) - \rho_0\, h\, \nabla M. && (32.84f)
\end{aligned}$$

In this relation we set $z = \eta$ for the vertical position at the center of the layer, introduced the Montgomery potential from Section 62.2.1

$$M \rho_0 = p + \rho\, g\, \eta, \tag{32.85}$$

and noted that ρ is a uniform constant layer density so that it commutes with the horizontal gradient operator computed along ρ surfaces. We also made use of the hydrostatic balance to approximate the interface pressures as

$$\begin{aligned}
p(\eta + h/2) &\approx p(\eta) + \frac{\partial p}{\partial z}\, \frac{h}{2} = p(\eta) - \rho\, g\, h/2 && (32.86a)\\
p(\eta - h/2) &\approx p(\eta) - \frac{\partial p}{\partial z}\, \frac{h}{2} = p(\eta) + \rho\, g\, h/2. && (32.86b)
\end{aligned}$$

The zonal mean of the zonal layer form stress is thus given by the correlation between the layer thickness fluctuations and fluctuations in the zonal derivative of the Montgomery potential

$$\overline{\Sigma}_x^{\text{layer form}} = -\rho_0\, \overline{h'\, \partial M'/\partial x}, \tag{32.87}$$

where we set $\overline{\partial M/\partial x} = 0$ due to zonal periodicity. As seen in Section 62.2.1, the Montgomery potential is the geostrophic streamfunction in isopycnal coordinates, so that the fluctuating meridional geostrophic velocity is given by

$$f\, v' = \partial_x M'. \tag{32.88}$$

Consequently, the zonal mean zonal form stress acting on the layer equals to the correlation between the thickness fluctuations and fluctuations in the meridional geostrophic velocity

$$\overline{\Sigma}_x^{\text{layer form}} = -\rho_0\, f\, \overline{v'\, h'}. \tag{32.89}$$

Hence, as the geostrophic eddies provide a net eastward acceleration to the layer (equation (32.83)), they also move volume meridionally within isopycnal layers, moving positive thickness

fluctuations equatorward.

FIGURE 32.9: Schematic of a constant density layer of an adiabatic, hydrostatic, Boussinesq fluid with thickness $h(x, y, t) = \eta_1(x, y, t) - \eta_2(x, y, t) = (\eta + h/2) - (\eta - h/2)$, and uniform density $\rho =$ constant. East points to the right and north is oriented into the page. The zonal form stress, Σ_x^{form}, acting on the upper and lower interfaces at a horizontal position (x, y) are shown by the thick horizontal vectors. The zonal form stress is the horizontal component of the pressure force per area acting on the layer interfaces, with the sign of the form stress determined by the slope of the layer interface. For a zonally periodic fluid layer, the net zonal pressure force acting on the layer arises from the zonal form stress integrated over the layer interfaces.

To further understand the physics of the form stress in equation (32.89), parameterize the velocity-thickness eddy correlation, $\overline{v'\,h'}$, by downgradient diffusion of thickness

$$\overline{v'\,h'} = -\kappa\,\partial_y \overline{h}, \tag{32.90}$$

where $\kappa > 0$ is a nonzero kinematic diffusivity (dimensions of squared length per time). This parameterization is suggested by the work of *Gent and McWilliams* (1990) as discussed in Section 66.3.6. As noted there, thickness diffusion as a parameterization reflects the general tendency of geostrophic eddies to reduce horizontal gradients in layer thickness as they reduce the available potential energy of the flow. In this case the zonal mean zonal form stress is

$$\overline{\Sigma}_x^{\text{layer form}} = \rho_0\, f\, \kappa\, \partial_y \overline{h}. \tag{32.91}$$

So in the northern hemisphere in regions where the zonal mean layer thickness increases to the north, $\partial_y \overline{h} > 0$, there is a corresponding eastward zonal mean zonal form stress arising from parameterized geostrophic eddies acting on layer thickness. This situation corresponds to the case in Section 32.6.1, where we saw that geostrophic eddies preferentially transport positive buoyancy anomalies poleward and negative buoyancy anomalies equatorward. In the present analysis, meridional changes to the layer thickness correspond to a nonzero thermal wind shear. If layer thickness increases poleward, as for the case of weaker vertical stratification in the high latitudes, then the zonal velocity has a positive vertical shear, thus contributing an eastward zonal mean form stress.

32.6.3 Comments and further study

A key feature of geostrophic eddies exposed by this discussion concerns the connection between zonal form stress (providing an eastward force on the zonally periodic channel flow) and meridional eddy transport of buoyancy (positive buoyancy anomalies are transported poleward) and thickness (positive thickness anomalies are transported equatorward). The periodic channel domain is highly idealized. Nonetheless, the basic ideas form the roots for much of how we think about geostrophic eddies in the middle latitude atmosphere and the Southern Ocean. Further generalizations lead to the generalized Lagrangian mean, whose kinematic rudiments are discussed in Section 65.3, as well as the thickness weighted average, discussed in Chapter 63.

The fundamental role of form stress in geostrophic turbulent flows is pedagogically treated by *Vallis* (2017). See, in particular, his Chapter 21 for a thorough and insightful discussion of circulation in the Southern Ocean. We also return to form stress within the shallow water fluid in Section 37.4. That discussion complements the presentation given here, with a focus on a layer of shallow water fluid. We also touch on the notions of form stress when discussing the *Gent and McWilliams* (1990) mesoscale eddy parameterization in Section 66.3.

32.7 Exercises

EXERCISE 32.1: SMALL ROSSBY NUMBER AT HUMAN SCALES
Consider motion of a car at a speed $U \sim 10^5$ m hour^{-1} and a length scale of $L \sim 10$ m. Furthermore, assume the car is moving at 30°N latitude so that $f_{\text{human}} = 2\,\Omega_{\text{human}} \sin\phi = \Omega_{\text{human}}$.

(a) What is the rotation rate of the planet and corresponding rotation period, $T_{\text{human}} = 2\pi/\Omega_{\text{human}}$, required to render a unit Rossby number (Ro = 1) for the given "human" sized scales? Give resulting rotation rate in units of inverse seconds and period in seconds.

(b) If the earth rotated at the angular speed Ω_{human}, what would be the rigid-body speed for a point at rest on the earth's surface at the equator? Give result in units of meter per second.

(c) How does the rigid-body speed compare to the speed of sound at standard atmospheric conditions? What about the root-mean-square speed for air molecules? Hint: read Section 17.3.4.

(d) Discuss an astronomical object that has a very large rotational speed. Hint: 1993 Nobel Prize in physics.

EXERCISE 32.2: THE BETA SPIRAL
Consider a steady state Boussinesq planetary geostrophic fluid in the absence of mixing. Write the geostrophic velocity as

$$u = |\boldsymbol{u}| \cos\Delta \qquad v = |\boldsymbol{u}| \sin\Delta, \tag{32.92}$$

where Δ is the angle measured counter-clockwise from east. Use thermal wind and the steady state perfect fluid buoyancy equation to determine an expression for $\partial\Delta/\partial z$. Show that for $f > 0$ (northern hemisphere) and $\partial b/\partial z = N^2 > 0$ (gravitationally stable fluid column; see Section 31.5), then $\partial\Delta/\partial z$ has opposite sign from the vertical velocity, w. This spiralling of the geostrophic velocity is known as the *beta spiral* in oceanography.

EXERCISE 32.3: ALTERNATIVE FORM OF THERMAL WIND
Consider a fluid with density a function of pressure and potential temperature

$$\rho = \rho(\theta, p). \tag{32.93}$$

A physical realization of this equation of state is a lake. Show that the thermal wind shear for a hydrostatic and *compressible* fluid with this equation of state can be written in the form

$$\frac{\partial \boldsymbol{u}}{\partial z} = \left[\frac{N^2}{f\,\rho\,g}\right] (\hat{\boldsymbol{z}} \times \nabla_\theta p), \tag{32.94}$$

where

$$N^2 = -\frac{g}{\rho}\frac{\partial\rho}{\partial\theta}\frac{\partial\theta}{\partial z} = g\,\alpha_\theta\,\frac{\partial\theta}{\partial z} > 0 \tag{32.95}$$

is the squared buoyancy frequency, assumed positive so that the fluid is gravitationally stable in the vertical (see Section 31.5.4). The term α_θ is the thermal expansion coefficient written in terms of potential temperature (Section 31.3.4),

$$\alpha_\theta = -(1/\rho)\,\partial\rho/\partial\theta > 0. \tag{32.96}$$

Finally, the horizontal gradient projected onto constant θ surfaces is given by (see Section 59.12.2)

$$\nabla_\theta = \hat{\boldsymbol{x}}\left[\frac{\partial}{\partial x}\right]_{y,\theta} + \hat{\boldsymbol{y}}\left[\frac{\partial}{\partial y}\right]_{x,\theta} \tag{32.97a}$$

$$= \nabla_z - \left[\frac{\nabla_z\theta}{\partial\theta/\partial z}\right]\frac{\partial}{\partial z}. \tag{32.97b}$$

Hint: This exercise requires careful use of the chain rule and the hydrostatic relation, along with the equations given in the problem statement. Furthermore, assume the fluid is fully compressible.

Hint: Some may wish to "warm-up" by showing that the result holds for the simpler equation of state $\rho = \rho(\theta)$. Some of the steps used for the simpler case are relevant for the case with $\rho = \rho(\theta, p)$.

Chapter 33

Tangent plane flow balances

We here consider a variety of inviscid tangent plane (horizontal) flow regimes characterized by a balance between a subset of terms appearing in the horizontal momentum equation. This discussion allows us to directly compare the geostrophically balanced flow of Chapter 32 to a variety of other balanced flows such as gradient wind, inertial motion, and cyclostrophic balance. We provide a categorization of the flow following *natural coordinates* or *intrinsic coordinates*, which offer a concise means to compare the relative magnitudes of the Coriolis, pressure, and centrifugal accelerations acting on a fluid element moving horizontally.[1]

READER'S GUIDE TO THIS CHAPTER

We make use of the hydrostatic primitive equations from Section 28.1, along with the Boussinesq aporoximation from Section 30.1. We also assume an understanding of the geostrophic balance from Chapter 32, and use of some geometric notions discussed in Chapter 7, though most of the salient math points are revisited here so that Chapter 7 is an option rather than a requirement. Throughout this chapter we assume a tangent plane geometry and associated equations from Section 25.5, thus allowing for Cartesian coordinates. Also, we ignore all vertical motion. Some of this material is used in subsequent chapters, in particular Chapter 34 on Ekman dynamics as well as Chapters 44 and 46 on quasi-geostrophy.

[1] It is important to recall from Section 13.10.4 that motion on a geopotential incorporates the acceleration from both the central gravitational field and the planetary centrifugal acceleration. This property holds for the tangent plane approximation assumed in this chapter, whereby a geopotential is assumed to be horizontal. Consequently, planetary centrifugal acceleration is absorbed by the geopotential and so it does not appear here.

33.1 Loose ends

- How to determine whether the velocity field is divergent or non-divergent for the cyclostrophic and gradient wind motions?
- Exercises needed for this chapter.

33.2 Horizontal flow described by natural coordinates

In this section we decompose the horizontal Boussinesq momentum equation into motion parallel to and motion perpendicular to the instantaneous trajectory of a fluid element moving along a constant geopoential surface. That is, we characterize the velocity and acceleration according to the local flow direction. Furthermore, we are only concerned with motion on a constant geopotetial using the tangent plane approximation; i.e., horizontal motion.[2] The *natural coordinates* arising from this description exposes the centripetal/centrifugal acceleration that arises from curvature in the trajectory as measured by the radius of curvature. This non-inertial acceleration is distinct from the centrifugal acceleration that arises from planetary rotation, with planetary centrifugal acceleration already contained within the effective gravitational acceleration that acts in the local vertical direction (see Section 13.8.1). We also decompose the accelerations from pressure, friction, and Coriolis into their natural coordinate components.

33.2.1 Natural coordinates

Natural coordinates for horizontal motion are defined by a locally orthogonal set of unit vectors (see Figure 33.1)

$$\hat{\boldsymbol{z}} = \hat{\boldsymbol{u}} \times \hat{\boldsymbol{n}} = \text{vertical direction} \tag{33.1a}$$

$$\hat{\boldsymbol{u}} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}} = \text{tangent to horizontal velocity} \tag{33.1b}$$

$$\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{u}} = \text{normal direction to the left of motion.} \tag{33.1c}$$

The unit vector, $\hat{\boldsymbol{u}}$, is tangent to the velocity vector (which is horizontal), so that

$$\boldsymbol{u} = |\boldsymbol{u}|\,\hat{\boldsymbol{u}} = \frac{\mathrm{D}s}{\mathrm{D}t}\,\hat{\boldsymbol{u}}, \tag{33.2}$$

[2] The two-dimensional motion considered here can be generalized to three-dimensional motion through use of the *Frenet equations* from differential geometry. An introduction to this approach for fluid motion is provided by Section 20 of *Serrin* (1959).

FIGURE 33.1: Illustrating the decomposition of horizontal motion of a fluid element into natural coordinate directions. These directions are defined by a unit tangent vector, $\hat{\boldsymbol{u}}$, pointing in the direction of the fluid element motion, and a unit normal vector, $\hat{\boldsymbol{n}}$, pointing to the left of the motion facing downstream.

where s is the arc-length measured along the trajectory as introduced in Section 2.4. The unit vector, $\hat{\boldsymbol{n}}$, is perpendicular to the velocity and points to the left of the trajectory facing downstream.

33.2.2 Material acceleration

When writing the velocity according to equation (33.2), we decompose the acceleration into the change in speed and change in direction

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t}\,\hat{\boldsymbol{u}} + |\boldsymbol{u}|\,\frac{\mathrm{D}\hat{\boldsymbol{u}}}{\mathrm{D}t}. \tag{33.3}$$

Following our discussion of rigid-body rotational motion in Section 11.2 (see Figure 11.2), the magnitude of the direction change can be written in terms of the infinitesimal angle swept out by the motion as the fluid element moves along a trajectory

$$|\delta\hat{\boldsymbol{u}}| = |\delta\vartheta|. \tag{33.4}$$

The infinitesimal angle swept out by the trajectory is related to the radius of curvature, R (Figure 33.2), and the arc-length increment, δs, traversed by the trajectory

$$\delta\vartheta = \frac{\delta s}{R}. \tag{33.5}$$

Finally, the infinitesimal change in tangent, $\delta\hat{\boldsymbol{u}}$, is directed normal to the motion, which we see by noting

$$\hat{\boldsymbol{u}}\cdot\hat{\boldsymbol{u}} = 1 \Longrightarrow \delta\hat{\boldsymbol{u}}\cdot\hat{\boldsymbol{u}} = 0. \tag{33.6}$$

That is, $\delta\hat{\boldsymbol{u}}$ is orthogonal to $\hat{\boldsymbol{u}}$, so that it points either parallel or anti-parallel to $\hat{\boldsymbol{n}}$. We detailed this property of rotating unit vectors in Section 2.1.4 (see Figure 2.2). Our convention is that $\hat{\boldsymbol{n}}$ points to the left of $\hat{\boldsymbol{u}}$, so that if the trajectory turns to the left, then $\delta\hat{\boldsymbol{u}}$ points parallel to $\hat{\boldsymbol{n}}$, whereas if the trajectory turns to the right then $\delta\hat{\boldsymbol{u}}$ points anti-parallel to $\hat{\boldsymbol{n}}$. That is, $\delta\hat{\boldsymbol{u}}$ always points towards the center of the circle used to compute the radius of curvature as in Figure 33.2.

Bringing these results together leads to the expression for the infinitesimal unit vector change

$$\delta\hat{\boldsymbol{u}} = \hat{\boldsymbol{n}}\,\frac{\delta s}{R}. \tag{33.7}$$

Our sign convention takes $R > 0$ for a fluid element turning in the direction of $\hat{\boldsymbol{n}}$ (to the left facing downstream) and $R < 0$ when turning opposite to $\hat{\boldsymbol{n}}$ (to the right facing downstream). Hence,

FIGURE 33.2: Illustrating the radius of curvature associated with turning motion of a fluid element. The radius of curvature equals to the radius of a tangent circle (the *curvature circle*) that approximates, to second order accuracy, the trajectory at a particular point. The radius is smaller in magnitude when the trajectory is highly curved, and $|R| = \infty$ when the trajectory is straight. The radius is positive when the trajectory turns into the normal direction as depicted here (to the left; concave as defined by $\hat{\boldsymbol{n}}$) and negative when turning in the opposite direction (to the right; convex as defined by $\hat{\boldsymbol{n}}$). See Section 7.2 for more details on curvature, with Figure 7.4 offering more details for how to determine the radius of curvature.

the material time change is

$$\frac{\mathrm{D}\hat{\boldsymbol{u}}}{\mathrm{D}t} = \frac{\mathrm{D}\hat{\boldsymbol{u}}}{\mathrm{D}s}\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\hat{\boldsymbol{n}}}{R}\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\hat{\boldsymbol{n}}}{R}\,|\boldsymbol{u}|, \tag{33.8}$$

where the speed is given by the time change of the arc-length along the trajectory

$$|\boldsymbol{u}| = \frac{\mathrm{D}s}{\mathrm{D}t}. \tag{33.9}$$

Combining these results renders the acceleration

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t}\,\hat{\boldsymbol{u}} + \frac{|\boldsymbol{u}|^2}{R}\,\hat{\boldsymbol{n}} = \frac{\mathrm{D}^2 s}{\mathrm{D}t^2}\,\hat{\boldsymbol{u}} + \frac{|\boldsymbol{u}|^2}{R}\,\hat{\boldsymbol{n}}. \tag{33.10}$$

The acceleration has thus been decomposed into the change in speed of the fluid element along the direction of the motion, plus the centripetal acceleration due to curvature of the trajectory. In Section 33.2.3 we justify referring to $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$ as the *centripetal* acceleration.

33.2.3 Centripetal and centrifugal accelerations

The centripetal acceleration points towards the concave side of a turning trajectory: "centripetal" means "towards the center." Its opposing partner, the centrifugal ("away from center") acceleration points to the convex side (see Figure 33.3). So how do we interpret $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$? For motion turning to the left, towards $\hat{\boldsymbol{n}}$, the radius of curvature is positive, $R > 0$, so that $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$ points to the concave side of the trajectory (left side). For a trajectory turning to the right then $R < 0$, which again means that $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$ points to the concave side (now on the right). We conclude that the acceleration $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$ indeed represents a centripetal acceleration and $-\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$ is the centrifugal acceleration.

33.2.4 Coriolis and pressure gradient

The Coriolis acceleration takes the following form in natural coordinates

$$-f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -(\hat{\boldsymbol{z}} \times \hat{\boldsymbol{u}})\,f\,|\boldsymbol{u}| = -\hat{\boldsymbol{n}}\,f\,|\boldsymbol{u}|, \tag{33.11}$$

FIGURE 33.3: Centripetal acceleration of a turning fluid element, $\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$, points to the concave side of the curve (towards the center) whereas the centrifugal acceleration, $-\hat{\boldsymbol{n}}\,|\boldsymbol{u}|^2/R$, points to the convex side (away from the center). The centripetal and centrifugal accelerations are paired action/reaction accelerations. The normal unit vector, $\hat{\boldsymbol{n}}$, always points to the left of the motion, whereas the radius of curvature, R, is positive or negative depending on the direction of the turning motion. For a left turning trajectory (in direction of $\hat{\boldsymbol{n}}$), the concave side is on the left and has positive radius of curvature, $R > 0$, whereas for the right turning trajectory (opposite direction of $\hat{\boldsymbol{n}}$) the concave side is to the right with $R < 0$. To help remember the signs, note that centrifugal means "away from the center" whereas centripetal means "towards the center". It is the centrifugal acceleration that pulls one away from the center of a merry-go-round whereas one's arms and hands provide the balancing centripetal acceleration.

so that the Coriolis acceleration always points to the right of the flow direction for $f > 0$. In contrast, the pressure gradient has two components

$$\nabla p = \hat{\boldsymbol{u}}\,(\hat{\boldsymbol{u}}\cdot\nabla p) + \hat{\boldsymbol{n}}\,(\hat{\boldsymbol{n}}\cdot\nabla p) = \hat{\boldsymbol{u}}\,\frac{\partial p}{\partial s} + \hat{\boldsymbol{n}}\,\frac{\partial p}{\partial n}, \tag{33.12}$$

one pointing along the flow direction and one normal to the direction.

33.2.5 Horizontal momentum equation and local Rossby number

Bringing the above results together leads to the horizontal momentum equation as decomposed into natural coordinates

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = -\frac{1}{\rho_0}\,\frac{\partial p}{\partial s} + \boldsymbol{F}\cdot\hat{\boldsymbol{u}} \qquad \text{motion in } \hat{\boldsymbol{u}} \text{ direction} \tag{33.13a}$$

$$\frac{|\boldsymbol{u}|^2}{R} + f\,|\boldsymbol{u}| = -\frac{1}{\rho_0}\,\frac{\partial p}{\partial n} + \boldsymbol{F}\cdot\hat{\boldsymbol{n}} \qquad \text{motion in } \hat{\boldsymbol{n}} \text{ direction (perpendicular to } \hat{\boldsymbol{u}}\text{)}, \tag{33.13b}$$

where $\boldsymbol{F}$ is the frictional acceleration and ρ_0 is the reference density for the Boussinesq ocean. These equations decompose the accelerations into those acting parallel to and normal to the trajectory. It is notable that the equation for the normal component is purely diagnostic; there is no time derivative in equation (33.13b). Instead, it is a balance containing accelerations from centripetal, Coriolis, normal pressure gradient, and normal component of friction. In the next few sections we consider certain limiting cases as revealed by the equations of motion (33.13a) and (33.13b). Friction remains zero in this chapter but is nonzero for the discussion of Ekman mechanics in Chapter 34.

Steady frictionless flow

The frictionless balanced motions considered in this chapter all occur with a fixed velocity magnitude for the fluid element, so that the along-trajectory component of the momentum equation

(33.13a) for frictionless motion reduces to

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = -\frac{1}{\rho_0}\frac{\partial p}{\partial s} = 0. \tag{33.14}$$

Hence, there is no pressure gradient along the direction of the fluid element motion. Correspondingly, the frictionless fluid motion preserves its kinetic energy

$$\frac{1}{2}\frac{\mathrm{D}(\boldsymbol{u}\cdot\boldsymbol{u})}{\mathrm{D}t} = |\boldsymbol{u}|\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = 0. \tag{33.15}$$

Local Rossby number

As discussed in Section 32.3, the Rossby number is the ratio of the acceleration from velocity advection to the Coriolis acceleration. In the normal component to the momentum equation (33.13b), we have the advection term manifest as the local centrifugal term. Following Chapter 1 of *van Heijst* (2010) we define the *local Rossby number* as the ratio of the centrifugal acceleration to the Coriolis acceleration

$$\mathrm{Ro}_{\mathrm{local}} = \frac{|\boldsymbol{u}|^2/R}{f/|\boldsymbol{u}|} = \frac{|\boldsymbol{u}|}{R\,f}, \tag{33.16}$$

where, again, R is the radius of curvature for the motion. In this chapter we consider flow regimes as determined by values of the local Rossby number.

33.2.6 Decomposition of the acceleration

The horizontal equations of motion (33.13a) and (33.13b) offer a relatively simple and insightful description of the motion. We here provide a connection with the traditional Eulerian form of the equations of motion.

Advective form of the acceleration

The standard form of the material time derivative for horizontal motion is given by

$$\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} = \frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t}\,\hat{\boldsymbol{u}} + \frac{|\boldsymbol{u}|^2}{R}\,\hat{\boldsymbol{n}}, \tag{33.17}$$

so that

$$\hat{\boldsymbol{u}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}\right] = \frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = -\frac{1}{\rho_0}\frac{\partial p}{\partial s} + \boldsymbol{F}\cdot\hat{\boldsymbol{u}} \tag{33.18a}$$

$$\hat{\boldsymbol{n}}\cdot\left[\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}\right] = \frac{|\boldsymbol{u}|^2}{R} = -f\,|\boldsymbol{u}| - \frac{1}{\rho_0}\frac{\partial p}{\partial n} + \boldsymbol{F}\cdot\hat{\boldsymbol{n}}. \tag{33.18b}$$

Depending on the information provided by a field measurement or numerical simulation, one might more readily diagnose the kinematic expressions on the left side of these equations or the force balances on the right side.

Expressions for the radius of curvature

The radius of curvature is an emergent property of the flow. From equation (33.18b), we find two means to diagnose the radius of curvature, given either the flow field itself or the forces

contributing to the flow

$$R^{-1} = \underbrace{\frac{\hat{\boldsymbol{n}} \cdot [\partial \boldsymbol{u}/\partial t + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u}]}{|\boldsymbol{u}|^2}}_{\text{kinematic method}} = \underbrace{\frac{-f\,|\boldsymbol{u}| - \rho_0^{-1}\, \partial p/\partial n + \boldsymbol{F} \cdot \hat{\boldsymbol{n}}}{|\boldsymbol{u}|^2}}_{\text{dynamic method}}. \tag{33.19}$$

A particularly elegant form for the kinematic expression arises for steady flow, in which case

$$|\boldsymbol{u}|^2\, R^{-1} = \hat{\boldsymbol{n}} \cdot [(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u}]. \tag{33.20}$$

This expression reveals how the normal projection of the self-advection operator is identical, for steady flows, to the magnitude of the centrifugal acceleration arising from the curved trajectory. If we furthermore assume the steady flow also occurs with constant speed, then

$$\mathrm{D}|\boldsymbol{u}|/\mathrm{D}t = (\boldsymbol{u} \cdot \nabla)|\boldsymbol{u}| = 0, \tag{33.21}$$

in which case the inverse radius of curvature is given by

$$R^{-1} = \hat{\boldsymbol{n}} \cdot [(\hat{\boldsymbol{u}} \cdot \nabla)\, \hat{\boldsymbol{u}}]. \tag{33.22}$$

Vector invariant form of the acceleration

We can transform the self-advection term using the vector identity (see Section 2.3.4)

$$(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} = \nabla K - \boldsymbol{u} \times \zeta\, \hat{\boldsymbol{z}}, \tag{33.23}$$

where $K = \boldsymbol{u} \cdot \boldsymbol{u}/2$ is the kinetic energy per mass in the horizontal flow, and $\zeta = \partial_x v - \partial_y u$ is the vertical component to the relative vorticity (see Chapter 38). The acceleration, $\boldsymbol{u} \times \zeta\, \hat{\boldsymbol{z}}$, is known as the *Magnus acceleration* and was discussed in Section 25.4. Projecting into the $\hat{\boldsymbol{u}}$ and $\hat{\boldsymbol{n}}$ directions leads to

$$\hat{\boldsymbol{u}} \cdot \frac{\partial \boldsymbol{u}}{\partial t} = -\frac{\partial (p/\rho_0 + K)}{\partial s} + \boldsymbol{F} \cdot \hat{\boldsymbol{u}} \tag{33.24a}$$

$$\hat{\boldsymbol{n}} \cdot \frac{\partial \boldsymbol{u}}{\partial t} = -(f + \zeta)\, |\boldsymbol{u}| - \frac{\partial (p/\rho_0 + K)}{\partial n} + \boldsymbol{F} \cdot \hat{\boldsymbol{n}}. \tag{33.24b}$$

The gradient acceleration is affected by both pressure and the *dynamical pressure* afforded by the kinetic energy per mass. The Magnus acceleration appears only in the normal component equation, which is expected since it acts just as the Coriolis acceleration to deflect the trajectory in a perpendicular direction. Following the example in Figure 25.1, consider a positive relative vorticity, $\zeta > 0$. For this case, the Magnus acceleration points to the right of the flow; i.e., opposite to the normal direction, which points to the left as per our convention in Figure 33.1.

33.2.7 Further study

Section 3.2 of *Holton* (1992) details the use of natural coordinates for geophysical flows, with a similar decomposition provided in Section 7.10 of *Gill* (1982) and Section 2.9 of *Vallis* (2017). Natural coordinates are also used in describing flows in non-rotating reference frames as in Section 20 of *Serrin* (1959) and as illustrated in this video.

33.3 Exact geostrophic balance

Frictionless flow parallel to pressure contours experiences no pressure gradient ($\partial p/\partial s = 0$), so that the speed of a fluid element remains constant. Furthermore, if this motion occurs with an infinite radius of curvature (straight line motion parallel to pressure contours), then the force balance is between the normal pressure gradient and Coriolis. In this case the local Rossby number (33.16) vanishes

$$\mathrm{Ro}_{\mathrm{local}} = \frac{|\boldsymbol{u}|}{R\,f} = 0 \quad \text{if } |R| = \infty. \tag{33.25}$$

More precisely, exact geostrophic balance occurs under the following conditions.

- Fluid moves on a straight line so that the radius of curvature is infinite, $|R| = \infty$, thus making the centripetal acceleration and local Rossby number both vanish;
- Fluid moves along lines of constant pressure so that $\partial p/\partial s = 0$;
- Friction is zero.

In this case the equations of motion (33.13a) and (33.13b) take the form

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = 0 \tag{33.26a}$$

$$f\,|\boldsymbol{u}| = -\frac{1}{\rho_0}\,\frac{\partial p}{\partial n}. \tag{33.26b}$$

Equation (33.26a) says that the speed of a fluid element is constant, so that the horizontal kinetic energy likewise is constant. Equation (33.26b) says that the pressure gradient normal to the motion balances the Coriolis acceleration. We refer to this flow, depicted in Figure 33.4, as *exact geostrophic balance* since it is an exact solution under the above assumptions.

Writing the horizontal advection of speed in the form

$$\boldsymbol{u}\cdot\nabla|\boldsymbol{u}| = |\boldsymbol{u}|\,\hat{\boldsymbol{u}}\cdot\nabla|\boldsymbol{u}| = |\boldsymbol{u}|\,\frac{\partial|\boldsymbol{u}|}{\partial s}, \tag{33.27}$$

allows us to write the material constancy of the flow speed as

$$\frac{\partial|\boldsymbol{u}|}{\partial t} + |\boldsymbol{u}|\,\frac{\partial|\boldsymbol{u}|}{\partial s} = 0. \tag{33.28}$$

Hence, a steady flow speed, with $\partial|\boldsymbol{u}|/\partial t = 0$, only holds for the exact geostrophic balance if the flow speed is fixed along each trajectory path

$$\frac{\partial|\boldsymbol{u}|}{\partial s} = 0 \Longrightarrow \frac{\partial|\boldsymbol{u}|}{\partial t} = 0. \tag{33.29}$$

What is required for this condition to hold? We examine two cases, again restricted to a tangent plane.

33.3.1 Steady f-plane flow

Geostrophic motion on an f-plane is horizontally non-divergent (Section 32.4)

$$\nabla\cdot\boldsymbol{u} = \nabla\cdot(\hat{\boldsymbol{u}}\,|\boldsymbol{u}|) = 0. \tag{33.30}$$

FIGURE 33.4: Exact geostrophic balance on a tangent plane occurs when the flow is horizontal, frictionless, straight, and follows contours of constant pressure. For this case the pressure gradient exactly balances the Coriolis acceleration so that the motion is perpendicular to both of these accelerations. We here depict motion assuming $f > 0$ as for the northern hemisphere. If flow is on an f-plane then the exact geostrophic balance is steady for any arbitrary flow direction. On a β-plane, steady exact geostrophic balance holds only for zonal flow.

Flow in a straight line, with each trajectory parallel to one another, has the trajectory direction independent of space. Hence, the non-divergent condition means that

$$0 = \nabla \cdot (\hat{\boldsymbol{u}}\,|\boldsymbol{u}|) = (\hat{\boldsymbol{u}} \cdot \nabla)\,|\boldsymbol{u}| = \frac{\partial |\boldsymbol{u}|}{\partial s}, \tag{33.31}$$

which proves that exact geostrophic flow on an f-plane is steady.

33.3.2 Steady β-plane flow

The geostrophic velocity in the presence of a meridional gradient of the Coriolis parameter, $f = f(y)$, satisfies (Section 32.4)

$$\nabla \cdot (f\,\boldsymbol{u}) = 0. \tag{33.32}$$

Making use of $\nabla \cdot \hat{\boldsymbol{u}} = 0$ for straight line trajectories leads to

$$\nabla \cdot (f\,\boldsymbol{u}) = \frac{\partial (f\,|\boldsymbol{u}|)}{\partial s} = 0. \tag{33.33}$$

We conclude that $\partial|\boldsymbol{u}|/\partial s = 0$ holds only for trajectories that are parallel to latitude lines, in which case $\partial f/\partial s = \partial f/\partial x = 0$. Therefore, exact geostrophic motion on the β-plane is steady only for trajectories that follow constant latitude lines; i.e., zonal trajectories as depicted in Figure 33.4.

33.3.3 What about geostrophic balance with curved motion?

The geostrophically balanced flows discussed in Chapter 32 generally have curvature, such as for the geostrophic motion around a pressure center as shown in Figure 32.3. But as emphasized by the natural coordinate decomposition as per equations (33.13a) and (33.13b), curved motion has an associated centrifugal acceleration. So when speaking of geostrophic balance for flow that has a nonzero curvature, then the local Rossby number (33.16) is not precisely zero. Rather, its magnitude is small but nonzero

$$|\mathrm{Ro}_{\mathrm{local}}| \ll 1 \quad \text{approximate geostrophic flow.} \tag{33.34}$$

In this limit it is accurate to ignore the centrifugal acceleration, which is commonly the case for large-scale flows. Even so, it is an approximation, with the centrifugal acceleration identically

zero only for straight line motion on a plane.

33.4 Inertial motion

Inertial motion occurs under the following conditions:

- vanishing pressure gradient
- vanishing friction,

so that the equations of motion (33.13a) and (33.13b) take the form

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = 0 \tag{33.35a}$$

$$\frac{|\boldsymbol{u}|^2}{R} + f\,|\boldsymbol{u}| = 0. \tag{33.35b}$$

Equation (33.35a) says that inertial motion occurs with constant speed, whereas equation (33.35b) says that the motion maintains the balance between Coriolis and centrifugal accelerations

$$f\,|\boldsymbol{u}| = -\frac{|\boldsymbol{u}|^2}{R}. \tag{33.36}$$

Hence, local Rossby number has a unit magnitude

$$|\mathrm{Ro}_{\mathrm{local}}| = \frac{|\boldsymbol{u}|}{|R|\,|f|} = 1. \tag{33.37}$$

33.4.1 Anti-cyclonic circular motion on f-plane

To further understand inertial motion, rearrange equation (33.36) so that

$$f = -\frac{|\boldsymbol{u}|}{R}, \tag{33.38}$$

in which case the radius for the inertial circle is

$$R = -|\boldsymbol{u}|/f. \tag{33.39}$$

Equation (33.38) can be satisfied in the northern hemisphere ($f > 0$) only for motion turning to the right (in which $R < 0$). The opposite orientation occurs in the southern hemisphere, where inertial motion turns to the left so that the radius of curvature is positive, $R = -|\boldsymbol{u}|/f > 0$ (see Figure 33.2 for the sign convention on the radius of curvature). Hence, inertial motion is oriented anti-cyclonically (orientated opposite to the earth's rotation). If the Coriolis parameter is constant, then the motion is circular, as depicted in Figure 33.5.

To emphasize the balance, return to equation (33.36) and recall that the Coriolis acceleration in the northern hemisphere points to the right when facing downstream, as per equation (33.11). Hence, the balance (33.36) is between the Coriolis acceleration pointing to the right and the centrifugal acceleration pointing to the left. That is, the Coriolis acceleration provides the centripetal acceleration to balance the centrifugal acceleration.

FIGURE 33.5: Inertial motion of a fluid on a plane occurs when the flow is horizontal, frictionless, and the centrifugal acceleration balances the Coriolis in the presence of zero pressure gradient. We here depict motion assuming $f > 0$ as for the northern hemisphere, revealing that inertial motion is an anti-cyclonic circular motion with radius $|R| = |\boldsymbol{u}|/|f|$. When turning to the right as in the northern hemisphere, the radius of curvature for the inertial circle is negative (see Figure 33.2 for sign convention), so that $R = -|\boldsymbol{u}|/f < 0$.

33.4.2 Period for inertial motion

Equation (33.39) says that the speed of a fluid element is given by the radius of curvature times the magnitude of the Coriolis parameter

$$|\boldsymbol{u}| = R\,|f|. \tag{33.40}$$

The time for a fluid element to traverse an inertial circle is given by the circumference of the circle, $2\pi R$, divided by the constant speed, thus yielding the inertial period

$$T_{\text{inertial}} = \frac{2\pi R}{|\boldsymbol{u}|} = \frac{2\pi}{|f|}. \tag{33.41}$$

We encountered this inertial period in Section 14.5 when considering inertial oscillations for a point particle.

33.4.3 Observing inertial motion

Inertial motion is rarely observed in the atmosphere since fluid motion nearly always occurs in the presence of a pressure gradient. In contrast, surface ocean flow is commonly generated by wind stresses that setup motion even in the absence of pressure gradients. The moving fluid then engenders a Coriolis acceleration, in which case there can be a balance between centrifugal and Coriolis for the moving ocean fluid. As a result, the observed surface ocean currents have nontrivial power within the inertial frequency band, rivaling energy contained in frequencies associated with astronomical tides (e.g., see Figure 3.3 of *Holton* (1992)).

How large is an inertial circle? Consider a surface ocean current speed of $|\boldsymbol{u}| \sim 0.1$ m s^{-1}, which is not atypical of current speeds outside of strong boundary currents or mesoscale eddies, and assume the Coriolis parameter $f = 10^{-4}$ s^{-1}. In this case the inertial radius is

$$R_{\text{inertial}} \approx 10^3 \text{ m}. \tag{33.42}$$

Observations of inertial motion, such as that reproduced in Figure 8.3 of *Gill* (1982), confirm that the radii are indeed on the order of a few kilometers.

33.4.4 Inertial motion is Lagrangian

The analysis in this section concerns a fluid element moving without feeling the impacts from pressure forces. The fluid thus exhibits the same force balance as the point particle discussed in Section 14.5. So although we can measure inertial motion at a fixed point in space, the present considerations are Lagrangian in nature, focusing on motion of fluid elements. Furthermore, the inertial period refers to the time it takes for a fluid element to move around the inertial circle at its constant speed. It does not refer to the period of a wave, for example, and yet there are inertial waves (Chapter 51) with this period as well as inertia-gravity waves that have periods close to the inertial period (Section 53.8),

33.4.5 "Inertial" motion does not refer to an inertial reference frame

We make use of the term "inertial" when referring to inertial motion since both the Coriolis and centrifugal accelerations are nonzero only in the presence of motion; i.e., they require the inertia obtained by a moving massive body. Hence, as noted in Section 14.5.5, "inertial motion" in this context does *not* refer to the motion viewed in an inertial reference frame.

33.4.6 Inertial motion on a sphere

In the analysis thus far, we have assumed an f-plane so that inertial motion is circular. Without solving the spherical equations for inertial motion we can anticipate what happens when such motion occurs on a sphere. As a fluid element moves to higher latitudes the magnitude of the Coriolis parameter increases, thus decreasing the radius of curvature. The opposite happens when moving equatorward. This effect of planetary sphericity leads to an egg-shaped pattern that does not close but instead drifts to the west. Now consider inertial motion that spans the equator. As the fluid crosses the equator, where $f = 0$, the radius of curvature is infinite so that the motion is straight. When moving away from the equator the Coriolis parameter increases in magnitude, which causes a fluid element to turn and close its path, again with a drift to the west. Motion north of the equator turns to the right whereas motion to the south turns left, so that inertial motion that spans the equator forms a figure-eight path. We illustrate this motion in Figure 33.6.

33.5 Cyclostrophic balance

Cyclostrophic balance occurs under the following conditions:

- fluid elements move along lines of constant pressure so that $\partial p/\partial s = 0$;
- vanishing Coriolis acceleration;
- vanishing friction.

The resulting equations of motion (33.13a) and (33.13b) take the form

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = 0 \tag{33.43a}$$

$$\frac{|\boldsymbol{u}|^2}{R} = -\frac{1}{\rho_0}\frac{\partial p}{\partial n}. \tag{33.43b}$$

With a vanishing Coriolis acceleration we see that cyclostrophic balance corresponds to local Rossby number that has an infinite magnitude

$$|\mathrm{Ro}_{\mathrm{local}}| = \infty \quad \text{if } f = 0. \tag{33.44}$$

FIGURE 33.6: Depicting inertial motion on a sphere. As the fluid element moves poleward, f increases so that the radius of curvature decreases. Correspondingly, the fluid motion does not close, but instead the path drifts to the west. This westward drift holds for both hemispheres, where the sense of the motion is anti-cyclonic. The only closed and circular inertial motions are those that encircle the pole. Fluid elements that cross the equator exhibit a figure-eight pattern that also drifts to the west. This figure is taken after Figure 4-14 of *von Arx* (1962).

Approxiate cyclostrophic balance holds when $|\mathrm{Ro}_{\mathrm{local}}| \gg 1$.

Again, equation (33.43a) says that the speed is constant following a material fluid element. Equation (33.43b) says that cyclostrophic flow occurs when the centrifugal acceleration balances the pressure gradient, with the squared speed given by

$$|\boldsymbol{u}|^2 = -\frac{R}{\rho_0}\frac{\partial p}{\partial n}. \tag{33.45}$$

This equation can be satisfied for either clockwise or counter-clockwise motion around a low pressure center, as shown in Figure 33.7. For clockwise flow, the radius of curvature is negative, $R < 0$, whereas $\partial p/\partial n > 0$. The signs are swapped for counter-clockwise flow. Cyclostrophic balance cannot be maintained around a high pressure center. The reason is that if both the pressure and centrifugal accelerations point away from the circle's center, then they are unable to balance one another.

Cyclostrophic balance is relevant for scales on the order of a tornado, with a radius on the order of 300 m where tangential speeds are on the order of 30 m s^{-1} (see Section 3.2.4 of *Holton* (1992)). For this flow scale, the Rossby number is on the order of 1000 at middle latitudes, thus justifying neglect of the Coriolis acceleration. Although tornadoes in cyclostrophic balance can rotate either clockwise or counter-clockwise, they are more often observed rotating cyclonically given that they are generally embedded within cyclonic storm systems. In contrast, smaller motions such as dust devils and water spouts are quite often seen rotating in either direction.

33.6 Gradient wind balance

Gradient wind balance occurs under the following conditions:

- fluid elements move along lines of constant pressure so that $\partial p/\partial s = 0$;
- vanishing friction.

FIGURE 33.7: Cyclostrophic motion of a fluid element on a tangent plane occurs when the flow is horizontal, non-rotating, frictionless, with constant speed, and where the centrifugal acceleration balances the pressure gradient normal to the flow direction. We here depict motion for clockwise and counter-clockwise cyclostrophic flow, both around a low pressure center. Left panel: clockwise motion with radius of curvature, $R < 0$, and the pressure gradient pointing in the direction of the normal, $\partial p/\partial n > 0$. Right panel: counter-clockwise motion with radius of curvature, $R > 0$, and the pressure gradient pointing opposite to the direction of the normal, $\partial p/\partial n < 0$. Cyclostrophic balance does not occur for flow around a high pressure center. The reason is that if both the pressure and centrifugal accelerations point away from the center, then they are unable to balance one another.

The resulting equations of motion (33.13a) and (33.13b) take the form

$$\frac{\mathrm{D}|\boldsymbol{u}|}{\mathrm{D}t} = 0 \tag{33.46a}$$

$$\frac{|\boldsymbol{u}|^2}{R} + f\,|\boldsymbol{u}| = -\frac{1}{\rho_0}\frac{\partial p}{\partial n}, \tag{33.46b}$$

Again, equation (33.46a) says that the speed is constant following a material fluid element. Equation (33.46b) says that gradient wind balanced flow occurs when the centrifugal and Coriolis accelerations balance the pressure gradient acting normal to the motion.

The local Rossby number is order unity for the gradient wind balance

$$|\mathrm{Ro}_{\mathrm{local}}| = \frac{|\boldsymbol{u}|}{|R|\,|f|} \sim 1, \tag{33.47}$$

meaning that both centrifugal and Coriolis accelerations are important as they balance the pressure gradient. Recall that the inertial motion from Section 33.4 has $|\mathrm{Ro}_{\mathrm{local}}| = 1$, which arises when the pressure gradient vanishes so that the Coriolis and centrifugal terms have equal but opposite magnitudes. The nonzero pressure gradient makes gradient wind flow fundamentally distinct from inertial motion.

33.6.1 Constraints on gradient wind flow

The quadratic formula leads to the following expression for the speed of gradient wind flow

$$|\boldsymbol{u}| = \frac{R}{2}\left[f \pm \sqrt{f^2 - \frac{4}{R}\frac{1}{\rho_0}\frac{\partial p}{\partial n}}\right]. \tag{33.48}$$

The speed is a real number if the pressure gradient, Coriolis parameter, and radius of curvature satisfy

$$f^2 > \frac{4}{R}\frac{1}{\rho_0}\frac{\partial p}{\partial n} \Longrightarrow \frac{1}{\rho_0}\left|\frac{\partial p}{\partial n}\right| \leq \frac{|R|\,f^2}{4}. \tag{33.49}$$

This relation has direct implications for the structure of the pressure field depending on the sign of the radius of curvature. In particular, as seen in the following, this constraint implies that

FIGURE 33.8: The variety of gradient wind balances available in the northern hemisphere ($f > 0$). Gradient wind balance occurs when the flow is horizontal, frictionless, with constant speed, and where the centrifugal, pressure, and Coriolis accelerations balance under a variety of magnitudes. To reduce clutter, we use the following shorthand for the accelerations: $P = -\rho_0^{-1}\,\partial p/\partial n$, $Co = f\,|\boldsymbol{u}|$, and $Ce = |\boldsymbol{u}|^2/R$. Upper left panel: motion around a regular high pressure center, whereby the centrifugal acceleration helps the pressure acceleration to balance the Coriolis acceleration. The pressure acceleration is larger in magnitude than the centrifugal. This flow is termed "regular" as it directly corresponds to geostrophic flow around a high pressure center. Lower left panel: motion around an anomalous high pressure center, whereby the centrifugal acceleration helps the pressure acceleration to balance the Coriolis acceleration, with the pressure acceleration smaller in magnitude than the centrifugal. This flow is termed "anomalous" as the pressure acceleration is subdominant to the centrifugal, in contrast to the case of geostrophic flow. Upper right panel: motion around a regular low pressure center, whereby the Coriolis and centrifugal accelerations balance the pressure acceleration. Lower right panel: motion around an anomalous low pressure center, whereby the Coriolis and pressure accelerations balance the centrifugal acceleration. Note the opposite flow orientation between the regular and anomalous lows, whereas the regular and anomalous highs have the same flow orientation.

the pressure gradient at the center of a high pressure region must go to zero as the radius of curvature vanishes, which renders the pressure field relatively flat near the center of highs. In contrast, there is no analogous limit for the magnitude of the pressure gradient approaching a low pressure center. This asymmetry between high and low pressures manifests in atmospheric flow with low pressure centers (cyclonic lows) having stronger magnitude than high pressure centers (anti-cyclonic highs).

33.6.2 The variety of gradient wind flows

We now identify the following force balances available with a gradient wind balance, with illustrations provided in Figure 33.8.

Regular high pressure center (right turn with high pressure on right)

A *regular high pressure* occurs with $R < 0$ and $\partial p/\partial n \leq 0$. This case occurs with the centrifugal and pressure accelerations pointing away from the center, and these balance the Coriolis acceleration pointing to the high pressure center (upper left panel of Figure 33.8).

The inequality (33.49) provides a bound to the size of the pressure gradient since

$$\frac{1}{\rho_0}\frac{\partial p}{\partial n} \leq \frac{R\,f^2}{4} \quad \text{with} \quad R \leq 0 \quad \text{and} \quad \frac{\partial p}{\partial n} \leq 0 \Longrightarrow \frac{1}{\rho_0}\left|\frac{\partial p}{\partial n}\right|_{\max} = \frac{|R|\,f^2}{4}. \tag{33.50}$$

That is, the pressure gradient for a regular high cannot be larger than this bound in order for there to be a gradient wind solution. Since $R \to 0$ as the center is approached, the normal pressure gradient, $\partial p/\partial n$, in turn must vanish towards the center. *Holton* (1992) identifies two subcases for this balance depending on the relative size of the pressure and centrifugal accelerations, with the anomalous high the case where the pressure gradient acceleration is weaker than the centrifugal (lower left panel of Figure 33.8).

Regular low (left turn with low pressure on left)

This flow occurs with $R \geq 0$ and $\partial p/\partial n \leq 0$, so that the inequality (33.49) is always satisfied

$$\frac{1}{\rho_0}\frac{\partial p}{\partial n} \leq \frac{R\,f^2}{4} \quad \text{with} \quad R \geq 0 \quad \text{and} \quad \frac{\partial p}{\partial n} \leq 0 \Longrightarrow \text{arbitrary size to } \left|\frac{\partial p}{\partial n}\right|. \tag{33.51}$$

Hence, there is no constraint imposed by gradient wind balance on the size of the pressure gradient magnitude, $|\partial p/\partial n|$. So the low pressure center can be arbitrarily strong and still maintain a gradient wind balance. Furthermore, the Coriolis and centrifugal accelerations point away from the low pressure center, and these two accelerations balance the pressure acceleration that points toward the center (upper right panel of Figure 33.8).

Anomalous low (right turn with low pressure on right)

This flow occurs with $R < 0$ and $\partial p/\partial n \geq 0$. This case occurs with the Coriolis and pressure accelerations pointing toward the low pressure center, and these two accelerations balance the centrifugal acceleration pointing away from the center (lower right panel of Figure 33.8). As with the regular low, the inequality (33.49) provides no bound to the magnitude of the low pressure. Note the opposite orientation for the flow around an anomalous low relative to the regular low.

Left turn with high pressure on left

In this case $R > 0$ and $\partial p/\partial n > 0$. There is no solution for the northern hemisphere since all accelerations point to the right of the motion thus disallowing any balance.

33.6.3 Comments

As noted in Section 3.2 of *Holton* (1992), the difference between gradient wind speeds and geostrophic wind speeds is no more than 10% to 20% in middle latitude synoptic atmosphere flow. In the tropics, where geostrophy becomes less relevant, it is important to apply the gradient wind relation to capture the balanced flow states. Furthermore, *van Heijst* (2010) and Chapter 18 of *Cushman-Roisin and Beckers* (2011) make use of a gradient wind analysis for the study of ocean vortices. The deviations from geostrophy become important when considering relatively small ocean vortices and/or tropical vortices.

Chapter 34

Ekman mechanics

A *boundary layer* is a region of the fluid flow that is directly affected by boundaries. For geophysical applications we have in mind the solid-earth boundary that interacts with both the ocean and atmosphere; the ocean-atmosphere boundary; the ocean-cryosphere boundary; and the atmosphere-cryosphere boundary. The fluid flow in geophysical boundary layers is generally very turbulent, thus causing rapid mixing and the transfer of properties within the boundary layer, along with the transport of properties between the boundary layer and the less turbulent fluid interior. Boundary layer physics is a well developed discipline for geophysical as well as engineering applications. Our treatment is relatively superficial by comparison to the focused treatments given by books such as *Tennekes and Lumley* (1972), *Stull* (1988), and *Thorpe* (2005).

Here, we are particularly focused on the rudiments of *Ekman mechanics*, which is concerned with flow affected by accelerations from horizontal pressure gradients, vertical friction, and Coriolis, with particular attention given to regions near boundaries where friction is especially large and *Ekman boundary layers* form. The leading role for Coriolis acceleration causes Ekman boundary layers to exhibit behaviors quite distinct from their non-rotating cousins mentioned in Section 26.10.7. In particular, Ekman boundary layer flows are horizontally divergent, thus leading to the vertical exchange of mass, tracers, momentum, and vorticity between the boundary layer and the fluid region outside of the boundary layer (i.e., the fluid interior). In so doing, the Ekman layer flow imparts a stretching and squeezing of interior fluid columns that strongly couples the boundary layer to vorticity and circulation of the fluid interior. This role for Ekman layers is especially crucial for the ocean general circulation.

READER'S GUIDE TO THIS CHAPTER

To introduce the subject we exhibit the role of friction in producing a down pressure gradient component to the flow, making use of natural coordinates from Chapter 33 for this purpose. The remainder of the chapter focuses on the mechanics of Ekman boundary layers, with this study greatly extending our understanding of strongly rotating flows from Chapter 32. Indeed, the addition of friction to an otherwise geostrophically balanced flow provides a surprising level of richness that motivates the variety of perspectives presented in this chapter.

Ekman boundary layers are a key element in the study of ocean circulation, particularly the wind-driven circulation. We here borrow liberally from the material in Section 9.2 of *Gill* (1982), Section 6.2 of *Apel* (1987), Section 7.4 of *Marshall and Plumb* (2008), Chapter 8 of *Cushman-Roisin and Beckers* (2011), Section 5.7 of *Vallis* (2017), and materials from *Thorpe* (1988) and *Thorpe* (2005). A presentation consistent with engineering boundary layers can be found in Section 5.3 of *Tennekes and Lumley* (1972).

34.1 The dynamical balances

Throughout this chapter we make use of a steady, linear, Boussinesq, hydrostatic primitive equations that maintain a balance between the horizontal accelerations from Coriolis, pressure, and friction

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\frac{1}{\rho_0}\nabla_z p + \boldsymbol{F}. \tag{34.1}$$

This balance is most relevant over large horizontal length scales as per the planetary geostrophic equations of Section 32.5.

The frictional acceleration, $\boldsymbol{F}$, of interest in this chapter arises from the vertical exchange of horizontal momentum between fluid layers. Turbulence induced viscous exchange is especially large in boundary regions such as the ocean surface, the atmospheric planetary boundary layer, and next to the ocean and atmosphere bottom where they interact with the solid earth. In such turbulent boundary layer regions we make use of the eddy viscosity, which is much larger than molecular values

$$\nu^{\text{eddy}} \gg \nu. \tag{34.2}$$

We have more to say regarding the frictional operator in Section 34.3.1.

For conceptual and mathematical convenience, we find it useful to separate the horizontal velocity into two components. The first is the geostrophic velocity defined by a balance between

pressure gradient and Coriolis accelerations

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\frac{1}{\rho_0}\nabla_z p \Longrightarrow \boldsymbol{u}_{\mathrm{g}} = \frac{1}{f\rho_0}\,\hat{\boldsymbol{z}} \times \nabla_z p. \tag{34.3}$$

In some treatments, $\boldsymbol{u}_{\mathrm{g}}$ is referred to as the *pressure driven velocity*. The second is an *ageostrophic* or Ekman component defined by a balance between the frictional and Coriolis accelerations

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{e}} = \boldsymbol{F} \Longrightarrow \boldsymbol{u}_{\mathrm{e}} = -f^{-1}\,\hat{\boldsymbol{z}} \times \boldsymbol{F}, \tag{34.4}$$

so that $\boldsymbol{u}_{\mathrm{e}}$ is the *frictional driven velocity*.

This velocity decomposition has the appearance of superposing linearly independent flows, one geostrophic (pressure driven) and one ageostrophic (friction driven). However, the flows are coupled and thus not linearly independent. Namely, ageostrophic motions alter the pressure field which in turn affects the geostrophic flow. So the presence of friction and the associated ageostrophic flows lead to geostrophic flows differing from the inviscid case. Conversely, geostrophic flows affect the level of friction. Hence, the above decomposition does not reflect a physical decoupling of geostrophic and ageostrophic flows. Rather, it is only meant to help conceptually understand and describe the flow and the various force balances.

34.2 Horizontal balances in natural coordinates

Motion in Ekman boundary layers is both horizontal and vertical. Here, we introduce the role of friction in rotating flows by just focusing on the horizontal motion on a tangent plane. In particular, we study balances occuring in horizontal flows that maintain a frictional geostrophic balance. As per the definition (34.3), geostrophic motion occurs along lines of constant pressure, with frictionally induced deviations crossing isobars and providing a down pressure gradient component to the fluid trajectory. Motivated by the discussion in Chapter 33, we make use of natural coordinates for the kinematics.

34.2.1 Natural coordinates according to isobars

We represent the horizontal flow according to natural coordinates defined along an arbitrary geopotential surface. Instead of defining the natural coordinates according to the flow direction, as done in Section 33.2 for the frictionless case, we here decompose the motion according to pressure contours (isobars). The unit vector, $\hat{\boldsymbol{s}}$, is defined tangent to isobars in the horizontal plane and directed along the direction of geostrophic flow. We define the direction, $\hat{\boldsymbol{n}}$, to be perpendicular to isobars and oriented down the horizontal pressure gradient

$$\hat{\boldsymbol{n}} = -\frac{\nabla_z p}{|\nabla_z p|}. \tag{34.5}$$

As illustrated in Figure 34.1, in the northern hemisphere $\hat{\boldsymbol{n}}$ points to the left of the geostrophic velocity, whereas it is to the right in the southern hemisphere. We thus have the northern hemisphere triplet of unit vectors

NORTHERN HEMISPHERE TRIPLET OF DIRECTIONS

$$\hat{\boldsymbol{z}} = \hat{\boldsymbol{s}} \times \hat{\boldsymbol{n}} = \text{vertical direction} \tag{34.6a}$$

$$\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{s}} = \text{down pressure gradient direction} \tag{34.6b}$$

$$\hat{\boldsymbol{s}} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}} = \text{tangent to isobar in direction of geostrophic flow.} \tag{34.6c}$$

In the southern hemisphere, since $\hat{\boldsymbol{n}}$ points to the right of $\hat{\boldsymbol{s}}$, the triplet of directions becomes

SOUTHERN HEMISPHERE TRIPLET OF DIRECTIONS

$$\hat{\boldsymbol{z}} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{s}} = \text{vertical direction} \tag{34.7a}$$

$$\hat{\boldsymbol{n}} = \hat{\boldsymbol{s}} \times \hat{\boldsymbol{z}} = \text{down pressure gradient direction} \tag{34.7b}$$

$$\hat{\boldsymbol{s}} = \hat{\boldsymbol{z}} \times \hat{\boldsymbol{n}} = \text{tangent to isobar in direction of geostrophic flow.} \tag{34.7c}$$

FIGURE 34.1: Natural coordinates defined along an arbitrary geopotential surface according to isobars in the horizontal plane, here depicted for the northern hemisphere. The normal direction, $\hat{\boldsymbol{n}} = -\nabla_z p/|\nabla_z p|$, is oriented down the horizontal pressure gradient so that it points to the left of the geostrophic velocity (facing downstream) in the northern hemisphere and to the right in the southern hemisphere. The tangent direction, $\hat{\boldsymbol{s}}$, points along the isobar in the direction of the geostrophic velocity.

34.2.2 Geostrophic and Ekman balances

As found when studying the geostrophic balance in Section 33.3, the geostrophic velocity flows along isobars and so only has a component in the $\hat{\boldsymbol{s}}$ direction

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\mathrm{g}} = -\frac{1}{f\rho_0}\frac{\partial p}{\partial n} \quad \text{and} \quad \hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\mathrm{g}} = 0 \tag{34.8}$$

In contrast, the Ekman velocity has a component both along and across isobars. For the northern and southern hemispheres we have

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\mathrm{e}} = |f|^{-1}\,\hat{\boldsymbol{n}} \cdot \boldsymbol{F} \quad \text{and} \quad \hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\mathrm{e}} = -|f|^{-1}\,\hat{\boldsymbol{s}} \cdot \boldsymbol{F}. \tag{34.9}$$

As expected, the Ekman velocity vanishes when the frictional acceleration vanishes, in which case the flow reduces to the geostrophic flow that moves along isobars so that $\hat{\boldsymbol{s}} = \hat{\boldsymbol{u}}$. However, when there is a nonzero friction aligned along isobars, that drives an Ekman velocity across isobars. Conversely, friction aligned across isobars drives Ekman velocities along isobars.

We arrive at a complementary perspective on the origin of cross-isobar flow through the following considerations. Without friction, the Coriolis and pressure gradient accelerations balance when the flow is geostrophic. In the presence of friction, the velocity is slowed so that the Coriolis acceleration weakens. If the pressure gradient acceleration is retained, as occurs if it is determined by large scale balances outside of the Ekman layer, then the Coriolis acceleration no longer balances the pressure gradient. Consequently, flow is diverted from isobars and develops a component down the pressure gradient.

34.2.3 Rayleigh drag

The relative simplicity of Rayleigh drag facilitates analytical expressions for the Ekman velocity using natural coordinates, written in terms of the geostrophic velocity (equation (34.8)). In doing so we are afforded an explicit illustration of how friction provides a cross-isobar component to the flow in the direction down the pressure gradient. Before developing the Ekman flows we here summarize elements of Rayleigh drag.

In Section 27.3.3 we studied how Rayleigh drag affects the kinetic energy budget. As a reminder, consider a frictional acceleration in the form of a Rayleigh drag acting on the velocity field

$$\boldsymbol{F} = -\frac{U_{\text{fric}}\,\boldsymbol{u}}{\delta} = -\gamma\,\boldsymbol{u}, \tag{34.10}$$

where δ is a vertical scale and U_{fric} is a friction velocity scale with dimensions L/T. The ratio

$$\gamma = \frac{U_{\text{fric}}}{\delta} \tag{34.11}$$

has dimensions T^{-1} and is an inverse spin-down time. That is, if only Rayleigh drag affected changes to the horizontal momentum, $\partial_t \boldsymbol{u} = -\gamma\,\boldsymbol{u}$, then the flow would exponentially come to a halt with an e-folding time γ^{-1}. The drag is relatively large over rough surfaces, thus leading to a small e-folding time. In particular, drag on the lower atmospheric winds is larger over land than over the ocean. The reason is that trees, cities, and mountains dissipate more of the atmosphere's mechanical energy than interactions with the relatively smooth ocean surface.

Rayleigh drag dissipates all flow features regardless of their spatial structure. That is, Rayleigh drag does not prefer any particular length scales in the fluid flow. This lack of scale selectivity contrasts to the Laplacian friction discussed in Section 34.3.1, with Laplacian friction dissipating small spatial scales more strongly than large scales. Correspondingly, Rayleigh drag does not generally provide the means to produce a boundary layer.[1] Hence, when studying physics within the Ekman boundary layer in Section 34.3 we make use of Laplacian friction. But for now, Rayleigh drag provides a means to analytically illustrate the role of friction in producing spiral flows with non-zero horizontal divergence.

34.2.4 Cross isobar flow driven by Rayleigh drag

Making use of the Rayleigh drag (34.10) brings the northern hemisphere expressions (34.9) for the Ekman velocity into the form

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\text{e}} = f^{-1}\,\hat{\boldsymbol{n}} \cdot \boldsymbol{F} = -(\gamma/f)\,\hat{\boldsymbol{n}} \cdot \boldsymbol{u} = -(\gamma/f)\,\hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\text{e}} \tag{34.12a}$$

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\text{e}} = -f^{-1}\,\hat{\boldsymbol{s}} \cdot \boldsymbol{F} = (\gamma/f)\,\hat{\boldsymbol{s}} \cdot \boldsymbol{u} = (\gamma/f)\,\hat{\boldsymbol{s}} \cdot (\boldsymbol{u}_{\text{e}} + \boldsymbol{u}_{\text{g}}). \tag{34.12b}$$

Similar considerations for the southern hemisphere lead to the general result for both hemispheres

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\text{e}} = -(\gamma/|f|)\,\hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\text{e}} \tag{34.13a}$$

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\text{e}} = (\gamma/|f|)\,\hat{\boldsymbol{s}} \cdot (\boldsymbol{u}_{\text{e}} + \boldsymbol{u}_{\text{g}}). \tag{34.13b}$$

[1] In Section 34.3.3 we provide further discussion of what is needed mathematically and physically to produce a boundary layer.

FIGURE 34.2: Illustrating frictional geostrophic flow in the northern hemisphere ($f > 0$). Left panel: geostrophic flow, $\boldsymbol{u}_{\rm g}$, around a low pressure center is counter-clockwise and aligned with pressure isobars. Friction aligned along the isobars drives Ekman flow, $\boldsymbol{u}_{\rm e}$, that has a component down the pressure gradient (normal to the geostrophic flow) as well as a component that is directed opposite the geostrophic flow. Consequently, the total velocity, $\boldsymbol{u}_{\rm g}+\boldsymbol{u}_{\rm e}$, spirals into the low pressure center. Right panel: the opposite oriented flow occurs around high pressure centers, where fluid spirals away from the high due to the cross-isobar flow driven by friction. By the definition given by equation (34.6b), the normal direction, $\hat{\boldsymbol{n}}$, is directed down the pressure gradient, whereas $\hat{\boldsymbol{s}}$ is tangent to the isobar and directed along the geostrophic flow direction.

Rearrangement of these equations allows us to express the Ekman velocity in terms of the geostrophic velocity (equation (34.8)), with results for both hemispheres given by

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{u}_{\rm e} = \hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm g} \left[\frac{\gamma \, |f|}{f^2 + \gamma^2} \right] \tag{34.14a}$$

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm e} = -\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm g} \left[\frac{\gamma^2}{\gamma^2 + f^2} \right], \tag{34.14b}$$

where equation (34.8) expresses the geostrophic velocity in terms of the normal pressure gradient. Equation (34.14a) says that the normal component to the Ekman velocity is directed down the pressure gradient. Equation (34.14b) says that the component of the Ekman velocity along the pressure isobar is directed opposite to the geostrophic velocity. We provide an example of an Ekman velocity in Figure 34.2 for the northern hemisphere.

Bringing all pieces together leads to the components for the total velocity, $\boldsymbol{u} = \boldsymbol{u}_{\rm g} + \boldsymbol{u}_{\rm e}$, and its squared magnitude

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm g} = -\frac{1}{f \rho_0} \frac{\partial p}{\partial n} \qquad \text{geostrophic velocity (aligned along isobars)} \tag{34.15a}$$

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u} = \hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm g} \left[\frac{f^2}{f^2 + \gamma^2} \right] \qquad \text{isobaric velocity component} \tag{34.15b}$$

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{u} = (\gamma / |f|) \, \hat{\boldsymbol{s}} \cdot \boldsymbol{u} \qquad \text{normal velocity component} \tag{34.15c}$$

$$(\hat{\boldsymbol{s}} \cdot \boldsymbol{u})^2 + (\hat{\boldsymbol{n}} \cdot \boldsymbol{u})^2 = \frac{(\hat{\boldsymbol{s}} \cdot \boldsymbol{u}_{\rm g})^2}{1 + (\gamma / f)^2} \qquad \text{horizontal kinetic energy per mass.} \tag{34.15d}$$

The cross-isobar flow (equation (34.15c)) is directly driven by the Rayleigh drag, and it is directed down the normal pressure gradient so long as the flow has a positive projection onto the tangent direction

$$\hat{\boldsymbol{s}} \cdot \boldsymbol{u} > 0 \Longrightarrow \hat{\boldsymbol{n}} \cdot \boldsymbol{u} > 0. \tag{34.16}$$

When flow is moving counter-clockwise around a low pressure in the northern hemisphere, where $\hat{\boldsymbol{n}}$ points towards the low pressure center, then Rayleigh drag causes the fluid to spiral into the low pressure center. Conversely, when flow is moving clockwise around a high pressure, with $\hat{\boldsymbol{n}}$ pointing

away from the high pressure center, then Rayleigh drag causes the fluid to spiral away from the high pressure center. We depict these cases in Figure 34.2. Furthermore, equation (34.15d) shows that when $\gamma \neq 0$ the magnitude of the total flow is reduced relative to the geostrophic flow, thus reflecting the dissipation of kinetic energy arising from Rayleigh drag.[2]

34.2.5 Horizontal spiral plus vertical rising/sinking

Thus far, we have focused on the horizontal spiral motion as shown in Figure 34.2. Through continuity we infer a corresponding vertical motion induced by the convergence of mass into the low pressure center and the divergence of mass away from the high pressure center. Figure 34.3 illustrates the vertical motion in a bottom Ekman boundary layer of either the atmosphere or ocean whereby mass rises above a low pressure center in response to the horizontal convergence of mass in the Ekman layer. Conversely, mass diverges from the high pressure Ekman layer, with this divergence inducing a sinking motion over the high pressure to replace the diverging mass. In subsequent sections of this chapter we develop the formalism needed to compute the mass transport into and out of the Ekman boundary layer.

FIGURE 34.3: Illustrating the three-dimensional flow associated with Ekman layers in the northern hemisphere ($f > 0$) next to a bottom boundary. Left panel: flow spiralling into a low pressure center creates convergence of mass into the Ekman layer. Mass continuity means that flow must vertically leave the Ekman layer to thus enter the interior fluid above. Right panel: flow spiralling away from a high pressure center creates divergence of mass away from the Ekman layer. Mass continuity means that flow must vertically sink into the Ekman layer from above. The Ekman layer thickness is denoted by δ^{Ekman} (Section 34.3). An analogous picture holds for the surface Ekman layer in the ocean, yet with the Ekman layer at the top of the column rather than the bottom.

34.2.6 Further study

Our discussion of Ekman velocity arising from Rayleigh drag follows a similar treatment in Section 7.4 of *Marshall and Plumb* (2008).

34.3 Ekman number and Ekman layer thickness

Friction that is most prominent near surface and bottom boundaries arises from vertical shears in the horizontal velocity, with shears leading to flow instabilities and the development of turbulence and associated turbulent friction. There is no deductive theory for turbulent friction so we must rely on empirical expressions. These expressions are typically based on a Laplacian viscous

[2]See Section 27.3.3 for more on frictional dissipation of kinetic energy.

operator, partly motivated by the form arising from kinetic theory of gases briefly mentioned in Chapter 17. Most notably, this operator supports the development of a boundary layer through maintenance of both the no-slip (homogeneous Dirichlet) and stress (Neumann) boundary conditions.

34.3.1 Laplacian vertical friction

We introduced the Laplacian friction operator in Section 26.8.6 when studying stress in fluids. The Laplacian friction operator considered here is given just in terms of the vertical shears of horizontal stresses

$$\boldsymbol{F}^{\text{viscous}} = \frac{1}{\rho_0}\frac{\partial \boldsymbol{\tau}}{\partial z} = \frac{\partial}{\partial z}\left[\nu^{\text{eddy}}\,\frac{\partial \boldsymbol{u}}{\partial z}\right], \tag{34.17}$$

with $\nu^{\text{eddy}} > 0$ a turbulent kinematic viscosity with dimensions $\text{L}^2\ \text{T}^{-1}$. This form of the friction operator emulates the Laplacian operator representing molecular viscous friction (equation (26.87)). It is also the form most commonly used in theoretical and numerical models that focus on boundary layers where rotation is important.

Expanding the derivative in equation (34.17) reveals that the Laplacian friction is nonzero where there is curvature in the vertical profile of the horizontal velocity, and where there is vertical dependence to the viscosity and velocity

$$\boldsymbol{F}^{\text{viscous}} = \frac{\partial \nu^{\text{eddy}}}{\partial z}\,\frac{\partial \boldsymbol{u}}{\partial z} + \nu^{\text{eddy}}\,\frac{\partial^2 \boldsymbol{u}}{\partial z^2}. \tag{34.18}$$

The turbulent viscosity generally has a vertical dependence, with larger values in the boundary layer where turbulence is most energetic. This form of the friction preferentially acts on velocity exhibiting nontrivial vertical structure, thus acting to smooth any vertical dependence. In Section 64.4 we discuss further mathematical properties of Laplacian friction.

34.3.2 Non-dimensionalization

We non-dimensionalize the equations to isolate non-dimensional numbers affecting the flow regime. In particular, we identify the Ekman number as a measure of the importance of friction relative to rotation, with friction important where the Ekman number is order unity or larger, and unimportant where the Ekman number is much smaller than unity.[3]

We make use of the following scales and associated non-dimensional quantities

$$(x, y) = L\,(\hat{x}, \hat{y}) \qquad z = H\,\hat{z} \qquad (u, v) = U\,(\hat{u}, \hat{v}) \qquad f = f_0\,\hat{f} \qquad p = P\,\hat{p} \tag{34.19}$$

where the hat terms are non-dimensional,[4] and we introduced typical scales for horizontal length (L), vertical length (H), velocity (U), Coriolis parameter (f_0), and pressure (P). For the pressure scale we assume it follows geostrophic scaling so that it can be writen[5]

$$P = f_0\,\rho_0\,U\,L. \tag{34.20}$$

Inserting the relations (34.19) into equation (34.1) leads to the non-dimensional frictional geostrophic

[3]For flows unaffected by rotation, the Reynolds number is the key non-dimensional number (Section 26.9) determining where viscous friction is important.

[4]In Section 33.2.1 we defined $\hat{\boldsymbol{u}}$ as the unit vector pointing along the trajectory of a fluid element. In contrast, we here let $\hat{\boldsymbol{u}}$ be the non-dimensional horizontal velocity.

[5]Recall that in Section 30.2.3 we considered pressure in a non-rotating system to scale according to the dynamical pressure scale, U^2, where U is a horizontal flow speed scale.

equation

$$\hat{\boldsymbol{f}} \times \hat{\boldsymbol{u}} = -\hat{\nabla}\hat{p} + \frac{\boldsymbol{F}}{f_0\, U}. \tag{34.21}$$

34.3.3 Defining the Ekman number and layer thickness

The *Ekman number* is a non-dimensional measure of the relative importance of the frictional acceleration due to vertical shears versus the Coriolis acceleration

$$\mathrm{Ek} = \frac{\text{frictional acceleration from vertical shears}}{\text{Coriolis acceleration}}. \tag{34.22}$$

The Ekman number increases when there is more boundary layer turbulence, in which case the eddy viscosity, ν^{eddy}, is large relative to its small values in the interior region outside of the boundary layer. Additionally, the Ekman number increases when moving towards the equator, where the Coriolis parameter reduces.[6]

For the viscous stress form of Laplacian vertical frictional acceleration (equation (34.17))

$$\boldsymbol{F}^{\mathrm{viscous}} = \frac{\nu^{\mathrm{eddy}}\, U}{H^2}\, \frac{\partial^2 \hat{\boldsymbol{u}}}{\partial \hat{z}^2}, \tag{34.23}$$

the Ekman number is given by

$$\mathrm{Ek} = \frac{\nu^{\mathrm{eddy}}}{f_0\, H^2}. \tag{34.24}$$

If we take the vertical scale, H, equal to the length scale over which interior flow processes occur, then the Ekman number will be very small, even if the eddy viscosity is relatively large. In this case we conclude that friction is negligible, as indeed it is for many purposes where the boundary layer is not of concern.

However, the Ekman number multiplies the highest derivative in equation (34.21). So setting the Ekman number to zero represents a *singular limit*, whose mathematial meaning is that we change the order of the differential equation when setting $\mathrm{Ek} = 0$. Reducing the order of the differential equation then means we can only satisfy a reduced number of boundary conditions relative to the $\mathrm{Ek} > 0$ case. In particular, with $\mathrm{Ek} = 0$ we can no longer satisfy the no-slip condition at the solid-fluid boundary. In contrast, with any non-zero value of $\mathrm{Ek} > 0$, viscosity will drag the flow to zero towards the boundary within a *boundary layer* where friction is leading order. We expect a boundary layer to form within a boundary layer thickness, $H = \delta^{\mathrm{Ekman}}$, in which the Ekman number is order unity so where friction is of leading order importance

$$H = \delta^{\mathrm{Ekman}} \Longrightarrow \mathrm{Ek} = \frac{\nu^{\mathrm{eddy}}}{f_0\, (\delta^{\mathrm{Ekman}})^2} = 1. \tag{34.25}$$

Turning this equation around we see that the vertical scale, δ^{Ekman}, defines the viscous Ekman boundary layer thickness as a function of the eddy viscosity and Coriolis parameter

$$\mathrm{Ek} = 1 \Longrightarrow \delta^{\mathrm{Ekman}} = \delta^{\mathrm{viscous}} = \sqrt{\nu^{\mathrm{eddy}}/f_0}. \tag{34.26}$$

34.3.4 Estimates for the vertical eddy viscosity

The eddy viscosity is not readily available from direct measurements or first principles theory. However, measuring the boundary layer thickness provides a means to infer a bulk viscosity for

[6] When getting very close to the equator, our assumption of a frictional geostrophic balance breaks down so that other terms in the momentum equation, such as advection, become important.

the boundary layer

$$\nu^{\text{eddy}} = f_0 \, (\delta^{\text{Ekman}})^2. \tag{34.27}$$

In the atmosphere, the boundary layer thickness is order 1000 m, so that at mid-latitudes, with $f_0 = 10^{-4}$ s^{-1}, we expect

$$\nu^{\text{eddy}}_{\text{atmos}} \sim 10^2 \text{ m}^2 \text{ s}^{-1}. \tag{34.28}$$

In the ocean, the upper ocean boundary layer depth, outside of the deep convection regions, is roughly 50 m, in which case

$$\nu^{\text{eddy}}_{\text{ocean}} \sim 0.25 \text{ m}^2 \text{ s}^{-1}. \tag{34.29}$$

34.4 Ocean surface Ekman layer

It is possible to establish integrated mass transport properties of the Ekman layer even without specifying details of the friction (i.e., the viscosity) or the stratification. The key ingredient is the boundary stress. This stress is commonly estimated for the surface ocean given information about the wind speed and atmospheric stratification. Hence, Ekman theory has found much application to studies of the wind-driven ocean circulation, with the integrated properties the most consequential results from Ekman theory. We here focus on the ocean surface Ekman layer and then consider bottom Ekman boundaries for the atmosphere and ocean in Section 34.5.

Before starting, we emphasize that the stress is the key ingredient in computing properties of the Ekman layer. And yet, determining the stress is a nontrivial exercise in boundary layer physics, which is outside our scope. Additionally, the turbulent boundary stress exchanged between the fluid and its boundary (either another fluid, ice, or the solid earth) arises within Ekman boundary layers, where flow spirals relative to the interior geostrophic flow. So the boundary stress is generally rotated some amount relative to the interior geostrophic flow. We consider an analytic example of this rotation when studying the bottom Ekman layer in Section 34.5. For now, we simply recognize that the story is relatively simple when assuming the stress is given, but the stress itself can be rather difficult to accurately determine.

34.4.1 Horizontal mass transport within the Ekman layer

FIGURE 34.4: Ekman layer at the ocean surface, defined for vertical position $\eta_e(x, y, t) \leq z \leq \eta(x, y, t)$, with η_e specifying the Ekman layer bottom and η the free surface vertical position. Boundary stress from winds and/or sea ice imparts horizontal momentum to the upper ocean that is transmitted throughout the Ekman layer via the vertical divergence of turbulent horizontal shear stresses. As studied in Section 34.6, there is also a bottom Ekman layer created by stresses active next to the ocean bottom.

We are concerned with the mass budget for the ocean surface Ekman layer sitting between the Ekman layer bottom and the ocean free surface

$$\eta_{\mathrm{e}}(x,y,t) \leq z \leq \eta(x,y,t), \tag{34.30}$$

as depicted in Figure 34.4. Knowledge of the mass budget has implications for how mechanical energy imparted to the boundary layer drives circulation well within the interior of the ocean. This transport and associated circulation are how Ekman mechanics, limited to the boundary layer, affect large-scale ocean circulation throughout the fluid column.

Integrating the horizontal Ekman balance (34.4) over the vertical scale of the Ekman layer leads to

$$\boldsymbol{M}_{\mathrm{e}} = \int_{\eta_{\mathrm{e}}}^{\eta} \rho_0 \, \boldsymbol{u}_{\mathrm{e}} \, \mathrm{d}z \Longrightarrow f \, \hat{\boldsymbol{z}} \times \boldsymbol{M}_{\mathrm{e}} = \int_{\eta_{\mathrm{e}}}^{\eta} \rho_0 \, \boldsymbol{F} \, \mathrm{d}z, \tag{34.31}$$

with $\boldsymbol{M}_{\mathrm{e}}$ the vertically integrated ageostrophic horizontal mass transport within the Ekman boundary layer. Assuming friction to be in the form of a vertical stress divergence as in equation (34.17) leads to the horizontal Ekman mass transport

$$\boldsymbol{M}_{\mathrm{e}} = -f^{-1} \, \hat{\boldsymbol{z}} \times \, [\boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_{\mathrm{e}})]. \tag{34.32}$$

Stress at the bottom of the Ekman layer, $\boldsymbol{\tau}(\eta_{\mathrm{e}})$, matches to the stress in the ocean interior. The stress in the fluid interior is generally much smaller than stress in the turbulent upper ocean surface, $\boldsymbol{\tau}(\eta)$, so that we can neglect $\boldsymbol{\tau}(\eta_{\mathrm{e}})$ when computing the mass transport. We are thus led to the expression for the surface stress induced ageostrophic horizontal mass transport within the upper ocean Ekman layer

$$\boldsymbol{M}_{\mathrm{e}} = -f^{-1} \, \hat{\boldsymbol{z}} \times \, \boldsymbol{\tau}(\eta) = f^{-1} \, [\hat{\boldsymbol{x}} \, \tau^{y}(\eta) - \hat{\boldsymbol{y}} \, \tau^{x}(\eta)]. \tag{34.33}$$

The surface stress induced mass transport given by equation (34.33) is very useful in practice. Notably, we do not need to know the thickness of the Ekman layer. Rather, the mass transport is determined solely by the surface boundary stress.[7] Furthermore, the horizontal mass transport within the Ekman layer is directed at right angles to the surface stress, as depicted in Figure 34.5, with mass transport to the right of the surface stress in the northern hemisphere and to the left in the southern hemisphere.

34.4.2 Example Ekman mass transports

Consider an example with an eastward zonal boundary stress, $\boldsymbol{\tau}(\eta) = |\tau| \, \hat{\boldsymbol{x}}$ (i.e., westerly winds). In this case, the Ekman transport in the upper ocean is meridional

$$\boldsymbol{M}_{\mathrm{e}} = -(|\tau|/f) \, \hat{\boldsymbol{y}}, \tag{34.34}$$

which points equatorward in both hemispheres. Conversely, in the equatorial region where winds are predominantly from the east (easterly winds) so that $\boldsymbol{\tau}(\eta) = -|\tau| \, \hat{\boldsymbol{x}}$, then the horizontal Ekman mass transport causes waters to move poleward away from (diverge from) the equator. Mass continuity is then satisfied by upwelling waters along the equator within the Ekman layer. We sketch the elements of this flow in Figure 34.6. Exercise 34.1 considers an analogous situation

[7] As noted at the start of this section, determining the stress, $\boldsymbol{\tau}(\eta)$, transferred to the ocean requires information about the boundary layer processes in both the ocean and the adjoining media (either the atmosphere or cryosphere). Nevertheless, by expressing the mass transport, $\boldsymbol{M}_{\mathrm{e}}$, in terms of the boundary stress provides a clear delineation of the causes for boundary layer transport. It has thus offered an important foundation for theories of wind-driven ocean circulation.

FIGURE 34.5: Horizontal transport integrated over the thickness of the surface ocean Ekman layer in the region $\eta_e(x, y, t) \leq z \leq \eta(x, y, t)$. The net mass transport is directed perpendicular to the boundary stress, oriented to the right in the northern hemisphere and to the left in the southern hemisphere. Here, the boundary stress, $\boldsymbol{\tau}$, is shown directed to the north so that in the northern hemisphere ($f > 0$), the vertically integrated horizontal Ekman transport, $\boldsymbol{M}_e$, is to the east. This perpendicular mass transport is the result of the vertically spiralling Ekman flow. The Ekman mass transport resulting from boundary stress is independent of the assumptions made about ocean friction within the ocean boundary layer, and it is independent of the stratification assumed for the Ekman layer.

for a channel in the southern hemisphere, thus illustrating a basic feature of the wind-driven overturning circulation in the Southern Ocean.

FIGURE 34.6: Easterly winds along the equator drive poleward horizontal mass transport within the upper ocean Ekman layer, as per equation (34.34). Furthermore, as discussed in Section 34.4.3, a steady state Ekman layer mass budget is typically realized by the upwelling of interior waters into the Ekman layer.

A second example concerns the case of a wind stress with a component aligned with a coastline as depicted in Figure 34.7. When the horizontal Ekman mass transport is directed away from the coast, a steady mass balance in the Ekman layer is associated with the upwelling of waters from beneath the Ekman layer. Conversely when the horizontal mass transport is directed toward the coast, steady mass balance is realized by coastal downwelling. This process is very important for coastal physical and biological oceanography.

34.4.3 Mass budget for the Ekman layer

As seen in Figure 34.3, the horizontal transport of fluid within the Ekman layer induces a vertical transport into or out of the Ekman layer. To obtain a mathematical expression for the vertical transport, integrate the continuity equation $\nabla \cdot \boldsymbol{v} = 0$ over the vertical extent of the Ekman layer

$$\frac{\partial}{\partial x}\left[\int_{\eta_e}^{\eta} u \,\mathrm{d}z\right] + \frac{\partial}{\partial y}\left[\int_{\eta_e}^{\eta} v \,\mathrm{d}z\right] + [w(\eta) - \boldsymbol{u}(\eta)\cdot\nabla\eta] - [w(\eta_e) - \boldsymbol{u}(\eta_e)\cdot\nabla\eta_e] = 0. \tag{34.35}$$

For a Boussinesq fluid, the kinematic boundary condition at the ocean free surface is given by equation (22.5)

$$w + \frac{Q_m}{\rho_0} = \frac{\partial \eta}{\partial t} + \boldsymbol{u}\cdot\nabla\eta \qquad \text{at} \;\; z = \eta(x, y, t). \tag{34.36}$$

FIGURE 34.7: Wind stresses with a component that is parallel to coastlines lead to horizontal mass transport away from or towards the coast. Mass continuity then leads to coastal upwelling or downwelling of waters into or out of the Ekman layer. Here we depict the various scenarios for the northern hemisphere (top row) and southern hemisphere (bottom row), with the gray regions representing land, the black vectors the wind stresses, and the red arrows the horizontal wind induced mass transports in the Ekman layer. This figure is adapted from Figure 4-24 of *von Arx* (1962).

Similarly, at the bottom of the Ekman layer we measure the volume transport through this layer by computing the dia-surface transport, $w^{(\dot{\eta}_e)}$, according to equation (60.38)

$$w^{(\dot{\eta}_e)} = w - (\partial_t z + \boldsymbol{u} \cdot \nabla z) \qquad \text{at} \;\; z = \eta_e(x, y, t). \tag{34.37}$$

The sign convention is such that $w^{(\dot{\eta}_e)} > 0$ means that volume enters (entrains into) the surface Ekman layer through its base, whereas $w^{(\dot{\eta}_e)} < 0$ means that volume leaves (detrains from) the surface Ekman layer base.

Using the kinematic boundary conditions (34.36) and (34.37) in the vertically integrated volume budget (34.35), and rearranging, leads to the Ekman layer mass budget

$$\rho_0 \, w^{(\dot{\eta}_e)} + Q_m = \rho_0 \, \partial h_e / \partial t + \nabla \cdot \boldsymbol{M}. \tag{34.38}$$

In this equation we wrote

$$h_e = \eta - \eta_e \tag{34.39}$$

for the thickness of the Ekman layer and

$$\boldsymbol{M} = \rho_0 \int_{\eta_e}^{\eta} \boldsymbol{u} \, dz \tag{34.40}$$

for the Ekman layer integrated horizontal mass transport. As a check on the above manipulations, let the Ekman layer go to the ocean bottom (so that $w^{(\dot{\eta}_e)} = 0$ and $\eta_e = \eta_b$), in which case the mass budget equation (34.38) correctly reduces to the kinematic free surface equation for the full ocean column as given by equation (22.81)

$$\rho_0 \frac{\partial \eta}{\partial t} = Q_m - \rho_0 \, \nabla \cdot \boldsymbol{U}, \tag{34.41}$$

with $\boldsymbol{U} = \int_{\eta_b}^{\eta} \boldsymbol{u} \, dz$ the vertically integrated horizontal velocity.

FIGURE 34.8: Mass budget over the surface Ekman layer of the ocean, with contributions from the surface mass flux, $Q_{\rm m}$, flux through the bottom of the layer, $w^{(\dot{\eta}_{\rm e})}$, and vertically integrated horizontal flux, $\boldsymbol{M}$, within the layer. If there are any imbalances then the layer thickness will have a nonzero time tendency, $\partial h_{\rm e}/\partial y \neq 0$. Our sign convention is such as $w^{(\dot{\eta}_{\rm e})} > 0$ corresponds to water entering (entraining into) the Ekman layer (vertically upward motion) through the Ekman layer base at $z = \eta_{\rm e}$, and likewise $Q_{\rm m} > 0$ correspondes to water entering the Ekman layer through the free surface at $z = \eta$. Entrainment through the base of the Ekman layer is referred to as *Ekman suction* or *Ekman upwelling*. The opposite case is referred to as *Ekman pumping* or *Ekman downwelling* when water leaves the Ekman layer and enters the ocean interior.

The horizontal mass transport given by equation (34.40) has a contribution from both the Ekman transport and remaining processes, such as geostrophic flow and ageostrophic flows not associated with Ekman. We write this mass transport in the form

$$\boldsymbol{M} = \boldsymbol{M}_{\rm e} + \boldsymbol{M}_{\rm other}. \tag{34.42}$$

The horizontal Ekman transport is determined by the boundary stress according to equation (34.33), with its divergence given by

$$\nabla \cdot \boldsymbol{M}_{\rm e} = \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)]. \tag{34.43}$$

This result brings the Ekman layer mass budget (34.38) into the form

$$\rho_0 \, w^{(\dot{\eta}_{\rm e})} + Q_{\rm m} = \rho_0 \, \frac{\partial h_{\rm e}}{\partial t} + \nabla \cdot \boldsymbol{M}_{\rm other} + \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)]. \tag{34.44}$$

The left hand side measures the mass transport crossing the bottom of the Ekman layer, $\rho_0 \, w^{(\dot{\eta}_{\rm e})}$, plus the transport crossing the free surface, $Q_{\rm m}$. This transport balances a time change in the Ekman layer thickness (first right hand side term), plus the horizontal divergence of mass within the layer (associed with non-Ekman and Ekman). A steady state Ekman layer thickness, $\partial h_{\rm e}/\partial t = 0$, is realized if the horizontal divergence of mass within the Ekman layer is exactly balanced by mass entering the Ekman layer through the top and/or bottom of the layer. We illustrate this budget in Figure 34.8. For example, in the equatorial case of Figure 34.6, the diverging horizontal Ekman layer flow induced by easterly winds (poleward Ekman transport on both sides of the equator) is balanced by water upwelling into the Ekman layer through the base, $w^{(\dot{\eta}_{\rm e})} > 0$, along with a generally smaller effects from surface mass fluxes through $Q_{\rm m}$ and possible other contributions through $\nabla \cdot \boldsymbol{M}_{\rm other}$.

FIGURE 34.9: Plan view depicting the steady state horizontal and vertical transport in the surface ocean Ekman layer (ignoring the possible transport across the ocean surface from Q_{m}). The left column shows horizontal wind-induced convergence in the Ekman layer that induces vertical pumping/downwelling, where $\nabla \cdot \boldsymbol{M}_{\mathrm{e}} = \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)] < 0$. The right column shows the horizontal divergence within the Ekman layer that is balanced by suction/upwelling, where $\nabla \cdot \boldsymbol{M}_{\mathrm{e}} = \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)] > 0$. The top row is for the northern hemisphere, with $f > 0$, and the bottom row is for the southern hemisphere. The red arrows depict the sense for the induced geostrophic circulation in the interior just below the Ekman layer. Note that the horizontal Ekman transport is to the right of the red circulating flow in the northern hemisphere and to the left in the southern. Ekman pumping is associated with anti-cyclonic circulation (clockwise in the northern hemisphere and anti-clockwise in southern hemisphere). In contrast, Ekman suction is associated with cyclonic circulation. The circulation is supported by pressure gradients, with high pressure in regions of Ekman convergence, $\nabla \cdot \boldsymbol{M}_{\mathrm{e}} < 0$, due to the accumulation of mass towards the center, thus giving rise to anti-cyclonic geostrophic flow in the interior. The opposite holds for regions of Ekman divergence, $\nabla \cdot \boldsymbol{M}_{\mathrm{e}} > 0$, where water leaves the region thus leaving a low pressure center and inducing a cyclonic interior geostrophic flow.

34.4.4 Ekman layer coupled to the geostrophic interior

The effects from boundary stress curl in equation (34.44) warrant particular attention whereby

$$\rho_0 \, w^{(\dot{\eta}_{\mathrm{e}})}_{\mathrm{Ekman}} \equiv \nabla \cdot \boldsymbol{M}_{\mathrm{e}} = \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)]. \tag{34.45}$$

The stress curl, as well as changes in f on the sphere, drive vertical motion through the base of the Ekman layer. The flow crossing the Ekman layer boundary acts to stretch or compress vertical fluid columns in the adjoining fluid interior. Interior fluid columns in a rotating fluid are stiffened through the effects of Taylor-Proudman (Section 32.5.3). From our understanding of vorticity (studied in Chapter 41), particularly the notions of vortex stretching, we see that the Ekman induced stretching/compression of interior fluid columns leads to a change in vorticity of the fluid interior, and can then lead to meridional motion due to the beta effect (see discussion of Sverdrup balance in Section 32.5.4).

Consider an example with $\nabla \cdot \boldsymbol{M}_{\mathrm{e}} = \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)] > 0$, so that winds induce a divergence within the Ekman layer. In a steady state, the interior flow accommodates this Ekman layer mass

divergence by upwelling water through the Ekman layer base, $w^{(\dot{\eta}_e)} > 0$. This process of entraining interior water into the Ekman layer is known as *Ekman suction* or *Ekman upwelling*. For the opposite case with $\hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}/f)] < 0$, water leaves (detrains) from the Ekman layer and moves into the interior. Water detraining from the Ekman layer is known as *Ekman pumping* or *Ekman downwelling*. As water diverges it produces a local low pressure so that the induced flow in the geostrophic interior is cyclonic around a region of Ekman divergence/upwelling. Conversely, the induced interior geostrophic flow is anti-cyclonic around a region of Ekman convergence/downwelling. Figure 34.9 provides an illustration for the variety of cases found in the northern and southern hemispheres.

In the language of vorticity, developed in Part VII of this book, Ekman upwelling with $w^{(\dot{\eta}_e)} > 0$ leads to vortex stretching of interior fluid columns, whereas Ekman downwelling with $w^{(\dot{\eta}_e)} < 0$ squashes the interior fluid columns. Vertical stiffening through Taylor-Proudman within the geostrophic interior, coupled to Ekman induced vortex stretching/squashing, makes what happens within the Ekman boundary layer of primary importance to the interior geostrophic flow. This boundary-interior coupling forms a key mechanism for how mechanical forcing from surface boundary stress creates the *wind driven* ocean circulation. It is notable that the coupling between boundary layer and interior flow is absent from non-rotating boundary layer flows. In Figure 34.10 we offer a highly idealized schematic of the circulation implied by Ekman dynamics in a homogeneous fluid on an f-plane, thus illustrating the coupling of the upper surface Ekman layer to the geostrophic interior and then to the bottom Ekman layer. We also discuss the *geostrophic Sverdrup balance* in Section 45.5, which builds on the ideas in this section.

FIGURE 34.10: Schematic ocean Ekman gyre circulation in a rectangular box in the northern hemisphere on an f-plane as forced by an anti-cyclonic wind stress curl. The wind stress curl causes fluid to pile up in the center of the gyre and develop an anti-cyclonic flow. The horizontal convergence of mass towards the center of the gyre leads to downwelling into the gyre interior below the Ekman layer (as per the upper left panel of Figure 34.9). This downwelling water enters the geostrophic interior and further into the bottom Ekman layer. As discussed in Section 34.5, the downwelling water in the bottom Ekman layer causes a horizontal divergence of mass. Assuming the domain has fixed vertical side walls, continuity requires an upwelling along the outer portion of the gyre. If the wind stress is symmetric about the center of the domain, then so is the flow. However, as studied in Section 40.7, the axial symmetry is broken on the β-plane, in which flow is stronger on the western side of the gyre even if the wind remains symmetric about the domain center. This figure is adapted from Figure 6-15 of *von Arx* (1962).

34.4.5 Further study

The following videos offer visuals to help develop further intuition for Ekman boundary flows.

- This 4-minute video from Science Primer provides an overview of how Ekman transport affects ocean circulation features near the coast and in open ocean gyres.

- This video from MIT Earth, Atmospheric, and Planetary Sciences illustrates the spiral flow found within an Ekman layer as realized in a rotating tank experiment.

- This video from the UCLA SpinLab, near the 18 minute mark, shows how Ekman transport helps to explain the garbage patches found near the center of the ocean's sub-tropical gyres.

- This video from the University of Chicago, starting near the 23 minute mark, provides examples of Ekman layers in a rotating tank. The other portions of this video exhibit many other novel aspects of rotating fluids and is highly recommended.

34.5 Bottom Ekman layer

In this section we study the mechanics of a bottom Ekman boundary layer. For the mass transport, we merely translate the results from the upper ocean Ekman layer considered in Section 34.4, whereby the mass transports are specified by the bottom boundary stress. We go further in this analysis by also providing an analytic expression for the velocity profile within the Ekman layer, with the velocity profile allowing us to diagnose the bottom boundary stress according to the Neumann boundary condition placed on the horizontal velocity (equation (34.58) below).

34.5.1 Horizontal mass transport within the Ekman layer

Turning the derivation from Section 34.4.1 upside-down leads to a bottom horizontal Ekman mass transport

$$\boldsymbol{M}_{\mathrm{e}} = \int_{\eta_{\mathrm{b}}}^{\eta_{\mathrm{e}}} \rho_0 \, \boldsymbol{u}_{\mathrm{e}} \, \mathrm{d}z = -f^{-1} \, \hat{\boldsymbol{z}} \times [\boldsymbol{\tau}(\eta_{\mathrm{e}}) - \boldsymbol{\tau}(\eta_{\mathrm{b}})] \approx f^{-1} \, \hat{\boldsymbol{z}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}}). \tag{34.46}$$

Note the sign swap relative to the upper Ekman layer transport in equation (34.33). Hence, the Ekman transport is directed to the left of the bottom stress in the northern hemisphere and to the right in the southern hemisphere. In general, care must be exercised when determining the stress, with examples given below, including an analytic example given in Section 34.5.3. In general, the stress is not aligned with the interior geostrophic flow, but instead is rotated by some amount.

Atmosphere-ocean Ekman layers

Consider the case where the bottom Ekman layer is the bottom of the atmosphere sitting over the ocean. The stress imparted to the bottom of the atmosphere is equal in magnitude yet oppositely directed to the stress acting on the upper ocean.[8] Hence, the frictional stress induced mass transport (34.33) for the upper ocean Ekman layer is equal and opposite to the frictional stress induced mass transport in the atmosphere Ekman layer

$$\boldsymbol{M}_{\mathrm{e}}^{\mathrm{ocn}} = -\boldsymbol{M}_{\mathrm{e}}^{\mathrm{atm}} \Longrightarrow \boldsymbol{M}_{\mathrm{e}}^{\mathrm{ocn}} + \boldsymbol{M}_{\mathrm{e}}^{\mathrm{atm}} = 0. \tag{34.47}$$

Since the density of the atmosphere and ocean are quite different, the equal Ekman mass transports correspond to very different volume transports.

[8] Recall our discussion of stress in Chapter 26, whereby stress on one side of an interface matches that on the other, which is a result following from Newton's third law.

Ocean-solid earth or atmosphere-solid earth Ekman layer

Consider the bottom Ekman layer next to the solid earth. Just like the atmosphere-ocean case, the stress imparted by the fluid on the earth is equal and opposite to the stress by the earth on the fluid. It is not generally simple to determine this stress, though we provide an example in Section 34.5.3 based on assuming information about the vertical viscosity profile within the boundary layer. From that example, we see that the stress is not directly aligned with the interior geostrophic flow just above the boundary layer. Instead, the stress is $\pi/4$ rotated to the left of the interior flow. The rotation is due to the spiralling structure of the boundary layer flow that gives rise to the stress.

34.5.2 Mass budget for the bottom Ekman layer

Following the derivation of the Ekman layer mass budget in Section 34.4.3, and assuming no mass enters through the solid earth, we are led to the mass budget for the bottom Ekman boundary layer[9]

$$\rho_0 \, w^{(\dot{\eta}_{\mathrm{e}})} = \rho_0 \, \frac{\partial h_{\mathrm{e}}}{\partial t} - \nabla \cdot \boldsymbol{M} \tag{34.48}$$

where $z = \eta_{\mathrm{e}}(x, y, t)$ is the vertical position for the top of the bottom Ekman layer, and

$$h_{\mathrm{e}} = \eta_{\mathrm{e}} - \eta_{\mathrm{b}} \tag{34.49}$$

is the Ekman layer thickness. For a steady state, the budget equation (34.48) says that the horizontal convergence of mass into the bottom Ekman boundary layer leads to a detrainment of mass from the Ekman layer into the interior fluid above (upwelling). Conversely, when fluid horizontally diverges from the bottom Ekman layer there is a balance from an entrainment (downwelling) of fluid from the interior into the Ekman layer. This orientation for the mass transport is illustrated in Figure 34.3 as part of our earlier discussion.

34.5.3 An analytic bottom Ekman spiral velocity

When studying the bottom boundary layer for the atmosphere or the surface boundary layer for the ocean, we are generally afforded an estimate of the frictional boundary stress, $\boldsymbol{\tau}(\eta)$. In turn, we can estimate the boundary stress induced mass transport and its divergence, and we can do so without making assumptions about the density profile or viscous stresses within the boundary layer. However, this estimate is less directly accessible for the ocean bottom Ekman layer, where we need $\boldsymbol{\tau}(\eta_{\mathrm{b}})$ to determine the mass transport. We here take an alternative approach that produces an analytic profile for the velocity within the Ekman layer, so long as we know the viscosity within the boundary layer. Knowing the velocity profile then affords an estimate of the boundary stress. This approach requires a few assumptions that are not always met, in particular it requires the viscosity. Even so, it provides physical insights that further our understanding of Ekman mechanics thus motivating the analysis.

Physical configuration

We assume flow above the boundary layer is geostrophic and supported by a prescribed vertically independent pressure gradient

$$f \, \rho_0 \, \boldsymbol{u}_g = \hat{\boldsymbol{z}} \times \nabla p. \tag{34.50}$$

[9] Note the sign swap in the budget (34.48) in front of the horizontal transport term as compared to the surface boundary layer mass budget (34.38).

FIGURE 34.11: A southward geostrophic flow in the northern hemisphere ($f > 0$) induced by an eastward pressure gradient acceleration (low pressure to the east; $\partial p/\partial x < 0$) that balances a westward Coriolis acceleration.

A specific example is given by Figure 34.11, where a southward geostrophic flow in the northern hemisphere has an eastward pressure gradient acceleration (low pressure to the east) balanced by a westward Coriolis acceleration.

For flow within the boundary layer, viscous stresses exchange horizontal momentum vertically between the inviscid interior and the bottom no-slip condition. This viscous exchange slows the boundary layer velocity relative to the interior velocity above the boundary layer. Since the pressure gradient is assumed to be vertically independent and prescribed, the slower velocity within the boundary layer means that the Coriolis acceleration is unable to balance the pressure gradient acceleration. This imbalance between pressure acceleration and Coriolis acceleration leads to a down pressure gradient component to the boundary layer velocity. As a result, the velocity spirals downward toward the bottom.

The key assumptions required to produce an analytic Ekman spiral velocity are: (i) the fluid within the Ekman layer has a constant density, ρ_0; (ii) the Coriolis parameter is a constant as per the f-plane; (iii) the prescribed pressure gradient is vertically independent so that the associated geostrophic velocity is vertically independent; (iv) the eddy viscosity is constant within the boundary layer and zero in the interior region above the boundary layer; (v) the flow is steady. The homogeneous density assumption is motivated by the rather small vertical scale of the bottom Ekman layer (tens of meters) relative to the horizontal scales over which density varies in the ocean bottom (tens to hundreds of kilometers). A constant viscosity is not always realistic since the turbulent viscosity is generally inhomogeneous within boundary layers. Even so, by assuming sufficient time for statistics to becone stationary we can expect to make good use of the time averaged viscosity.

Velocity profile within the Ekman layer

Bringing the above assumptions into the frictional geostrophic equations (34.1) leads to

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -(1/\rho_0)\,\nabla p + \nu^{\rm eddy}\,\partial_{zz}\,\boldsymbol{u} \qquad \text{frictional geostrophy} \tag{34.51a}$$

$$\partial_z(\nabla_z p) = 0 \qquad z\text{-independent horizontal pressure gradient} \tag{34.51b}$$

$$\boldsymbol{u}(\eta_{\rm b}) = 0 \qquad \text{no-slip bottom boundary condition} \tag{34.51c}$$

$$\boldsymbol{u}(\infty) = \boldsymbol{u}_{\rm g} \qquad \text{matching to geostrophic interior.} \tag{34.51d}$$

Decomposing the velocity into its geostrophic and ageostrophic components

$$\boldsymbol{u} = \boldsymbol{u}_{\rm g} + \boldsymbol{u}_{\rm e}, \tag{34.52}$$

leads to

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{e}} = \nu^{\mathrm{eddy}}\,\frac{\partial^2 \boldsymbol{u}_{\mathrm{e}}}{\partial z^2} \tag{34.53a}$$

$$\boldsymbol{u}_{\mathrm{e}}(\eta_{\mathrm{b}}) = 0 \tag{34.53b}$$

$$\boldsymbol{u}_{\mathrm{e}}(\infty) = 0. \tag{34.53c}$$

To reach this result we noted that the geostrophic velocity is vertically independent within the boundary layer where the density is constant, so that the geostrophic velocity does not contribute to the viscous friction operator. These coupled second order differential equations are equivalent to the two uncoupled fourth order differential equations

$$(f^2 + \nu^2\,\partial_{zzzz})\,\boldsymbol{u}_{\mathrm{e}} = 0 \tag{34.54a}$$

$$\boldsymbol{u}_{\mathrm{e}}(\eta_{\mathrm{b}}) = 0 \tag{34.54b}$$

$$\boldsymbol{u}_{\mathrm{e}}(\infty) = 0. \tag{34.54c}$$

A solution to these equations renders the Ekman boundary layer profile

$$u = u_{\mathrm{g}}\left[1 - e^{-\Delta z/h_{\mathrm{e}}}\cos(\Delta z/h_{\mathrm{e}})\right] - v_{\mathrm{g}}\,e^{-\Delta z/h_{\mathrm{e}}}\sin(\Delta z/h_{\mathrm{e}}) \tag{34.55a}$$

$$v = v_{\mathrm{g}}\left[1 - e^{-\Delta z/h_{\mathrm{e}}}\cos(\Delta z/h_{\mathrm{e}})\right] + u_{\mathrm{g}}\,e^{-\Delta z/h_{\mathrm{e}}}\sin(\Delta z/h_{\mathrm{e}}) \tag{34.55b}$$

$$h_{\mathrm{e}}^2 = 2\,\nu^{\mathrm{eddy}}/|f| \tag{34.55c}$$

$$\Delta z = z - \eta_{\mathrm{b}}. \tag{34.55d}$$

Properties of the Ekman spiral

The spiral velocity profile (34.55a)-(34.55b) vanishes at the bottom, $\Delta z = 0$ or $z = \eta_{\mathrm{b}}$, reflecting the no-slip bottom boundary condition. It also reduces to the interior geostrophic velocity at $\Delta z = \infty$. In moving downward through the boundary layer, the boundary layer current deflects to the left of the interior geostrophic current (deflection is to the right in the southern hemisphere). This deflection is consistent with the schematic in Figure 34.10. Making use of the integral identities

$$\int_{\eta_{\mathrm{b}}}^{\infty} e^{-\Delta z/h_{\mathrm{e}}}\cos(\Delta z/h_{\mathrm{e}})\,\mathrm{d}\Delta z = h_{\mathrm{e}}/2 \quad \text{and} \quad \int_{\eta_{\mathrm{b}}}^{\infty} e^{-\Delta z/h_{\mathrm{e}}}\sin(\Delta z/h_{\mathrm{e}})\,\mathrm{d}\Delta z = -h_{\mathrm{e}}/2 \tag{34.56}$$

leads to the frictionally induced mass transport within the Ekman layer

$$\boldsymbol{M}_{\mathrm{e}} = \rho_0 \int_{\eta_{\mathrm{b}}}^{\infty} \boldsymbol{u}_{\mathrm{e}}\,\mathrm{d}z \tag{34.57a}$$

$$= (h_{\mathrm{e}}\,\rho_0/2)\,[-\hat{\boldsymbol{x}}\,(u_{\mathrm{g}} + v_{\mathrm{g}}) + \hat{\boldsymbol{y}}\,(u_{\mathrm{g}} - v_{\mathrm{g}})] \tag{34.57b}$$

$$= f^{-1}\,\hat{\boldsymbol{z}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}}), \tag{34.57c}$$

where we introduced the bottom stress according to equation (34.46). Furthermore, this stress is given by the Neumann boundary condition placed on the horizontal velocity

$$\boldsymbol{\tau}(\eta_{\mathrm{b}}) = \rho_0\,\nu^{\mathrm{eddy}}\left[\frac{\partial \boldsymbol{u}_{\mathrm{e}}}{\partial z}\right]_{z=\eta_{\mathrm{b}}} = (f\,h_{\mathrm{e}}/2)\,[\hat{\boldsymbol{x}}\,(u_{\mathrm{g}} - v_{\mathrm{g}}) + \hat{\boldsymbol{y}}\,(u_{\mathrm{g}} + v_{\mathrm{g}})]. \tag{34.58}$$

Following from equation (34.48) we see that the bottom stress induced mass transport across the top of the bottom Ekman boundary layer is

$$\rho_0 \, w_{\text{Ekman}}^{(\dot{\eta}_{\text{e}})} = -\nabla \cdot \boldsymbol{M}_{\text{e}} = -\nabla \cdot [f^{-1} \, \hat{\boldsymbol{z}} \times \boldsymbol{\tau}(\eta_{\text{b}})] = (h_{\text{e}}/2) \, \zeta_{\text{g}}, \tag{34.59}$$

where we made use of the f-plane assumption to set $\nabla \cdot \boldsymbol{u}_{\text{g}} = 0$ and introduced the relative vorticity of the geostrophic flow

$$\zeta_{\text{g}} = \partial_x v_{\text{g}} - \partial_y u_{\text{g}}. \tag{34.60}$$

Hence, the relative vorticity of the interior geostrophic flow equals to the divergence to the horizontal mass transport within the bottom Ekman layer. We illustrate the Ekman mass transport and bottom stress in Figure 34.12.

FIGURE 34.12: Mass transport and bottom stress in a homogeneous bottom Ekman layer on an f-plane in the northern hemisphere. Note how the boundary layer stress is directed $\pi/4$ radians to the left of the prescribed interior geostrophic velocity. Furthermore, the horizontal Ekman transport is itself $\pi/2$ radians to the left of the stress, which is then $3\pi/4$ to the left of the geostrophic velocity.

34.5.4 Comments

The Ekman spiral is a striking solution to the linear frictional geostrophic equations in a homogeneous fluid next to a flat no slip boundary. Section 5.7 of *Vallis* (2017) provides further discussion of the Ekman spiral solution discussed here. The spiral profile has been measured in the atmosphere and can be produced in the laboratory. However, it has proven difficult to measure in the ocean (see *Gnanadesikan and Weller* (1995) for an example). Even so, the effects from Ekman transport are robust features of the theory developed in this chapter, with those results independent of details for the vertical viscosity.

34.6 Arrested bottom Ekman flows

When studying the vertical velocity profile within the bottom boundary layer in Section 34.5, we assumed the density to be uniform within the boundary layer. A uniform density is commonly assumed for Ekman layers. However, *MacCready and Rhines* (1991, 1993), and *Garrett et al.* (1993) questioned that assumption in their study of bottom boundary layers in the presence of a nonzero vertical density stratification next to sloping topography. They point out the remarkable possibility of a vanishing frictional stress within the sloping bottom boundary layer. That is, rather than nonzero friction leading to a zero flow next to the bottom, flow is arrested by a compensation of pressure gradient accelerations. The vanishing frictional stress motivates the

term *slippery Ekman layers*, whereas the equivalent term *arrested Ekman layer* refers to the zero boundary layer flow. We here briefly describe the arrested Ekman layer by studying Figure 34.13.

34.6.1 Description

FIGURE 34.13: In both panels we depict a prescribed barotropic pressure acceleration that acts eastward and has a corresponding southward geostrophic flow and westward Coriolis acceleration. The solid lines depict lines of constant buoyancy, also known as isopycnals (see Chapter 31). Top panel: As the flow enters the bottom boundary layer it slows so that its Coriolis acceleration no longer balances the barotropic pressure, thus sending water cross slope in the down pressure gradient direction. Bottom panel: The cross-slope movement of density creates a baroclinic pressure acceleration that counteracts the barotropic pressure acceleration. The steady state is realized when the two pressure accelerations balance, in which case flow within the boundary layer halts. In this halted state there are no frictional stresses since the flow halts due to pressure effects rather than friction. Note that isopycnals are shown intersecting the solid boundary in a perpendicular direction, which is implied by the no-flux bottom boundary condition (in the absence of geothermal heating) as discussed in Section 21.5.2. Geostrophic flow in the opposite direction leads to downwelling along the bottom rather than upwelling. This figure is adapted from Figure 5 of *Wåhlin et al.* (2012).

In both panels of Figure 34.13 we depict a prescribed vertically independent (barotropic) pressure acceleration that acts eastward and has a corresponding southward geostrophic flow ($f > 0$) and westward Coriolis acceleration. This configuration is identical to that shown in Figure 34.11 when studying the bottom Ekman spiral over a flat bottom. As the flow enters the bottom boundary layer it slows so that its Coriolis acceleration no longer balances the barotropic pressure gradient acceleration (we have seen this imbalance throughout this chapter). The bottom Ekman layer flow sends water cross-slope in the direction down the barotropic pressure gradient. In the configuration shown here, the cross-slope flow advects denser water upslope. In so doing, a horizontal depth-dependent (baroclinic) pressure acceleration develops adjacent to the bottom

boundary layer, with the baroclinic pressure acceleration pointing opposite to the barotropic pressure acceleration. A steady state is realized when the two pressure accelerations balance, in which case flow within the boundary layer halts.

It is remarkable that the dynamical balance for the arrested bottom boundary layer flow does not involve friction. Rather, arrest happens when the two pressure gradients balance and the Coriolis acceleration vanishes. That is, referring to the frictional geostrophic equation (34.1), each term separately vanishes in the arrested state.

34.6.2 Applications

MacCready and Rhines (1991, 1993) and *Garrett et al.* (1993) study the transient adjustment leading to the arrested state. They derive the expression for the time scale for adjustment to the arrest state

$$T_{\text{arrest}} = \frac{|f|}{N^2\, s^2}, \tag{34.61}$$

where s is the slope of the bottom and N^2 is the squared buoyancy frequency of the ambient water. The time is less in regions of strong stratification (N^2 relatively large), large topographic slopes (s^2 large), and low latitudes (f small). Conversely, the infinite time for either $N^2 = 0$ or $s^2 = 0$ indicates the need for both stratification and topographic slopes to render an arrest. Finally, we note the absence of any dissipation parameters (e.g., viscosity) from the time scale. Friction is needed to support the Ekman layer where flow crosses isobars, but the time to reach the arrest state is independent of friction.

Wåhlin et al. (2012) interpreted observations from the Amundsen Sea according to the arrested Ekman boundary layer and found T_{arrest} to be just a few hours. Additionally, the numerical model studies from *Spence et al.* (2017) and *Webb et al.* (2019) point to the ability of barotropic shelf waves around Antarctica to provide an onshore directed barotropic pressure acceleration. Through the arrested Ekman layer mechanism described here, they find that the barotropic pressure is compensated through an upslope transport of relatively warm deep water in regions of the Antarctic Peninsula. Extensions and refinements of these ideas support an active area of ongoing research (e.g., *Ruan et al.*, 2021; *Peterson and Callies*, 2022).

34.7 Exercises

EXERCISE 34.1: EKMAN MASS TRANSPORT IN A SOUTHERN CHANNEL

Consider a southern hemisphere zonally periodic channel (e.g., an idealized Southern Ocean) with a zonal wind stress that has a meridional dependence such as shown in Figure 34.14. Following the discussion in Sections 34.4.1 and 34.4.4, sketch the sense for the horizontal and vertical Ekman mass transport arising from this wind stress. Show the transport for regions to the north and to the south of the wind stress maximum. Ignore the β contribution by assuming the channel is not very wide and by noting that β is smaller in the high latitudes (as relevant to the Southern Ocean).

EXERCISE 34.2: RELATING EKMAN, ROSSBY, AND REYNOLDS NUMBERS

Under certain scalings, we can connect the Ekman number to the Rossby and Reynolds numbers. In detail, we have

$$\text{Ro} = \frac{U}{f_0\, L} \qquad \text{and} \qquad \text{Ek} = \frac{\nu^{\text{eddy}}}{f_0\, H^2} \qquad \text{and} \qquad \text{Re} = \frac{W\, H}{\nu^{\text{eddy}}}, \tag{34.62}$$

FIGURE 34.14: Zonal wind stress in a southern hemisphere zonally periodic channel with a maximum flanked by lower winds. What is the sense for the associated horizontal and vertical Ekman mass transport following from the discussion in Sections 34.4.1 and 34.4.4?

where

$$H = \text{vertical length scale} \tag{34.63a}$$
$$L = \text{horizonal length scale} \tag{34.63b}$$
$$U = \text{horizonal velocity scale} \tag{34.63c}$$
$$W = \text{vertical velocity scale.} \tag{34.63d}$$

and we defined the Reynolds number (Section 26.9) in terms of the vertical viscosity, vertical length scale, and vertical velocity scale. What is the ratio of the Rossby number to Reynolds if the flow is non-divergent?

EXERCISE 34.3: EKMAN BOUNDARY LAYERS AND RAYLEIGH DRAG

Rayleigh drag described in Section 34.2.3 allowed us to study the effects of friction on fluid trajectories. However, Rayleigh drag has no spatial derivatives, which contrasts to the Laplacian friction from Section 34.3.1 and used elsewhere in this chapter. Comment on whether Rayleigh drag can support the no-slip boundary condition and the corresponding development of a boundary layer.

Chapter 35

Space and time dependent gravity

We here formulate the dynamical equations for a geophysical fluid in the presence of a space and time dependent gravitational acceleration. This formulation has application to the study of astronomical tides in the ocean, thus motivating a discussion of the astronomical tidal forcing that follows the treatment given in Chapter 3 of *Pugh* (1987) and Section 5.15 of *Apel* (1987), with Chapter 2 of *Brown* (1999) and Section 17.4 of *Stewart* (2008) useful pedagogical supplements. Besides tides, a topic of interest to climate science concerns the study of how ocean sea level responds to changes in mass distributions associated with melting land ice. The nontrivial impact that melting land glaciers has on the earth's geoid and earth's rotation (*Farrell and Clark*, 1976; *Mitrovica et al.*, 2001; *Kopp et al.*, 2010) further motivates developing the dynamical equations of a liquid ocean in the presence of a space-time dependent gravity.

READER'S GUIDE TO THIS CHAPTER

This chapter assumes an understanding of the equations of motion derived in Chapter 25 as well as the gravitational and planetary centrifugal accelerations from Section 13.10. We dispense with tensor notation in this chapter, with subscripts used here as descriptive labels rather than tensor indices. No other chapter depends on the material in this chapter.

35.1 Gravitational potential

In this section we summarize elements of the gravitational force, including the case with a non-constant gravitational acceleration such as occurs from astronomical tidal forcing and changes to the mass distribution of the planet.

35.1.1 Simple geopotential

As detailed in Section 13.10, the effective gravitational field incorporates the effects from the planetary centrifugal acceleration. The effective gravitational field is conservative, so that the gravitational acceleration of a fluid element can be represented as the gradient of a scalar (see Section 13.10.4),

$$\boldsymbol{g} = -\nabla \Phi, \tag{35.1}$$

with Φ the geopotential. In most applications of this book, the local vertical direction is denoted by

$$z = r - R_{\mathrm{e}}, \tag{35.2}$$

with $z = 0$ the geopotential surface corresponding to a resting ocean and $R_{\mathrm{e}} = 6.367 \times 10^6$ m the average radius of the earth (Section 13.1). The geopotential in this case is given by

$$\Phi = \Phi_0 = g\, z, \tag{35.3}$$

with $g \approx 9.8\,\mathrm{m\,s^{-2}}$ the typical value used for the gravitational acceleration at the earth's surface.

35.1.2 General geopotential

Consider a generalized geopotential written in the form

$$\Phi = \Phi_0(r) + \Phi_1(r, \lambda, \phi, t), \tag{35.4}$$

where $\Phi_0(r)$ is the geopotential given by equation (35.3), and Φ_1 incorporates perturbations to the geopotential. For the study of ocean tides, the structure of Φ_1 arises from astronomical perturbations to the earth's gravity field. The calculation of ocean tides arising from astronomical forcing is formulated with a space-time dependent geopotential as in equation (35.4), with the radial dependence of Φ_1 neglected (e.g., Section 9.8 in *Gill*, 1982). *Arbic et al.* (2004) provide a discussion of global tide modelling.

Nontrivial Φ_1 variations also arise from perturbations in terrestrial masses, such as the melting of land ice such as that occurring on Greenland or Antarctica due to climate warming. These mass distribution changes lead to changes in the earth's gravitational field, its rotational moment of inertia, and the deformation of the crust (GRD as in *Gregory et al.* (2019)). Each of these effects lead to modifications in the *static equilibrium sea level*. In contrast to ocean tides, GRD perturbations associated with melting land ice are not periodic nor readily predictable. Furthermore, as evidenced by Figure 1 in *Mitrovica et al.* (2001), the amplitude of static equilibrium sea level changes can be far greater than typical open ocean tide fluctuations.

35.2 Momentum equation

As detailed in Section 25.2.3, the inviscid momentum equation for a rotating fluid in a gravitational field is given by

$$\rho \frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \rho\,\boldsymbol{v} = -\nabla p - \rho\,\nabla\Phi. \tag{35.5}$$

In writing the momentum equation in the form (35.5), we have chosen to retain an orientation afforded by the unperturbed geopotential, $\Phi_0(r)$, which are surfaces of constant z. This approach reflects that commonly used to study ocean tides. In the presence of a perturbed geopotential, Φ_1, the "horizontal" directions defined by surfaces of constant z are no longer parallel to geopotential surfaces. We thus may interpret the sum $\nabla_z p + \rho\,\nabla_z \Phi$ as an orientation of the pressure gradient

along surfaces of constant geopotential, where the geopotential is determined by $\Phi = \Phi_0 + \Phi_1$, rather than just the unperturbed geopotential Φ_0.

35.3 Hydrostatic primitive equations

As detailed in Section 28.1, the hydrostatic primitive equations reduce the vertical momentum equation to its static inviscid form, which is the hydrostatic balance

$$\frac{\partial p}{\partial z} = -\rho \frac{\partial \Phi}{\partial z} = -\rho\,(g + \partial_z \Phi_1). \tag{35.6}$$

The hydrostatic balance is modified from its traditional form for cases where the perturbation geopotential Φ_1 exhibits nontrivial depth dependence. Correspondingly, the horizontal momentum equation (making the Traditional Approximation from Section 28.1) takes the form

$$\rho \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \hat{\boldsymbol{z}}\, f \,\times\, \rho\, \boldsymbol{u} = -(\rho\, \nabla_z \Phi_1 + \nabla_z p) \tag{35.7}$$

where ∇_z is the horizontal gradient taken on surfaces of constant z. In their oceanic Boussinesq form (Chapter 30), the inviscid horizontal momentum equation becomes

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \hat{\boldsymbol{z}}\, f \,\times\, \boldsymbol{u} = -(1/\rho_0)\,(\rho_0\, \nabla_z \Phi_1 + \nabla_z p) \tag{35.8}$$

where ρ_0 is the constant reference density for a Boussinesq fluid. The Boussinesq form makes the addition of a perturbed geopotential quite straightforward, in which it is gradients in $\rho_0\, \Phi_1 + p$ that take the place of gradients in pressure p.

35.4 Depth independent perturbed geopotential

A particularly simple form of Φ_1 occurs when it is depth independent,

$$\Phi_1 = \Phi_1(\lambda, \phi, t), \tag{35.9}$$

in which case the hydrostatic balance (35.6) returns to its traditional form $\partial_z p = -\rho\, g$. This form is motivated by the scale analysis in Section 35.5.3 where we find that the radial component of the earth's gravitational field greatly exceeds that from the moon or other celestial bodies, so that it is the lateral variation in the gravitational acceleration that drive tidal motions. In this case it is convenient to write the geopotential as

$$\Phi_1 = -g\, h, \tag{35.10}$$

with $h = h(\lambda, \phi, t)$ the perturbed geopotential height field. The full geopotential is thus written

$$\Phi = g\,(z - h), \tag{35.11}$$

with this form revealing that the zero of the geopotential is now set by $z = h$ rather than $z = 0$. In the study of ocean tides, h is referred to as the *equilibrium tide*. In geodesy, h is referred to as the *static equilibrium sea level*.

Since the perturbed geopotential is depth independent, it only affects the depth integrated

horizontal momentum, and it does so through the term

$$-\int_{\eta_b}^{\eta} \nabla_z \Phi_1 \, \mathrm{d}z = g \int_{\eta_b}^{\eta} \nabla_z h \, \mathrm{d}z = g \left(-\eta_b + \eta\right) \nabla_z h. \tag{35.12}$$

Hence, modifications to the geopotential as embodied by the perturbed geopotential height field, $h = h(\lambda, \phi, t)$, are isolated to their impacts on the horizontal pressure gradients acting on the depth integrated horizontal momentum.

35.5 Forces contributing to ocean tides

We here describe the rudiments of forces that contribute to ocean tides as well as solid-earth tides. For simplicity we focus just on the earth-moon system, though note that the sun also plays an analogous role for observed tidal motion.

35.5.1 Tidal acceleration in a spherically symmetric gravity field

Before considering the earth-moon system, we introduce the notion of *tidal acceleration*, which arises on a finite sized body placed within a non-uniform gravitational field. Figure 35.1 depicts this situation where the finite sized body is a narrow rod whose axis points towards the center of a spherically symmetric massive body. One end of the rod experiences a different gravitational acceleration than the other since the gravitational field falls off as the inverse squared distance from the center of the sphere. It is this differential gravitational acceleration that we refer to as the tidal acceleration. As we will see, its key property is that the tidal acceleration falls off as the inverse cube of the distance rather than the more familiar inverse square.

To develop a mathematical expression for the tidal acceleration, focus on the spherically symmetric gravitational field in which the gravitational acceleration at a point is given by (Section 13.10.2)

$$\boldsymbol{g} = -\frac{GM}{r^2} \, \hat{\boldsymbol{r}}, \tag{35.13}$$

where r is the distance from the sphere's center, G is Newton's gravitational constant, M is the mass of the sphere, and $\hat{\boldsymbol{r}}$ is the radial unit vector. The minus sign indicates that the gravitational acceleration points toward the center of the sphere. For the rod in Figure 35.1, the difference between the gravitational acceleration acting at a point nearest to the sphere (point B) and a point furthest from the sphere (point A) is given by

$$\boldsymbol{g}(r_B) - \boldsymbol{g}(r_A) = \boldsymbol{g}(r_0 - L/2) - \boldsymbol{g}(r_0 + L/2), \tag{35.14}$$

where r_0 is the distance from the sphere's center to the center of the rod. Assuming the rod is not long, we can expand this difference in a Taylor series about the rod center at r_0, thus leading to an expression for the tidal acceleration

$$\boldsymbol{g}(r_B) - \boldsymbol{g}(r_A) \approx -L \, \frac{\partial \boldsymbol{g}}{\partial r} = -2L \, \frac{GM}{r_0^3} \, \hat{\boldsymbol{r}} = (2\, L/r_0) \, \boldsymbol{g}(r_0). \tag{35.15}$$

The key point to conclude from this example is that the tidal acceleration is proportional to the inverse cube of the distance to the center of the sphere. We see this property again when considering in Section 35.5.3 the gravitational acceleration generated from a remote body (e.g., the moon) acting on the surface of a sphere (e.g., the earth).

FIGURE 35.1: *Tidal acceleration* is the acceleration that acts on a finite sized object placed in a non-uniform gravitational field. The finite object is here depicted as a narrow rod of length L placed in the gravity field of a spherically symmetric body of mass M. That portion of the rod closer to the gravitating sphere (end B) experiences a stronger gravitational acceleration than the end that is further away (end A). The gradient in the gravitational acceleration constitutes the tidal acceleration acting on the rod.

35.5.2 Heuristics of tidal acceleration on the surface of a sphere

We now consider the tidal acceleration acting on the surface of a smooth massive sphere due to a spherically symmetric gravitational field generated by a neighboring massive body. Figure 35.2 depicts this system, which we consider an idealized earth-moon system where each body is assumed homogeneous and spherical. Given that they gravitationally attract one another, it is not astronomically possible for the two bodies to remain spatially fixed. Instead, they orbit around their common center of mass while conserving their angular momentum.

A central question of tidal studies is why there are generally two ocean tides per day (semi-diurnal tides) rather than just one (diurnal tides). We here offer two complementary arguments. The first is based on extending the tidal acceleration discussion of Section 35.5.1, whereas the second follows the more traditional account by considering a balance between gravitational and centrifugal accelerations.

General ideas

Every point on the surface of the earth is attracted to the earth's center by the earth's gravitational field. For a spherical earth, this attractive force is purely radial, so that it cannot lead to lateral motion on the surface of the perfect sphere. We thus conclude that the radial gravitational field is not the cause of tidal motion. Instead, tidal motion arises from a non-radial gravitational field.

The earth-moon gravitational field accelerates the earth and moon toward one another along the axis connecting their centers. Additionally, the spatial dependence of the moon's gravitational field over the earth leads to lateral forces along the earth's surface, thus providing the ingredient for ocean tidal motion. To capture the essence of this force, we examine how the moon's gravitational field acts on a point on the earth relative to its action at the center of the earth.

Sample tidal accelerations on the sphere

Again, we are tasked with computing the tidal acceleration from the moon's gravitational field for selected points on the earth, and we are computing these accelerations relative to the earth

FIGURE 35.2: Illustrating the tidal force on the surface of a sphere. The sphere is an ideal depiction of the earth and the smaller massive object is the moon. The distance between the center of the earth and moon is $R_{\rm em}$, and the radius of the earth is $R_{\rm e}$. The left panel shows representative moon-generated gravitational field lines. Two points along these field lines on the surface of the earth represent the two ends of an imaginary rod as depicted in Figure 35.1. The tidal acceleration acting at point B, relative to the earth's center, points toward the moon (equation (35.16)). In contrast, the tidal acceleration at point A, relative to the earth's center, points in the opposite direction (equation (35.17)). Points on the earth surface between A and B have tidal accelerations with a non-zero component directed along the surface of the earth. Symmetry of the configuration allows us to conclude that a layer of water on the surface of the sphere will accumulate to produce two bulges as shown in the right panel. It is the lateral component of the gravitational acceleration that causes the water to accumulate to produce tidal bulges at points A and B. In contrast, the radial component to the moon's gravitational field has no contribution to the tides. Note that as shown in Section 35.5.3, the bulge shown in the right panel is greatly exaggerated.

center. As for the rod in Figure 35.1, the tidal acceleration at point B relative to the center of the earth is given by

$$\boldsymbol{g}(r_B) - \boldsymbol{g}(R_{\rm em}) = (2R_{\rm e}/R_{\rm em})\,\boldsymbol{g}(R_{\rm em}). \tag{35.16}$$

This acceleration points towards the moon. In contrast, the tidal acceleration at point A relative to the center of the earth is given by

$$\boldsymbol{g}(r_A) - \boldsymbol{g}(R_{\rm em}) = -(2R_{\rm e}/R_{\rm em})\,\boldsymbol{g}(R_{\rm em}), \tag{35.17}$$

which is of equal magnitude but points away from the moon.

The tidal accelerations at points A and B act radially away from the earth's center. Hence, as noted above, these radial forces do not directly lead to tidal motion at those points. However, through symmetry of the configuration, points on the surface of the sphere between A and B have a tidal acceleration from the moon's gravitational field with a nonzero lateral component. These lateral forces lead to the accumulation of water at points A and B. We can compute the gravitational acceleration at intermediate points. However, the trigonometry is somewhat complex and we prefer to compute the forces in Section 35.5.3 through use of the gravitational potential. For the current discussion we appeal to symmetry to conclude that the lateral tidal accelerations act to pile up water at both points A and B as depicted in the second panel of Figure 35.2. This argument, though heuristic, provides the means to understand how a water covered spherical planet has two bulges, rather than one, due to spatial gradients in the moon's gravitational field. We confirm this argument in Section 35.5.3 by explicitly computing the gravitational potential

for this idealized earth-moon system and then taking the gradient to compute the gravitational acceleration (see Figure 35.4).

Including orbital motion

Thus far we have ignored the orbital motion of the earth-moon system around their common center of mass. As we will see, there are no fundamental changes to the above arguments when allowing for orbital motion.

In the absence of dissipation, as assumed here, the earth-moon distance remains constant due to their angular momentum conserving orbital motion. From a force-balance perspective, the two spherical bodies remain in a fixed orbit since the gravitational acceleration acting at their centers is balanced by their respective centrifugal accelerations, where the centrifugal acceleration is computed relative to the center of mass of the two-body system. The gravitational acceleration from the moon, acting at the center of the earth, is given by the *free fall* value $\boldsymbol{g}(R_{\text{em}})$, which has magnitude $GM_{\text{m}}/R_{\text{em}}^2$ and is directed along the axis connecting the earth and moon centers.

Furthermore, when a body exhibits orbital motion, each point on the body exhibits the same orbital motion and has the same linear velocity. Consequently, each point on the earth possess the same centrifugal acceleration

$$\boldsymbol{a}_{\text{orbital centrifugal}} = -\boldsymbol{g}(R_{\text{em}}). \tag{35.18}$$

This property of orbital motion is distinct from the spinning motion of a planet rotating about its axis, whereby points further from the rotational axis have larger centrifugal acceleration (see Section 13.10). To help understand orbital motion, move your hand in a circle while maintaining the arm in a single direction so that the hand exhibits an orbital motion rather than a spinning motion. Notice that all parts of the hand move with the same linear velocity and exhibit the same orbital motion. Hence, each point on the hand has the same centrifugal acceleration.

We can now ask about the acceleration felt by a point on the surface of the earth. The acceleration giving rise to tidal motions is the sum of the gravitational acceleration from the moon plus the centrifugal acceleration due to orbital motion. However, this calculation is identical to that considered previously, which led, for example, to the tidal accelerations for points B and A as given by equations (35.16) and (35.17). We are thus led to the same result as before.

35.5.3 Gravitational potential for an idealized earth-moon system

We now perform a more thorough calculation of the gravitational acceleration by computing the gradient of the gravitational potential. First recall the discussion of Newton's gravitational law in Section 13.10.2, whereby the gravitational potential for a point at distance r from the center of a spherical earth is given by

$$\Phi_{\text{e}}(r) = -\frac{GM_{\text{e}}}{r}, \tag{35.19}$$

where M_{e} is the mass of the earth. The corresponding radial gravitational acceleration is given by

$$\boldsymbol{g}_{\text{e}} = -\nabla\Phi_{\text{e}} = -\frac{GM_{\text{e}}\,\hat{\boldsymbol{r}}}{r^2}. \tag{35.20}$$

The same considerations hold for the moon's gravitational potential. Hence, referring to Figure 35.3, the moon's gravitational potential evaluated at a distance L from the moon's center is given by

$$\Phi_{\text{m}}(L) = -\frac{GM_{\text{m}}}{L}. \tag{35.21}$$

Trigonometry leads to the law of cosines relation

$$L^2 = (R_{\rm em} - r\cos\psi)^2 + (r\sin\psi)^2 = R_{\rm em}^2 + r^2 - 2\,r\,R_{\rm em}\cos\psi, \tag{35.22}$$

where again r is the distance to the earth's center and ψ is the polar angle relative to the $\hat{\boldsymbol{x}}$ axis pointing between the earth and moon centers (see Figure 35.3).

FIGURE 35.3: Geometry of an idealized earth-moon system. The center of the earth is a distance $R_{\rm em}$ from the center of the moon; the moon has a mass $M_{\rm m}$; and the earth has a radius $R_{\rm e}$. An arbitrary test point is shown a distance L from the center of the moon, r from the center of the earth, and with a polar angle ψ relative to the $\hat{\boldsymbol{x}}$ axis, where the $\hat{\boldsymbol{x}}$ axis points from the earth center to the moon center. Relative to the earth's center, the test point has Cartesian coordinates $(x, y) = r\,(\cos\psi, \sin\psi)$. See Section 10.3 for details on relating polar and Cartesian coordinates.

Identifying the leading order contributions

Assuming the test point in Figure 35.3 is closer to the earth than to the moon, we can perform a Taylor series expansion in the small parameter $r/R_{\rm em}$ to render

$$\Phi_{\rm m}(L) = -\frac{GM_{\rm m}}{L} = -\frac{GM_{\rm m}}{R_{\rm em}}\left[1 + \frac{r\cos\psi}{R_{\rm em}} + \frac{r^2}{2R_{\rm em}^2}\,(3\cos^2\psi - 1) + \mathcal{O}(r/R_{\rm em})^3\right]. \tag{35.23}$$

We thus identify the leading three terms to the geopotential

$$\Phi_{\rm m}^{(0)} = -\frac{GM_{\rm m}}{R_{\rm em}} \tag{35.24}$$

$$\Phi_{\rm m}^{(1)} = -\frac{GM_{\rm m}}{R_{\rm em}^2}\,r\cos\psi \tag{35.25}$$

$$\Phi_{\rm m}^{(2)} = -\frac{GM_{\rm m}}{2R_{\rm em}^3}\,r^2\,(3\cos^2\psi - 1). \tag{35.26}$$

Assuming the distance between the earth and moon remains fixed, the zeroth order term $\Phi_{\rm m}^{(0)}$ is a spatial constant and thus leads to no gravitational acceleration. We now examine the gravitational accelerations from the other two terms.

Acceleration maintaining the orbiting earth-moon system

For the first order term, $\Phi_{\rm m}^{(1)}$, we introduce the Cartesian coordinate as in Figure 35.3 to write

$$\Phi_{\rm m}^{(1)} = -\frac{GM_{\rm m}\,x}{R_{\rm em}^2}, \tag{35.27}$$

where $x = r\cos\psi$ is the distance along $\hat{\boldsymbol{x}}$. Hence, the gradient of $\Phi_{\rm m}^{(1)}$ leads to the gravitational acceleration

$$\boldsymbol{g}_{\rm m}^{(1)} = -\nabla\Phi_{\rm m}^{(1)} = \hat{\boldsymbol{x}}\,\frac{GM_{\rm m}}{R_{\rm em}^2}. \tag{35.28}$$

This gravitational acceleration has a constant magnitude at every point in space and it everywhere points in a direction parallel to the earth-moon axis. Furthermore, the magnitude of $\boldsymbol{g}_{\rm m}^{(1)}$ equals to that of the moon's gravitational acceleration, $\boldsymbol{g}_{\rm m}$, when evaluated at the earth's center. As seen in Section 35.5.2, the acceleration $\boldsymbol{g}_{\rm m}^{(1)}$ maintains the earth in orbit about the center of mass for the earth-moon system; i.e., this is the free fall acceleration towards the moon. Notably, at the earth's surface, the magnitude of $\boldsymbol{g}_{\rm m}^{(1)}$ is tiny relative to the gravitational acceleration from the earth itself, with their ratios given by

$$\frac{M_{\rm m}/R_{\rm em}^2}{M_{\rm e}/R_{\rm e}^2} \approx 3.4\times10^{-6}, \tag{35.29}$$

where we set

$$M_{\rm e} = 5.97\times10^{24}\ {\rm kg} \qquad M_{\rm m} = 7.35\times10^{22}\ {\rm kg} = (1/81.2)\,M_{\rm e} \tag{35.30a}$$

$$R_{\rm e} = 6.367\times10^{6}\ {\rm m} \qquad R_{\rm em} = 3.84\times10^{8}\ {\rm m} = 60.3\,R_{\rm e}. \tag{35.30b}$$

FIGURE 35.4: The tide producing gravitational acceleration $\boldsymbol{g}_{\rm m}^{(2)}$ given by equation (35.34). The moon is assumed to be positioned in the equatorial plane of the earth.

Tide producing geopotential

The main tide producing acceleration results from $\Phi_{\rm m}^{(2)}$. Introducing the second Cartesian coordinate, $y = r \sin\psi$, leads to

$$\Phi_{\rm m}^{(2)} = -\frac{G M_{\rm m}}{2 R_{\rm em}^3}\, r^2\, (3\cos^2\psi - 1) = -\frac{G M_{\rm m}}{2 R_{\rm em}^3}\, (2\, x^2 - y^2). \tag{35.31}$$

The corresponding perturbed geopotential height field (see equation (35.11)) is given by

$$h = -\frac{\Phi_{\rm m}^{(2)}}{g} = \frac{R_{\rm e}^2}{2\, R_{\rm em}^3}\, \frac{M_{\rm m}}{M_{\rm e}}\, r^2\, (3\cos^2\psi - 1). \tag{35.32}$$

Placing the test point on the earth surface, $r = R_{\rm e}$, renders

$$h = \frac{R_{\rm e}^4}{2\, R_{\rm em}^3}\, \frac{M_{\rm m}}{M_{\rm e}}\, (3\cos^2\psi - 1) \approx 2.8 \times 10^{-8}\, R_{\rm e}\, (3\cos^2\psi - 1). \tag{35.33}$$

Plugging in numbers for the earth-moon system suggests that the maximum perturbation to the geopotential height arising from the moon's gravity field is roughly 36 cm. Correspondingly, the bulge shown in Figure 35.2 is greatly exaggerated. Note that ocean tidal amplitudes can get much larger (order meters) than this "equilibrium tide" amplitude due to resonances from ocean geometry, with the Bay of Fundy in Nova Scotia a particularly striking example.

Tide producing acceleration

The gravitational acceleration arising from the tidal potential is determined by the gradient of the tidal geopotential

$$\boldsymbol{g}_{\rm m}^{(2)} = -\nabla \Phi_{\rm m}^{(2)} = \frac{G M_{\rm m}}{R_{\rm em}^3}\, (2\, x\, \hat{\boldsymbol{x}} - y\, \hat{\boldsymbol{y}}). \tag{35.34}$$

We illustrate the vector field $\boldsymbol{g}_{\rm m}^{(2)}$ in Figure 35.4. Note how the accelerations lead to two bulges on opposite sides of the planet. We can write this acceleration using polar coordinates by introducing the polar unit vectors $\hat{\boldsymbol{r}}$ and $\hat{\boldsymbol{\psi}}$ according to Section 10.3.2

$$\hat{\boldsymbol{r}} = \hat{\boldsymbol{x}} \cos\psi + \hat{\boldsymbol{y}} \sin\psi \tag{35.35a}$$

$$\hat{\boldsymbol{\psi}} = -\hat{\boldsymbol{x}} \sin\psi + \hat{\boldsymbol{y}} \cos\psi \tag{35.35b}$$

thus rendering

$$\boldsymbol{g}_{\rm m}^{(2)} = \frac{G M_{\rm m} R_{\rm e}}{R_{\rm em}^3}\, \left[\hat{\boldsymbol{r}}\, (3\cos^2\psi - 1) - (3/2)\, \hat{\boldsymbol{\psi}}\, \sin 2\psi\right], \tag{35.36}$$

where we evaluated the acceleration at the earth surface so that $r = R_{\rm e}$. Evaluating the acceleration at $\psi = 0, \pi$ verifies the heuristic calculation performed in Section 35.5.2 for points on the earth surface nearest and furthest from the moon. We can further gauge the magnitude of the tidal acceleration by introducing the acceleration due to the earth's gravity field

$$\boldsymbol{g}_{\rm m}^{(2)} = g_{\rm e} \frac{M_{\rm m}}{M_{\rm e}}\, \frac{R_{\rm e}^3}{R_{\rm em}^3}\, \left[\hat{\boldsymbol{r}}\, (3\cos^2\psi - 1) - (3/2)\, \hat{\boldsymbol{\psi}}\, \sin 2\psi\right], \tag{35.37}$$

where $g_{\rm e} = G\, M_{\rm e}/R_{\rm e}^2$ is the acceleration at the earth's surface from the earth's gravity field. The dimensional prefactor has magnitude $\approx 5.6 \times 10^{-8}\, g_{\rm e}$, so that the tidal acceleration is tiny relative to that from the earth's gravity field. It is for this reason that the radial component of the tidal

acceleration is largely irrelevant since it is dominated by the far larger radial component of the earth's gravity field. However, the angular component of the tidal acceleration, although small relative to the earth's radial gravitational acceleration, is able to move water along the surface of the planet as indicated by Figure 35.4, thus leading to tidal motion.

35.5.4 Concerning realistic tides

Our discussion of tides has been rather terse, aiming to identify key aspects of the tidal accelerations but giving little attention to details that impact real ocean tides. Here are a few points that must be considered for these purposes.

- As the earth spins under the tidal bulges, there are two high and two low tides per day. Additional orbital motion of the moon adds roughly 50 minutes per day to the diurnal (daily) tide and 25 minutes to the semi-diurnal (twice daily).

- The moon orbits the earth at a latitude of roughly $28.5°N$ rather than within the equatorial plane, so that the tidal bulges are offset from the equator. As the earth spins under the bulges, one of the high tides is generally larger than the other due to the offset. This offset in turn introduces a diurnal component to the tides in addition to the semi-diurnal.

- The sun contributes to tides in a manner similar to the moon. The sun is more massive than the moon, yet it is further away, so that the ratio of the magnitudes for the tidal producing accelerations is given by

$$\frac{\text{moon tidal acceleration}}{\text{sun tidal acceleration}} = \frac{M_{\mathrm{m}}/R_{\mathrm{em}}^3}{M_{\mathrm{s}}/R_{\mathrm{es}}^3} \approx 2.2 \tag{35.38}$$

  where we set

$$M_{\mathrm{s}} = 1.99 \times 10^{30}\ \mathrm{kg} \qquad R_{\mathrm{es}} = 23460\, R_{\mathrm{e}}. \tag{35.39}$$

  Hence, the moon has an impact on tides that is somewhat more than double that of the sun.

- The gravitational acceleration that leads to the tidal bulge moves around the mid-latitudes at roughly 330 m s^{-1}, which is faster than the $\approx$ 200 m s^{-1} wave speed for shallow water gravity waves. Hence, the ocean tidal motion is never equilibrated to the *equilibrium tides* defined by the tidal acceleration. In contrast, solid-earth waves are much faster and so the solid-earth tidal motions are mostly equilibrated with the equilibrium tidal acceleration. Solid-earth tides have an amplitude on the order of 10 cm with wavelengths spanning the planet. Hence, an accurate treatment of ocean tides must take into account the solid-earth tides.

- The movement of ocean mass modifies the earth's gravity field and the domain within with the ocean moves, and these effects are referred to as *self attraction and loading* (SAL). The loading term arises from alterations in the mass felt by the solid earth that leads the crust to expand or compress. Self-attraction arises from modifications to the gravity field due to self-gravity of both the load-deformed solid earth and the ocean tide itself. Locally, SAL can contribute to roughly 20% of the ocean tide amplitude, so that accurate tide modeling must include SAL. *Barton et al.* (2022) provide an example of global ocean tide modeling that includes a discussion of how to compute the SAL terms online during a simulation.

- Geometry of the ocean plays a leading role in determining tides at a particular location. We have incomplete information about the geometry of ocean basins, such as the presence

of deep ridges, troughs, and seamounts. In lieu of such information we can garner useful information based on the analysis of past tides, with that information used to fit sinusoidal waves to the measured time series for use in projecting forward in time.

35.5.5 Comments

A key feature of the tidal producing forces is that it is the lateral (along-earth) component of the moon's tidal gravitational force that produces the earth's tides. These lateral forces cause water to accumulate at the point nearest to and furthest from the moon (points A and B in Figure 35.2), thus producing the characteristic double-bulge pattern. Notably, many common literature presentations make it appear that it is the radial (i.e., pointing to the earth's center) component of the moon's gravitational force, and its gradient across the earth, that leads to the earth's tidal bulges. But as discussed in Section 35.5.2, radial gravitational forces cannot lead to tidal motions; what is needed is a force that leads to lateral motion. These key notions are nicely emphasized in this Space Time video.

Part VI

Shallow water flows

Adiabatic shallow water models consist of constant density homogeneous fluid layers whose interfaces are material (i.e., no matter is transferred between the immiscible layers). Thermodynamic processes are absent from the system, thus allowing us to focus on the dynamics of fluid layers. Pressure is hydrostatic, which means that motion occurs in columns whereby horizontal velocity is independent of the vertical position within a layer, whereas the column can expand and contract so that there is vertical motion within a layer. Furthermore, we make the approximations arising from the primitive equations in Section 28.1, so that the Coriolis acceleration is based on just the local vertical component to the planetary rotation. Horizontal momentum is transferred between shallow water layers via pressure form stresses that act on sloping layer interfaces.

Our goal in this part of the book is to develop an understanding of the shallow water model fundamentals and to study some basic dynamical features as realized in the model. We have further use of the shallow water model in our study of vorticity in Part VII, balanced flows in Part VIII, waves in Chapter 53, and generalized vertical coordinates in Part XI.

The shallow water model offers a suite of versatile theoretical models of use to deduce impacts on the flow from both rotation and (when multiple layers are used) stratification. Consequently, the shallow water model is featured in many areas of geophysical fluid mechanics as well as in ocean and atmosphere applications. Additionally, there is a direct analogy between shallow water flow and compressible fluid flow, in which the *in situ* density of a compressible fluid corresponds to the layer thickness of a shallow water fluid. Furthermore, the acoustic waves of compressible flow (Chapter 49) are directly analogous to the gravity waves of shallow water flow (Section 53.5). Shallow water flow is somewhat simpler, however, since it is horizontal within a layer. For these reasons, the shallow water model has found great use both inside and outside of geophysical fluid mechanics.

We offer a comment concerning the mathematics required for studying the shallow water model. Namely, the shallow water model is a vertically discrete realization of a continuously stratified fluid described by the isopyncal coordinates of Chapter 62. However, the mathematical formalism of generalized vertical coordinates developed in Part XI of this book is largely unnecessary when working with the shallow water model. The reason for the simplification is that columnar motion within a shallow water layer means that lateral gradients of properties need not be projected along the slope of the layer. In contrast, this projection is needed for a continuously stratified fluid described by generalized vertical coordinates (e.g., see Figure 59.4). So although we appreciate the beauty and power of generalized vertical coordinate mathematics for studying continuously stratified flows, it is liberating to avoid that formalism while still capturing much of the underlying physics associated with stratification (albeit discretely stratified). This feature of the shallow water model greatly adds to its allure and accessibility.

Chapter 36

Formulating shallow water models

In this chapter we formulate the kinematic and dynamic equations for a suite of shallow water models. For this purpose we develop the equations describing motion of a single shallow water layer; multiple shallow water layers (stacked shallow water); and reduced gravity models (models with one layer that is dynamically inactive). In mathematically formulating these models we also expose their physical basis.

READER'S GUIDE TO THIS CHAPTER

We make use of fluid kinematics and dynamics described in earlier chapters. Our presentation was inspired by Chapter 3 of *Vallis* (2017) as well as various sections in *Salmon* (1998). We make use of the formulation here for further study of the shallow water fluid mechanics, including dynamical balances in Chapter 37, vorticity mechanics in Chapter 40, and wave mechanics Chapter 53. This video offers a pedagogical introduction to shallow water waves and to the general phenomenlogy of a shallow water layer.

The horizontal velocity is vertically uniform within a shallow water layer, whereas the vertical velocity and hydrostatic pressure are linear functions of vertical position within the layer. When acting on a property that is vertically uniform within a layer, the gradient operator, ∇, results in a horizontal vector. To minimize notational clutter, we typically write ∇ for brevity, rather than the more clumsy ∇_{k} or ∇_z (with k the layer index). The meaning of the resulting vector equations are clear from the functional dependencies of the fields present in the equations.

36.2 A single shallow water layer

Consider a homogeneous layer of fluid in a uniform effective gravitational field (gravity plus planetary centrifugal as in Section 13.10.4), contained on its side by solid boundaries. If there are no lateral force imbalances, then the fluid remains static. Now perturb the fluid so that it has a nonuniform layer thickness, say with a bump in a particular region. Conservation of fluid mass (which translates into volume conservation for a uniform density layer) means that thicker fluid regions must be exactly compensated by thinner fluid regions. Furthermore, layer thickness gradients create pressure differences (thicker water has larger hydrostatic pressure than thinner water), which in turn drives fluid motion. If the fluid has much larger lateral extent than vertical, then the lateral motion occurs as an expanding and contracting column with no depth dependence to the horizontal pressure forces and thus the horizontal motion is depth independent.

The essence of a perfect fluid (i.e., no irreversible processes such as mixing) shallow water flow concerns the motion of fluid columns accelerated by pressure gradients created by layer thickness undulations, and the associated conservation of mass ensuring that the accumulation of fluid in one region is balanced by the depletion of fluid in another. Pressure gradients act to homogenize the layer thickness. However, rotation allows for layer thickness to be non-constant even in a steady state.

36.2.1 Pressure gradient force within the fluid layer

Figure 36.1 shows a single shallow water layer with a generally non-flat bottom and an undulating free surface height. We assume that each column of fluid within the layer is in hydrostatic balance,

FIGURE 36.1: A single layer of shallow water fluid with thickness $h = \eta - \eta_b$ that extends from the bottom at $z = \eta_b$ to the free surface at $z = \eta$. The area averaged thickness is defined by $H = \overline{h} = A^{-1} \int h \, dx \, dy = A^{-1} \int (\eta - \eta_b) \, dx \, dy = \overline{\eta} - \overline{\eta_b}$, where $A = \int dx \, dy$ is the horizontal area of the layer. The deviation of the free surface from $\overline{\eta}$ is given by $\eta' = \eta - \overline{\eta} = \eta - (\overline{\eta_b} + H)$ so that $\eta(x, y, t) = \eta_b(x, y) + h(x, y, t) = \overline{\eta_b} + H + \eta'(x, y, t)$. Likewise, the deviation of the bottom from $\overline{\eta_b}$ is given by $\eta'_b = \eta_b - \overline{\eta_b}$, so that $h = \eta - \eta_b = H + \eta' - \eta'_b$. Volume conservation for the layer is maintained in the absence of volume boundary fluxes, in which case $\overline{\eta'} = 0$. Note that the position of the reference height, $z = 0$, is arbitrary. Atmospheric conventions typically set $z = 0$ so that $\overline{\eta_b} = 0$, $\eta = H + \eta'$, and $\overline{\eta} = H$. Oceanic conventions typically choose $\overline{\eta} = 0$ so that $\eta = \eta'$ and $\overline{\eta_b} = -H$. We are only concerned with fluctuations that leave the free surface monotonic; i.e., we do not consider overturns or breaking waves. This assumption is implied by assuming that each column extending from $\eta_b \leq z \leq \eta$ maintains hydrostatic balance.

so that the vertical momentum equation reduces to

$$\frac{\partial p}{\partial z} = -\rho \, g. \tag{36.1}$$

Recall from Section 28.2 that the hydrostatic balance is consistent with lateral length scales much larger than vertical (small vertical to horizontal aspect ratio), which is satisfied by large-scale geophysical fluid motion. Hence, a shallow water fluid is a relevant idealization if we are considering horizontal scales that are very large relative to vertical scales.

Since the fluid density is assumed constant (i.e., the fluid is a homogeneous layer), we can integrate the hydrostatic balance from the surface to an arbitrary vertical position within the layer

$$p(x, y, z, t) = p_a(x, y, t) + g \, \rho \int_z^\eta dz = p_a(x, y, t) + g \, \rho \, [\eta(x, y, t) - z], \tag{36.2}$$

where $p_a(x, y, t)$ is the pressure applied to the layer free surface, say from the overlying atmosphere. Furthermore, the horizontal pressure gradient thus takes the form

$$\nabla_z p = \nabla_z p_a + g \, \rho \nabla_z \eta. \tag{36.3}$$

This pressure gradient is depth independent within the layer, as depicted in Figure 36.2.

For the left hand side of the pressure gradient in equation (36.3), it is useful to write ∇_z since the pressure within a layer is a function of z (equation (36.2)), whereas for the horizontal momentum equation we only want the horizontal pressure gradient. For the right hand side, p_a and η are independent of z, so that there is no need to expose the z subscript on the gradient operator. We thus drop the subscript when no ambiguity results, as per our convention noted at the start of the chapter.

FIGURE 36.2: The horizontal pressure gradient within a shallow water layer is independent of the depth within that layer. In this schematic we assume here are zero horizontal gradients in the applied surface pressure, $\nabla p_{\rm a} = 0$, in which case the horizontal acceleration from pressure within a single shallow water fluid layer is determined solely by the surface height, $-\nabla_z p = -g\rho\nabla_z\eta$. The acceleration is uniform throughout the layer and points from sea level highs towards sea level lows. Although bottom topography interacts with the flow and thus affects the shape of the free surface, the topography does not appear explicitly in the horizontal pressure gradient (though the bottom shape does affect bottom form stresses as per the discussion in Sections 29.1 and 37.4). Instead, we only need to know the shape of the free surface (and the applied pressure $p_{\rm a}$) to know the horizontal pressure force throughout the layer.

Layer depth independent pressure gradient force

We emphasize that although hydrostatic pressure within a shallow water layer is depth dependent as per equation (36.2), the horizontal pressure gradient, as given by equation (36.3), has no depth dependence within the layer. The acceleration from this hydrostatic pressure force points from highs in the effective sea level to lows in the effective sea level (see Figure 36.2). The depth-independence of the pressure gradient within a shallow water layer holds also for multiple shallow water layers as discussed in Section 36.4, in which case the horizontal velocity has no vertical structure within any layer.

Pressure gradient force only depends on layer interface gradients

It is notable that the horizontal pressure gradient is solely determined by properties at the upper interface of the layer. That is, we only need to know the shape of the free surface, $z = \eta$, and the applied pressure, $p_{\rm a}$, to know the horizontal pressure force acting throughout the layer. There is no explicit dependence on the shape of the bottom topography. The result also holds for the stacked shallow water model discussed in Section 36.4, whereby horizontal pressure gradients are determined by gradients in the layer interfaces and with no appearance of the bottom topography. This characteristic is specific to the use of a pressure gradient body force to describe the role of pressure on the layer momentum. As a complement, we saw in Chapter 29 how to formulate the pressure contact force. It is through the contact force perspective that we see, in Section 37.4, how bottom topography appears in the momentum balance of a shallow water layer. In particular, this perspective exposes the topographic form stresses that mechanically exchange momentum between the layer and the solid earth bottom.

36.2.2 Effective sea level and the inverse barometer sea level

When considering a nonzero atmospheric pressure, we sometimes find it useful to introduce an *effective free surface height*

$$\eta^{\rm eff} = \eta + p_{\rm a}/(\rho\, g), \tag{36.4}$$

with gradients in the effective sea level leading to horizontal motion. However, when considering motions on time scales longer than a few days, the ocean free surface adjusts under atmospheric loading towards an *inverse barometer sea level*. An inverse barometer sea level compensates to atmospheric pressure so that there is no horizontal pressure gradient, and so there is no motion induced by the atmospheric pressure. Hence, all that matters for motion are deviations from the inverse barometer sea level.[1]

We expose details to support the above comments by writing pressure within the shallow water layer as

$$p(z) = p_{\mathrm{a}} + \rho\, g\, (\eta - z) \tag{36.5a}$$

$$= \overline{p_{\mathrm{a}}} + (p_{\mathrm{a}} - \overline{p_{\mathrm{a}}}) + \rho\, g\, (\eta - z) \tag{36.5b}$$

$$= \overline{p_{\mathrm{a}}} + \rho\, g\, (\eta - \eta^{\mathrm{ib}} - z). \tag{36.5c}$$

In these equations we introduced the area mean atmospheric pressure, $\overline{p_{\mathrm{a}}}$, as well as the inverse barometer sea level

$$\rho\, g\, \eta^{\mathrm{ib}} = \overline{p_{\mathrm{a}}} - p_{\mathrm{a}}. \tag{36.6}$$

The inverse barometer sea level is defined according to deviations of the atmospheric pressure from its area mean. Hence, when the atmospheric pressure is higher than the area mean, $p_{\mathrm{a}} > \overline{p_{\mathrm{a}}}$, then the inverse barometer sea level is negative, $\eta^{\mathrm{ib}} < 0$, reflecting the downward depression of the inverse barometer sea level. In contrast, $\eta^{\mathrm{ib}} > 0$ for anomalously low pressures, $p_{\mathrm{a}} < \overline{p_{\mathrm{a}}}$.

Introducing the inverse barometer sea level brings the horizontal pressure gradient to the form

$$\nabla_z p = \nabla p_{\mathrm{a}} + g\, \rho\, \nabla \eta = \rho\, g\, \nabla \eta^{\mathrm{eff}} = \rho\, g\, \nabla(\eta - \eta^{\mathrm{ib}}). \tag{36.7}$$

If sea level adjusts to the atmospheric pressure so that $\nabla \eta = \nabla \eta^{\mathrm{ib}}$, then there is no horizontal pressure gradient in the shallow water layer, in which case there is no induced motion from the atmospheric pressure. It follows that for dynamical purposes, we can seamlessly incorporate atmospheric pressure into the formalism by working with deviations of sea level from the inverse barometer sea level, $\eta - \eta^{\mathrm{ib}}$.

36.2.3 Further comments on pressure in a homogeneous layer

The depth independence of the horizontal pressure gradient within the shallow water layer is a direct result of the assumed hydrostatic nature of the pressure within the layer. To emphasize this point, we certainly can imagine a homogeneous fluid layer in which the horizontal velocity has a vertical shear. For example, in Section 50.3 we study surface gravity waves in a homogeneous fluid layer. Such waves have an amplitude that exponentially decays with depth, and so the horizontal and vertical fluid motion associated with the waves have a non-zero vertical shear. Such motion clearly cannot be caused by a hydrostatic pressure gradient since it has no vertical dependence throughout the layer, in which case

$$\partial_z(\nabla_z p_{\mathrm{hydrostatic}}) = 0. \tag{36.8}$$

Hence, in a homogeneous fluid layer, hydrostatic pressure gradients can only drive a horizontal flow that is depth independent within that layer. So if the vertically sheared horizontal flow is found within a homogeneous fluid layer, and if pressure gradients cause this flow, then it can

[1] The discussion in this section follows Appendix C to *Griffies and Greatbatch* (2012), where further details are provided. In particular, they allow for continuously stratified density rather than the shallow water model considered here. Even so, the key points from the shallow water discussion hold for the continuously stratified case.

only be through gradients in the *non-hydrostatic pressure*. As discussed in Section 50.2.4, surface gravity waves indeed involve non-hydrostatic pressure forces that drive the vertical dependence to the wave amplitude.

Moving beyond the homogeneous layer assumption, we saw in Section 28.3.6 that a horizontal gradient in the density leads to a vertically dependent hydrostatic pressure gradient $\partial_z(\nabla_z p_{\text{hydrostatic}}) \neq 0$. This hydrostatic pressure force can impart vertical shears to the horizontal flow. Thermal wind shear is the canonical example whereby vertical shears in the horizontal velocity are present in geostrophically balanced fluids as driven by horizontal density gradients (Section 32.4.4). We encounter the shallow water version of thermal wind in Section 37.2.2.

36.2.4 Momentum equation

If there is no friction anywhere in the fluid, including at the upper and lower boundaries, then the horizontal momentum is effected only by the Coriolis and pressure forces. Following our discussion of the Traditional Approximation in Section 28.1.3, we retain only the local vertical component to the Coriolis acceleration, which is compatible with the hydrostatic approximation. We are thus led to the horizontal velocity equation

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla(g\,\eta + p_{\mathrm{a}}/\rho), \tag{36.9}$$

where

$$\boldsymbol{v} = (\boldsymbol{u}, w) \tag{36.10}$$

splits out the horizontal velocity vector, $\boldsymbol{u}$, from the vertical velocity component, w.

The Coriolis parameter, $\boldsymbol{f} = f\,\hat{\boldsymbol{z}}$, is independent of depth, as is the horizontal pressure force from gradients in the free surface and applied pressure. Consequently, if the horizontal velocity is initially independent of depth, it will remain so for all time. The material time derivative thus only has contributions from the local time derivative and from horizontal advection

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \left[\frac{\partial}{\partial t} + u\,\frac{\partial}{\partial x} + v\,\frac{\partial}{\partial y}\right]\boldsymbol{u} \tag{36.11}$$

so that the shallow water velocity equation (36.9) takes on the form

$$(\partial_t + u\,\partial_x + v\,\partial_y)\boldsymbol{u} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla(g\,\eta + p_{\mathrm{a}}/\rho). \tag{36.12}$$

36.2.5 Thickness equation

The mass of a shallow water layer is constant in the absence of sources, sinks, or boundary fluxes. Hence, changes in mass at a particular region in the fluid must arise from mass fluxed across the region boundaries, leaving one region and accumulating in another. For simplicity, we assume that no mass crosses the fluid top (the free surface) or the bottom (the solid earth). We consider the more general case of boundary mass transport in Section 36.6. Note that since the fluid density is constant, mass conservation is the same as volume conservation. Hence, the terms "mass conservation" and "volume conservation" are commonly used interchangeably when working with shallow water models.

Consider an infinitesimally thin (in horizontal cross-section) vertical column of shallow water fluid that is fixed in space and extending from $\eta_{\mathrm{b}} \leq z \leq \eta$. Let the horizontal cross-sectional area be written as $\mathrm{d}A$ and the thickness be $h = \eta - \eta_{\mathrm{b}}$ (see Figure 36.3). The total mass of fluid in

FIGURE 36.3: Mass budget for a column of shallow water fluid with fixed cross-sectional area, $\mathrm{d}A$, constant density, ρ, and layer thickness, $h(x, y, t)$. The column mass is affected only by horizontal transport (transport within the layer) in the absence of boundary mass fluxes through the top, $z = \eta$, or bottom, $z = \eta_\mathrm{b}$. Note that since the density of the layer is constant, then mass equals to the constant density times the volume.

this column is given by

$$M = \int_{\text{column}} \left[\int_{\eta_\mathrm{b}}^{\eta} \rho \, \mathrm{d}z \right] \mathrm{d}A = \rho \int_{\text{column}} (\eta - \eta_\mathrm{b}) \, \mathrm{d}A = \rho \int_{\text{column}} h \, \mathrm{d}A. \tag{36.13}$$

Time changes in the column mass thus arise from time changes in the layer thickness integrated over the horizontal area of the column

$$\frac{\mathrm{d}M}{\mathrm{d}t} = \rho \int_{\text{column}} \frac{\partial h}{\partial t} \, \mathrm{d}A, \tag{36.14}$$

where

$$\frac{\partial h}{\partial t} = \frac{\partial (\eta - \eta_\mathrm{b})}{\partial t} = \frac{\partial \eta}{\partial t}, \tag{36.15}$$

since the bottom topography at $z = \eta_\mathrm{b}(x, y)$ is static.

General derivation

The mass within a fluid column changes due to mass crossing the vertical column boundaries (again, we assume here that no mass crosses the top or bottom interfaces). The mass flux penetrating the vertical boundary is given by

$$\text{mass per time entering column} = -\rho \oint_{\text{column}} \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}, \tag{36.16}$$

where $\hat{\boldsymbol{n}}$ is the outward normal at the column boundary, and $\mathrm{d}\mathcal{S}$ is the area element along the column boundary. The area integral is computed over the boundary of the column, which involves a vertical integral and a circumferential line integral

$$\text{mass per time entering column} = -\rho \oint_{\text{column}} \left[\int \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}z \right] \mathrm{d}l, \tag{36.17}$$

where $\mathrm{d}l$ is the infinitesimal line element around the column circumference. Since $\hat{\boldsymbol{n}} \cdot \boldsymbol{u}$ is depth independent, we can perform the vertical integral to render

$$-\rho \oint_{\text{column}} \left[\int \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}z \right] \mathrm{d}l = -\rho \oint_{\text{column}} h \, \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}l = -\rho \int_{\text{column}} \nabla \cdot (h \, \boldsymbol{u}) \, \mathrm{d}A, \tag{36.18}$$

where the second equality follows from the divergence theorem applied to the horizontal cross-sectional area of the column. Equating this result to the mass time tendency (36.14), and noting that the horizontal cross-sectional area is arbitrary, yields an equation for the layer thickness

$$\partial_t h + \nabla \cdot (h \, \boldsymbol{u}) = 0. \tag{36.19}$$

This result means that the thickness of fluid at a fixed location increases if there is a convergence of thickness onto that location, and decreases if thickness diverges from the location. We may also write the thickness equation (36.19) in the material time derivative form

$$\frac{\mathrm{D}h}{\mathrm{D}t} = -h \, \nabla \cdot \boldsymbol{u}. \tag{36.20}$$

Hence, thickness of a material fluid column increases in regions where the horizontal flow converges.

Special case with a rectangular column

To further our understanding of the second step in equation (36.18), consider the special case of a rectangular column, for which the mass per time of fluid entering the column is given by

$$\begin{aligned} &\text{mass per time entering column} \\ &\quad = -\rho \int_{\text{column}} [(u \, h)_{\text{east}} - (u \, h)_{\text{west}}] \, \mathrm{d}y - \rho \int_{\text{column}} [(v \, h)_{\text{north}} - (v \, h)_{\text{south}}] \, \mathrm{d}x. \end{aligned} \tag{36.21}$$

Taking the limit as the horizontal cross-section of the column becomes infinitesimal leads to

$$\begin{aligned} &\text{mass per time entering column} \\ &\quad = -\rho \int_{\text{column}} \left[\frac{\partial (u \, h)}{\partial x} + \frac{\partial (v \, h)}{\partial y} \right] \mathrm{d}x \, \mathrm{d}y = -\rho \int_{\text{column}} \nabla \cdot (h \, \boldsymbol{u}) \, \mathrm{d}A, \end{aligned} \tag{36.22}$$

thus recovering the result (36.18).

36.2.6 Bottom kinematic boundary condition

Kinematic boundary conditions arise from geometric constraints placed on the fluid system. We consider here the kinematic boundary condition at the bottom interface in the case where there is no flow through this interface, and follow in Section 36.2.7 with the surface kinematic boundary condition.[2]

The ocean bottom is located at a vertical position, $z = \eta_{\mathrm{b}}(x, y)$. This location can equivalently

[2] From the discussion of fluid kinematics in Part III, we use the term *material surface* for any continuous surface or interface that is impenetrable to the flow of matter or thermal energy (mechanical energy can be transferred via pressure forces). In Section 20.4 we derived the kinematic boundary conditions for a fluid at interfaces. We here apply those ideas to the shallow water system, so that the presentation in Sections 36.2.6 and 36.2.7 offer a review of Section 20.4 as applied to a shallow water layer.

be specified mathematically by the surface

$$s(x, y, z) = z - \eta_{\rm b}(x, y) = 0. \tag{36.23}$$

The outward normal (pointing from the fluid into the rock) at this surface is given by

$$\hat{\boldsymbol{n}} = -\frac{\nabla s}{|\nabla s|} = \frac{\nabla \eta_{\rm b} - \hat{\boldsymbol{z}}}{\sqrt{1 + \nabla \eta_{\rm b} \cdot \nabla \eta_{\rm b}}}. \tag{36.24}$$

If the bottom is impenetrable to fluid then the velocity field is constrained to satisfy the no-normal flow boundary condition

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{at } z = \eta_{\rm b}. \tag{36.25}$$

Making use of the bottom outward normal (36.24) leads to

$$w = \boldsymbol{u} \cdot \nabla \eta_{\rm b} \qquad \text{at } z = \eta_{\rm b}. \tag{36.26}$$

For a flat bottom, with $\nabla \eta_{\rm b} = 0$, the no-normal flow condition means that $w(\eta_{\rm b}) = 0$. For the case of nontrivial bottom topography, $w(\eta_{\rm b}) = 0$ remains if flow occurs along lines of constant topography; i.e., along isobaths, in which case $\boldsymbol{u} \cdot \nabla \eta_{\rm b} = 0$. But more generally, sloping bottoms lead to a nonzero vertical velocity component. Dynamically, a nonzero bottom vertical velocity arises from forces at the bottom that cause the horizontal velocity to cross isobaths, $\boldsymbol{u} \cdot \nabla \eta_{\rm b} \neq 0$.

The kinematic result (36.26) is written in an Eulerian sense, with the velocity constrained to satisfy this relation at each point along the bottom interface. It has a dual material interpretation based on acknowledging that the bottom interface is a material surface. A fluid element on the bottom at $s = z - \eta_{\rm b} = 0$ will thus remain there; it does not cross the bottom interface. Rather, it can at most move tangentially to the bottom.[3] We can ensure the no-normal flow constraint by setting

$$\frac{{\rm D}s}{{\rm D}t} = \frac{{\rm D}\left(z - \eta_{\rm b}\right)}{{\rm D}t} = 0 \qquad \text{at } z = \eta_{\rm b}. \tag{36.27}$$

Rearrangement of this result leads to the Eulerian constraint (36.26). Equivalently, we can write this boundary condition in the form

$$w = \frac{{\rm D}\eta_{\rm b}}{{\rm D}t} \qquad \text{at } z = \eta_{\rm b}. \tag{36.28}$$

Since $\eta_{\rm b} = \eta_{\rm b}(x, y)$, this expression of the kinematic boundary condition is identical to equation (36.26).

36.2.7 Surface kinematic boundary condition

We here assume the surface boundary is a material surface to derive the surface kinematic boundary condition, with Section 36.6 considering the slightly more general case of volume crossing this surface. As a material surface, the surface kinematic boundary condition follows analogously to the bottom. However, there is a fundamentally new feature in that the layer's upper free surface is a time dependent moving boundary. We studied such boundaries in Section 20.4.2 when detailing the kinematic boundary conditions for a material surface. We here review some of that discussion.

The free surface is located at a vertical position $z = \eta(x, y, t)$. Equivalently, the free surface

[3] Details of the tangential motion along a material boundary require dynamical information such as boundary stresses (see Chapter 26). We are not concerned with such dynamical information here, rather our concern is solely with kinematics.

can be specified by a surface of constant s, where

$$s(x, y, z, t) = z - \eta(x, y, t) = 0. \tag{36.29}$$

The outward normal to the free surface is thus given by

$$\hat{\boldsymbol{n}} = \frac{\nabla s}{|\nabla s|} = \frac{\hat{\boldsymbol{z}} - \nabla \eta}{\sqrt{1 + \nabla \eta \cdot \nabla \eta}}. \tag{36.30}$$

We must account for motion of the surface when formulating the no-normal flow condition. To do so, write this no-normal flow condition as

$$(\boldsymbol{v} - \boldsymbol{v}^{(s)}) \cdot \hat{\boldsymbol{n}} = 0 \qquad \text{at } z = \eta(x, y, t), \tag{36.31}$$

where $\boldsymbol{v}^{(s)}$ is the velocity of a point on the ocean surface. The velocity of a point fixed on an arbitrary surface with specified s satisfies

$$\frac{\partial s}{\partial t} + \boldsymbol{v}^{(s)} \cdot \nabla s = 0. \tag{36.32}$$

As defined, $\boldsymbol{v}^{(s)}$ advects a fluid element in a manner to always keep the element fixed on the constant s surface. With $\hat{\boldsymbol{n}} = \nabla s / |\nabla s|$, we have

$$\boldsymbol{v}^{(s)} \cdot \hat{\boldsymbol{n}} = -\frac{\partial_t s}{|\nabla s|} = \frac{\partial_t \eta}{\sqrt{1 + \nabla \eta \cdot \nabla \eta}}. \tag{36.33}$$

Hence, if the surface remains static, then $\boldsymbol{v}^{(s)} \cdot \hat{\boldsymbol{n}} = 0$. But more generally, the surface is moving, and that movement is fundamental to the surface kinematic boundary condition.

Making use of the result (36.33) in the no-normal flow constraint (36.31) then leads to the surface kinematic boundary condition

$$w - \boldsymbol{u} \cdot \nabla \eta = \frac{\partial \eta}{\partial t} \qquad \text{at } z = \eta. \tag{36.34}$$

As for the bottom kinematic boundary condition written as (36.27), we can interpret the surface kinematic condition (36.34) materially, in which case

$$\frac{\mathrm{D}s}{\mathrm{D}t} = \frac{\mathrm{D}\,(z - \eta)}{\mathrm{D}t} = 0 \qquad \text{at } z = \eta. \tag{36.35}$$

That is, in the absence of flow across the surface boundary, that surface remains material. We can write this boundary condition in the equivalent form

$$w = \frac{\mathrm{D}\eta}{\mathrm{D}t} = (\partial_t + \boldsymbol{u} \cdot \nabla)\, \eta \qquad \text{at } z = \eta. \tag{36.36}$$

36.2.8 Column stretching and vertical velocity

Since the fluid has constant density, we know that the velocity has zero divergence

$$\nabla \cdot \boldsymbol{u} + \partial_z w = 0 \Longrightarrow \partial_z w = -\nabla \cdot \boldsymbol{u}. \tag{36.37}$$

This result also follows since material fluid elements in the constant density shallow water layer maintain a constant volume (see Section 22.2). Furthermore, since the horizontal velocity has

no depth dependence, we can vertically integrate the continuity equation from the bottom to an arbitrary depth within the layer to render

$$w(z) = w(\eta_{\rm b}) - (z - \eta_{\rm b})\, \nabla \cdot \boldsymbol{u}, \tag{36.38}$$

so that the vertical velocity is a linear function of depth within a shallow water layer. Applying this equation at the ocean surface yields

$$w(\eta) = w(\eta_{\rm b}) - (\eta - \eta_{\rm b})\, \nabla \cdot \boldsymbol{u}. \tag{36.39}$$

Eliminating the horizontal convergence between equations (36.38) and (36.39) leads to

$$w(z) - w(\eta_{\rm b}) = \left[\frac{z - \eta_{\rm b}}{\eta - \eta_{\rm b}}\right] [w(\eta) - w(\eta_{\rm b})]. \tag{36.40}$$

Making use of the surface kinematic boundary condition (36.36) and bottom kinematic boundary condition (36.28) renders the material form

$$\frac{1}{z - \eta_{\rm b}} \left[\frac{{\rm D}(z - \eta_{\rm b})}{{\rm D}t}\right] = \frac{1}{\eta - \eta_{\rm b}} \left[\frac{{\rm D}(\eta - \eta_{\rm b})}{{\rm D}t}\right]. \tag{36.41}$$

Finally, introducing the layer thickness $h = \eta - \eta_{\rm b}$ yields the material conservation law

$$\frac{\rm D}{{\rm D}t} \left[\frac{z - \eta_{\rm b}}{h}\right] = 0. \tag{36.42}$$

Again, $h = \eta - \eta_{\rm b}$ is the layer thickness and $z - \eta_{\rm b}$ is the height of a fluid element from the bottom interface (see Figure 36.1). Consequently, equation (36.42) means that the ratio of the fluid element height above the bottom to the layer thickness remains constant as the fluid element moves through the shallow water fluid. That is, a vertical column of shallow water fluid stretches or squeezes coherently within a shallow water layer, so that the relative vertical position remains fixed for a point within the column. Shallow water mechanics thus comprises the mechanics of coherent vertical fluid columns moving within a fluid layer. This constrained behavior results from the linear depth dependence of the vertical velocity, which itself is a result of the depth independence of the horizontal velocity, and which follows from the depth independence of the horizontal gradient of hydrostatic pressure.

36.2.9 Tracer concentration equation

Suppose there is a material substance, a tracer, contained within a shallow water layer.[4] We expect the tracer concentration, ψ, to have a non-uniform vertical structure within the layer, in addition to having horizontal structure: $\psi = \psi(x, y, z, t)$. If the tracer is advected through the layer without any diffusion, then the concentration satisfies the perfect fluid tracer equation (i.e., the *advection equation*)

$$\frac{\partial \psi}{\partial t} + \boldsymbol{u} \cdot \nabla_z \psi + w\, \partial_z \psi = 0. \tag{36.43}$$

For a shallow water layer, where the horizontal velocity has no depth dependence within a layer, we find it sufficient to study the depth averaged tracer concentration within the layer,

$$C(x, y, t) \equiv \frac{1}{h} \int_{\eta_{\rm b}}^{\eta} \psi(x, y, z, t)\, {\rm d}z. \tag{36.44}$$

[4] We developed the theory of material tracers in Chapter 21.

To develop the evolution equation for C, we vertically integrate the tracer equation (36.43) over the layer and make use of Leibniz's rule (Section 21.2.4)

$$\int_{\eta_b}^{\eta} \frac{\partial \psi}{\partial t}\, \mathrm{d}z = \partial_t (h\, C) - \psi(\eta)\, \partial_t \eta \tag{36.45a}$$

$$\int_{\eta_b}^{\eta} \boldsymbol{u} \cdot \nabla \psi\, \mathrm{d}z = \nabla \cdot (h\, C\, \boldsymbol{u}) - \psi(\eta)\, \boldsymbol{u}(\eta) \cdot \nabla \eta + \psi(\eta_b)\, \boldsymbol{u}(\eta_b) \cdot \nabla \eta_b - h\, C\, \nabla \cdot \boldsymbol{u} \tag{36.45b}$$

$$\int_{\eta_b}^{\eta} w\, \partial_z \psi\, \mathrm{d}z = w(\eta)\, \psi(\eta) - w(\eta_b)\, \psi(\eta_b) - h\, C\, \partial_z w. \tag{36.45c}$$

For these equations we made use of the z independence of $\boldsymbol{u}$ and $\partial_z w$ within the layer. Use of the kinematic boundary conditions from Sections 36.2.6 and 36.2.7, and the three dimensional continuity equation, $\nabla \cdot \boldsymbol{u} + \partial_z w = 0$, renders the equation for the layer depth averaged tracer concentration

$$\frac{\partial (h\, C)}{\partial t} + \nabla \cdot (h\, C\, \boldsymbol{u}) = 0 \Longleftrightarrow \frac{\partial C}{\partial t} + \boldsymbol{u} \cdot \nabla C = \frac{\mathrm{D}C}{\mathrm{D}t} = 0. \tag{36.46}$$

As a self-consistency check, note that if the tracer concentration has a horizontally uniform value, then the flux-form of the tracer equation (36.46) reduces to the thickness equation (36.19).

36.2.10 Summary comments

Key physical assumptions for the shallow water fluid

The shallow water fluid model is based on the following two assumptions.

- The fluid layer has a uniform density, which then means the fluid is incompressible.
- The pressure is hydrostatic.

Since the pressure gradient is depth-independent within the layer, an initial horizontal velocity that is depth independent will remain depth independent. That is, the fluid moves as columns within the layer, with the columns stretching and squashing depending on the divergence or convergence of volume towards the column.

The term "shallow" refers to the small vertical to horizontal aspect ratio, $H/L \ll 1$, which in turn is consistent with the hydrostatic approximation (Section 28.2). The term "water" refers to the incompressible nature of the fluid, which is a more relevant approximation for the ocean than for the atmosphere (see Section 30.1). Nonetheless, the shallow water model has direct applications to many features of both the atmosphere and ocean circulation, and as such it is widely used across the atmosphere and ocean sciences.

Shallow water fluid columns are not Taylor columns

The columnar motion of fluid within a shallow water layer is reminscent of the Taylor columns discussed in Section 32.5.3. However, the columnar motion of fluid within a Taylor column is fundamentally distinct from that of a column of shallow water fluid. Motion in a Taylor column holds for homogeneous fluids undergoing rapid rotation and moving over a flat surface. The horizontal fluid velocity within a Taylor column is non-divergent so that there is no vertical motion of the fluid. These properties allow one to interpret a Taylor column as a fluid mechanical realization of a column of rigid matter much like a solid body.

In contrast, shallow water fluid columns do not rely on rotation, but instead arise from the hydrostatic balance maintained within each homogeneous layer. Additionally, shallow water columns

are not rigid. Rather, they stretch and squash in the presence of nonzero divergence in the horizontal flow, thus leading to vertical motion of fluid within the column. Finally, shallow water columns remain coherent even as they move over topography, and yet, again, they can stretch and squash.

36.3 Reduced gravity model for the upper ocean

The *reduced gravity model* describes an active layer of uniform density, ρ_1, above a stagnant layer of density, ρ_2, and below a fluid of zero density, $\rho_0 = 0$. It is often referred to as the 1.5 layer model. This theoretical model has been used, to some success, as an idealization of the upper ocean circulation whereby an active layer (e.g., the region above the ocean pycnocline), sits above an inactive layer (the abyss) of much smaller motion (here assumed to be zero motion). In this way, we introduce the *level of no motion*, below which (baroclinic) currents vanish.

FIGURE 36.4: Reduced gravity model of shallow water fluid. The lower layer with density ρ_2 is dynamically inactive and thus has a zero velocity. The upper layer is dynamically active with thickness, $h = \eta_{1/2} - \eta_{3/2}$, and density, ρ_1. The dynamically active layer is bounded above by a zero density atmosphere, $\rho_0 = 0$. The lower inactive layer is assumed to be infinitely deep so that its continuity equation can be ignored; i.e., even though there are zero currents within this layer, the layer thickness can still undulate. The reduced gravity between the two layers is defined by $g^{\mathrm{r}}_{3/2} = g\,(\rho_2 - \rho_1)/\rho_{\mathrm{ref}} \ll g$, whereas the reduced gravity at the top interface is given by $g^{\mathrm{r}}_{1/2} = g$.

36.3.1 Momentum and thickness equations for the active layer

We develop the momentum equations for the reduced gravity model by making use of the hydrostatic balance, in which pressure at a depth, z, in the upper layer is computed as (see Figure 36.4)

$$p_1(x, y, z, t) = p_{1/2}(x, y, t) + g\,\rho_1\,[\eta_{1/2}(x, y, t) - z], \tag{36.47}$$

where we denote an interface value by a half-index, so that $\eta_{1/2}$ and $p_{1/2}$ are the interface height and pressure at the upper layer interface.[5] Since the fluid above the upper layer is assumed to have zero density, we set

$$p_{1/2} = 0. \tag{36.48}$$

[5]There is no general consensus on this notation, with some treatments, such as *Vallis* (2017) and *Cushman-Roisin and Beckers* (2011) using an integer to label an interface quantity, whereas some numerical model papers (e.g., *Griffies et al.* (2020)) use the half-index. We prefer the half-index since it removes any ambiguity concerning the ordering of the interfaces relative to the layer.

The horizontal momentum equation for the upper (active) layer is given by

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}\boldsymbol{u}_1}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_1 \right] = -g\,\rho_1\,\nabla\eta_{1/2}, \tag{36.49}$$

where the z dependent term in the pressure (36.47) drops out when computing the horizontal pressure gradient. Setting the reference density equal to the top layer density, $\rho_{\text{ref}} = \rho_1$, leads to the more tidy equation

$$\frac{\mathrm{D}\boldsymbol{u}_1}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_1 = -g\nabla\eta_{1/2}. \tag{36.50}$$

The equations for the upper layer are completed by volume conservation in the form of the thickness equation

$$\frac{\mathrm{D}h_1}{\mathrm{D}t} = -h_1\,\nabla\cdot\boldsymbol{u}_1. \tag{36.51}$$

36.3.2 Relating undulations of the top and bottom layer interfaces

The pressure in the lower stagnent layer is given by the weight per horizontal area of fluid above it, and it can be written

$$p_2(x,y,z,t) = g\,\rho_1\,(\eta_{1/2} - \eta_{3/2}) + g\,\rho_2\,(\eta_{3/2} - z) \tag{36.52a}$$

$$= g\,\rho_1\,\eta_{1/2} + g\,(\rho_2 - \rho_1)\,\eta_{3/2} - g\,\rho_2\,z \tag{36.52b}$$

$$= \rho_{\text{ref}}\,(g^{\text{r}}_{1/2}\,\eta_{1/2} + g^{\text{r}}_{3/2}\,\eta_{3/2}) - g\,\rho_2\,z. \tag{36.52c}$$

In this equation we introduced the reference density and *reduced gravities*

$$\rho_{\text{ref}} = \rho_1 \quad \text{and} \quad g^{\text{r}}_{1/2} = g \quad \text{and} \quad g^{\text{r}}_{3/2} = g\,(\rho_2 - \rho_1)/\rho_{\text{ref}} \ll g. \tag{36.53}$$

Taking the reference density as the top layer density is common for Boussinesq shallow water models, and will be assumed in our formulations with multiple layers in Section 36.4. We employ the half-index notation for the reduced gravities since they are computed by differencing the densities between two adjacent layers, and as such they are considered an interface property. Additionally, the reduced gravities multiply a corresponding interface gradient, which also uses the half-integer notation.

For the reduced gravity model we assume the lower layer is motionless. To maintain zero motion in the lower layer requires the lower layer horizontal pressure gradient to vanish

$$\rho_{\text{ref}}^{-1}\,\nabla_z p_2 = g^{\text{r}}_{1/2}\,\nabla\eta_{1/2} + g^{\text{r}}_{3/2}\,\nabla\eta_{3/2} = 0. \tag{36.54}$$

This constraint links the undulations of the top and bottom interfaces of the dynamically active layer

$$\nabla\eta_{1/2} = -\frac{g^{\text{r}}_{3/2}}{g^{\text{r}}_{1/2}}\,\nabla\eta_{3/2} = -[(\rho_2 - \rho_1)/\rho_{\text{ref}}]\,\nabla\eta_{3/2} \Longrightarrow \eta_{1/2} = -\eta_{3/2}\,[(\rho_2 - \rho_1)/\rho_{\text{ref}}] + \text{constant}. \tag{36.55}$$

The density ratio, $(\rho_2 - \rho_1)/\rho_{\text{ref}}$, is positive but typically much smaller than unity. Hence, the relation (36.55) means that undulations of the free surface, $\eta_{1/2}$, are of opposite sign and of much smaller amplitude than undulations in the lower interface, $\eta_{3/2}$. This behavior is typical for undulations of the pycnocline region of the ocean and the free surface as depicted in Figure 36.5.

36.3.3 Momentum equation with reduced gravity

Relation (36.54) can be used to write the momentum equation (36.50) in the form

$$\frac{\mathrm{D}\boldsymbol{u}_1}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_1 = g^{\mathrm{r}}_{3/2}\,\nabla\eta_{3/2}. \tag{36.56}$$

It is common to make use of the momentum equation in the form (36.56), rather than the original form (36.50). The reason is that historically, ocean hydrography measurements[6] have allowed for an estimate of the pycnocline slope, $\nabla\eta_{3/2}$, whereas it was not until precise satellite altimetry measurements starting in the 1990s that we could estimate the far smaller sea level slope, $\nabla\eta_{1/2}$.

FIGURE 36.5: A vertical slice through a reduced gravity, or 1.5 layer, ocean in hydrostatic balance. Shown here is a plug of dynamically active light water, as may occur in a warm core eddy to the subtropical gyres, sitting on top of heavy water of zero motion. The free surface corresponds to $\eta_{1/2}$ in Figure 36.4, whereas the pycnocline (heavy black line) corresponds to the lower interface $\eta_{3/2}$ of Figure 36.4. The sea surface experiences an applied pressure $p = p_{\mathrm{a}}$, assumed to be uniform for this idealized situation. Note how sea level is a maximum above the pycnocline minimum, with this geometry reflected in equation (36.55). In the ocean, the slope of the pycnocline is about 100-300 times larger than the slope of the sea level. That is, sea level may show undulations on the order of a metre, whereas the pycnocline undulations are on the order of 100-300 m.

36.3.4 Reduced gravity and relative buoyancy

Equation (36.54)

$$g\,\nabla\eta_{1/2} = -g^{\mathrm{r}}_{3/2}\,\nabla\eta_{3/2}, \tag{36.57}$$

says that with $g^{\mathrm{r}}_{3/2} \ll g$, the free surface slopes are much smaller than interior slopes

$$|\nabla\eta_{1/2}| \ll |\nabla\eta_{3/2}|. \tag{36.58}$$

We thus infer that the interior interface has less resistance to vertical motion than the free surface. To help understand this result, recall the study of Archimedean buoyancy in Section 31.4. We see that the reduced gravity, $g^{\mathrm{r}}_{3/2}$, is the Archimedean buoyancy of layer 1 relative to layer 2, with normalization given by the reference density as per the Boussinesq approximation

$$\text{buoyancy layer 1 relative to layer 2} = -g\,(\rho_1 - \rho_2)/\rho_{\mathrm{ref}} = g^{\mathrm{r}}_{3/2}. \tag{36.59}$$

[6] In oceanography, hydrography refers to measurements of temperature, salinity, and pressure; see *Talley et al.* (2011).

A small relative buoyancy between two density layers renders little resistence for motion of the layer interface. Indeed, as the density difference vanishes, so too does the buoyant resistance to motion of the layer interface. For the upper free surface, the buoyancy of layer 0 (a zero mass atmosphere) relative to layer 1 equals to the full gravitational acceleration.

$$\text{buoyancy layer 0 relative to layer 1} = -g\,(\rho_0 - \rho_1)/\rho_{\text{ref}} = g, \tag{36.60}$$

where we assumed that $\rho_{\text{ref}} = \rho_1$ and $\rho_0 = 0$. Evidently, the relative buoyancy between the top shallow water layer and the atmosphere is given by the full gravity acceleration, which indicates the large buoyant resistence to vertical motion of the free surface.

It is for this reason that the interior interface is more flexible than the free surface, as depicted in Figure 36.5. Even for an atmosphere with mass, so that $\rho_0 > 0$, the upper interface's reduced gravity is close to g since the atmosphere is roughly 1000 times less dense than seawater. This result holds in general, whereby increasing the reduced gravity between density layers, and thus increasing the vertical density stratification, increases the resistance to motion of the layer interface and thus reduces the interface's flexibility.

36.3.5 Further study

The material in this section is inspired by Section 3.2 of *Vallis* (2017). *Tomczak and Godfrey* (1994) make use of the reduced gravity model for interpretating aspects of the observed ocean. Additional use is made by *Griffies et al.* (2014) for interpreting large-scale sea level patterns.

36.4 Stacked shallow water equations

In studies of shallow water fluids, much of the formalism developed for a single layer can be readily extended to an arbitrary number of layers. We here pursue this extension and thereby expose the underlying kinematics and dynamics of stacked shallow water models. We assume the layers are immiscible so that matter and thermal properties are not exchanged between the layers. Consequently, the layers couple only through mechanical forces arising from pressure form stress (Chapter 29). Furthermore, we continue to assume that the horizontal velocity has no depth-dependence within each shallow water layer, which in turn means the horizontal pressure gradient is depth independent within each layer. The notation for our derivations is depicted in Figure 36.6 in the case of three active layers.

In Section 62.2 we develop the equations for a continuosly stratified Boussinesq fluid making use of isopycnal vertical coordinates. Although the vertical stratification is continuous in that case, we find that the isopycnal equations are isomorphic to the stacked shallow water equations. Hence, besides being of intrinsic interest as a versatile theoretical model, the stacked shallow water model offers a suitable step towards studies of a continuously stratified fluid using isopycnal coordinates.

36.4.1 Formulation of a 2-layer model

We here display the equations for two layers, thus offering the seeds for an extension to N layers in Section 36.4.2.

FIGURE 36.6: Three dynamically active layers of stacked shallow water fluid ($N = 3$). The notation corresponds to that for the reduced gravity model of Figure 36.4, yet here with three dynamically active layers. In particular, $\eta_{1/2}$ is the free surface, $\eta_{1/2} = \eta$, whereas $\eta_{N+1/2} = \eta_b$ is the bottom interface. Hence, the total thickness of a column is $h_1 + h_2 + h_3 = \eta_{1/2} - \eta_b$. The "atmosphere" above the layers is assumed to apply a pressure, p_a, to the upper surface. The horizontal velocity is depth-independent within each layer, as is the horizontal pressure gradient, so that both are discontinuous across a layer interface. In contrast, the pressure is a linear function of depth within a layer and is continuous across a layer interface. Finally, the vertical velocity is also a linear function of depth within a layer but it is discontinuous across a layer interface. The reduced gravity defined between each layer is given by $g^r_{k+1/2} = g\,(\rho_{k+1} - \rho_k)/\rho_{ref}$. We take the reference density as $\rho_{ref} = \rho_1$, which results in a tidy set of layer equations.

Thickness and tracer equations

Each shallow water layer satisfies its own independent thickness equation and tracer equation, representing the conservation of volume and tracer content for each layer

$$\frac{\partial h_1}{\partial t} + \nabla \cdot (h_1\, \boldsymbol{u}_1) = 0 \tag{36.61a}$$

$$\frac{\partial h_2}{\partial t} + \nabla \cdot (h_2\, \boldsymbol{u}_2) = 0 \tag{36.61b}$$

$$\frac{\partial (h_1\, C_1)}{\partial t} + \nabla \cdot (h_1\, C_1\, \boldsymbol{u}_1) = 0 \tag{36.61c}$$

$$\frac{\partial (h_2\, C_2)}{\partial t} + \nabla \cdot (h_2\, C_2\, \boldsymbol{u}_2) = 0. \tag{36.61d}$$

We emphasize that there is no explicit coupling between these equations, as each layer separately must satisfy volume conservation and tracer conservation. However, the velocities are coupled through the pressure force, as we now discuss.

Pressure within a layer

To compute the pressure within a layer, we make use of the hydrostatic balance and integrate down from the surface, which results in the pressure fields

$$p_1 = \rho_1 \, g \, (\eta_{1/2} - z) + p_{\mathrm{a}} \tag{36.62}$$

$$p_2 = \rho_1 \, g \, (\eta_{1/2} - \eta_{3/2}) + \rho_2 \, g \, (\eta_{3/2} - z) + p_{\mathrm{a}}. \tag{36.63}$$

As for the reduced gravity model in equation (36.52c), it is convenient to write pressure in layer-two using the reduced gravity, which leads to

$$p_2 - p_{\mathrm{a}} = \rho_1 \, g \, (\eta_{1/2} - \eta_{3/2}) + \rho_2 \, g \, (\eta_{3/2} - z) \tag{36.64a}$$

$$= g \, \eta_{1/2} \, \rho_1 + g \, (\rho_2 - \rho_1) \, \eta_{3/2} - g \, \rho_2 \, z \tag{36.64b}$$

$$= \rho_{\mathrm{ref}} \, (g^{\mathrm{r}}_{1/2} \, \eta_{1/2} + g^{\mathrm{r}}_{3/2} \, \eta_{3/2}) - g \, \rho_2 \, z \tag{36.64c}$$

with the Boussinesq reference density and reduced gravities given by

$$\rho_{\mathrm{ref}} = \rho_1 \quad \text{and} \quad g^{\mathrm{r}}_{1/2} = g \quad \text{and} \quad g^{\mathrm{r}}_{3/2} = g \, (\rho_2 - \rho_1)/\rho_{\mathrm{ref}} \ll g. \tag{36.65}$$

As for the reduced gravity model in equation (36.53), we set the reference density equal to the top layer density. As per the discussion around equation (36.75), $\rho_{\mathrm{ref}} = \rho_1$ results in a somewhat tidier set of layer velocity equations.

Boussinesq reference density and the reduced gravity

We are formulating the shallow water model according to Boussinesq ocean equations from Chapter 30, whereby fluid elements conserve their volume rather than their mass. According to our discussion of the Boussinesq momentum equation in Section 30.1.2, density is set to a constant reference density when measuring the inertial mass of a fluid element, yet density remains the *in situ* density when measuring weight of a fluid element. For the shallow water model, we multiply the inertial acceleration and Coriolis acceleration with a reference density,

$$\rho_{\mathrm{ref}} = \text{shallow water reference density}, \tag{36.66}$$

whereas pressure and potential energy maintain the density, ρ_{k}, of the shallow water layer.

We further make use of the Boussinesq ocean when computing the buoyancy frequency (Section 31.5.4). Namely, with ϱ the potential density, the Boussinesq form of the squared buoyancy frequency is

$$N^2 = -g \left[\frac{1}{\rho_{\mathrm{ref}}} \frac{\partial \varrho}{\partial z} \right] \approx -\frac{g}{\rho_{\mathrm{ref}}} \frac{\Delta \rho}{\Delta z} = -g^{\mathrm{r}}/\Delta z. \tag{36.67}$$

It is for this reason that we take ρ_{ref} for the denominator of the reduced gravity throughout all of the shallow water layers, thus defining

$$g^{\mathrm{r}}_{\mathrm{k}-1/2} = g \, (\rho_{\mathrm{k}} - \rho_{\mathrm{k}-1})/\rho_{\mathrm{ref}} \quad \text{and} \quad g^{\mathrm{r}}_{1/2} = g. \tag{36.68}$$

Horizontal velocity equations

The horizontal velocity equations for the two layers take the form

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_1 \boldsymbol{u}_1}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_1 \right] = -\nabla p_1 \tag{36.69a}$$

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_2 \boldsymbol{u}_2}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_2 \right] = -\nabla p_2, \tag{36.69b}$$

where we introduced the layer material time derivatives

$$\frac{\mathrm{D}_k}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{u}_k \cdot \nabla \quad \text{for } k = 1, 2. \tag{36.70}$$

Making use of expressions (36.62) and (36.64c) for layer pressures leads to the horizontal momentum equations

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_1 \boldsymbol{u}_1}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_1 \right] = -g\, \rho_1\, \nabla[\eta_{1/2} + p_{\text{a}}/(g\, \rho_1)] \tag{36.71a}$$

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_2 \boldsymbol{u}_2}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_2 \right] = -g\, \rho_1\, \nabla[\eta_{1/2} + p_{\text{a}}/(g\, \rho_1)] - g^{\text{r}}_{3/2}\, \rho_{\text{ref}}\, \nabla \eta_{3/2}. \tag{36.71b}$$

It is convenient to express the interface heights in terms of layer thicknesses, h_1 and h_2, since the layer thicknesses are the prognostic fields determined by time stepping the thickness equations (36.61a) and (36.61b). We thus write

$$\eta_{1/2} = \eta_{\text{b}} + h_1 + h_2 \qquad \text{and} \qquad \eta_{3/2} = \eta_{\text{b}} + h_2, \tag{36.72}$$

so that

$$p_1 - p_{\text{a}} = \rho_1\, g\, (\eta_{\text{b}} + h_1 + h_2) - g\, \rho_1\, z \tag{36.73a}$$

$$p_2 - p_{\text{a}} = \rho_1\, g\, (\eta_{\text{b}} + h_1 + h_2) + \rho_{\text{ref}}\, g^{\text{r}}_{3/2}\, (\eta_{\text{b}} + h_2) - g\, \rho_2\, z, \tag{36.73b}$$

thus resulting in the horizontal momentum equations

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_1 \boldsymbol{u}_1}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_1 \right] = -\rho_1\, g\, \nabla[\eta_{\text{b}} + h_1 + h_2 + p_{\text{a}}/(g\, \rho_1)] \tag{36.74a}$$

$$\rho_{\text{ref}} \left[\frac{\mathrm{D}_2 \boldsymbol{u}_2}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_2 \right] = -\rho_1\, g\, \nabla[\eta_{\text{b}} + h_1 + h_2 + p_{\text{a}}/(g\, \rho_1)] - \rho_{\text{ref}}\, g^{\text{r}}_{3/2}\, \nabla(\eta_{\text{b}} + h_2). \tag{36.74b}$$

Notice how layer thickness from one layer appears in the other layer's pressure gradient. In this way, changes in the thickness of one layer have a direct impact on pressure forces and flow in the adjacent layer. Also notice how the bottom topography appears in the bottom pressure gradient, which arises due to our switch from layer interfaces to layer thicknesses.

As already noted, it is common for a stacked shallow water model to choose

$$\rho_{\text{ref}} = \rho_1. \tag{36.75}$$

We here see why taking this choice is desirable, since doing so results in the tidy layer velocity

equations

$$\frac{\mathrm{D}_1 \boldsymbol{u}_1}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_1 = -g\nabla[\eta_\mathrm{b} + h_1 + h_2 + p_\mathrm{a}/(g\,\rho_1)] \tag{36.76a}$$

$$\frac{\mathrm{D}_2 \boldsymbol{u}_2}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_2 = -g\nabla[\eta_\mathrm{b} + h_1 + h_2 + p_\mathrm{a}/(g\,\rho_1)] - g^\mathrm{r}_{3/2}\nabla(\eta_\mathrm{b} + h_2). \tag{36.76b}$$

Vertical shear in horizontal velocities between layers

The difference in layer velocities, $\boldsymbol{u}_1 - \boldsymbol{u}_2$, represents the vertical shear in the layers. This difference is affected by a pressure gradient arising just from bottom topography and the interior layer thickness, h_2

$$\frac{\mathrm{D}_1 \boldsymbol{u}_1}{\mathrm{D}t} - \frac{\mathrm{D}_2 \boldsymbol{u}_2}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times (\boldsymbol{u}_1 - \boldsymbol{u}_2) = g^\mathrm{r}_{3/2}\nabla\,(\eta_\mathrm{b} + h_2). \tag{36.77}$$

That is, the vertical shear does not directly feel undulations of the free surface, $\eta_{1/2}$, or the applied pressure, p_a. Rather, it feels these surface undulations only indirectly via nonlinear terms appearing in the advection on the left hand side. We further discuss this result in Section 37.2.2 by introducing thermal wind and the Margules' Relation.

36.4.2 N-layer model equations

The 2-layer equations from Section 36.4.1 can be generalized to N-layers. The thickness equation and tracer equation represent volume and tracer conservation for each layer

$$\frac{\partial h_\mathrm{k}}{\partial t} + \nabla \cdot (\boldsymbol{u}_\mathrm{k}\, h_\mathrm{k}) = 0 \tag{36.78a}$$

$$\frac{\partial (h_\mathrm{k}\, C_\mathrm{k})}{\partial t} + \nabla \cdot (\boldsymbol{u}_\mathrm{k}\, h_\mathrm{k}\, C_\mathrm{k}) = 0, \tag{36.78b}$$

where $\mathrm{k} = 1, N$ is the discrete layer index and there is no implied summation on this label.[7]

Expressions for the pressure

Some work is needed to generalize the pressure gradient appearing in the velocity equation. For that purpose, write the interface height as

$$\eta_{\mathrm{k}+1/2} = \eta_\mathrm{b} + \sum_{\mathrm{j}=\mathrm{k}+1}^{N} h_\mathrm{j} \quad \text{with } \eta_{N+1/2} = \eta_\mathrm{b} \text{ and } \eta_{1/2} = \eta. \tag{36.79}$$

For example, the layer interfaces with $N = 3$ layers are given by

$$\eta_{1/2} = \eta_\mathrm{b} + h_1 + h_2 + h_3 \qquad \eta_{3/2} = \eta_\mathrm{b} + h_2 + h_3 \qquad \eta_{5/2} = \eta_\mathrm{b} + h_3 \qquad \eta_{7/2} = \eta_\mathrm{b}. \tag{36.80}$$

In turn, the hydrostatic pressure within layer-k is given by

$$p_\mathrm{k} = -g\,\rho_\mathrm{k}\, z + p_\mathrm{a} + \rho_\mathrm{ref} \sum_{\mathrm{j}=0}^{\mathrm{k}-1} g^\mathrm{r}_{\mathrm{j}+1/2}\, \eta_{\mathrm{j}+1/2} = p_{\mathrm{k}-1/2} + g\,\rho_\mathrm{k}\,(\eta_{\mathrm{k}-1/2} - z), \tag{36.81}$$

[7] To help distinguish the layer index, k, from a tensor index, k, we write the layer index using an upright Roman font whereas a tensor index is slanted.

where the reduced gravities are defined according to equation (36.68)

$$g^{\mathrm{r}}_{\mathrm{j}-1/2} = g\,(\rho_{\mathrm{j}} - \rho_{\mathrm{j}-1})/\rho_{\mathrm{ref}} > 0 \quad \text{with} \quad g^{\mathrm{r}}_{1/2} = g. \tag{36.82}$$

As an example, the layer pressures for $N = 3$ are given by

$$p_1 = p_{\mathrm{a}} + g\,\rho_1\,(\eta_{1/2} - z) \qquad p_2 = p_{3/2} + g\,\rho_2\,(\eta_{3/2} - z) \qquad p_3 = p_{5/2} + g\,\rho_3\,(\eta_{5/2} - z). \tag{36.83}$$

The half-integer pressures are evaluated on the corresponding interface, and the hydrostatic balance yields the pressure difference

$$p_{\mathrm{k}+1/2} - p_{\mathrm{k}-1/2} = g\,\rho_{\mathrm{k}}\,h_{\mathrm{k}} = g\,\rho_{\mathrm{k}}\,(\eta_{\mathrm{k}-1/2} - \eta_{\mathrm{k}+1/2}). \tag{36.84}$$

Summary of the thickness weighted velocity equation

The velocity equation for an arbitrary layer-k is given by

$$\rho_{\mathrm{ref}}\left[\frac{\mathrm{D}_{\mathrm{k}}\boldsymbol{u}_{\mathrm{k}}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}_{\mathrm{k}}\right] = -\nabla p_{\mathrm{k}} \Longleftrightarrow [\partial_t + (\boldsymbol{u}_{\mathrm{k}}\cdot\nabla)]\boldsymbol{u}_{\mathrm{k}} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}_{\mathrm{k}} = -\rho_{\mathrm{ref}}^{-1}\,\nabla p_{\mathrm{k}}. \tag{36.85}$$

Use of the layer thickness equation (36.78a) readily leads to the thickness-weighted momentum equation

$$\partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\otimes\boldsymbol{u}_{\mathrm{k}}) + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}}. \tag{36.86}$$

We study the thickness-weighted momentum equation in Section 37.3, where we find it offers a more suitable framework than the velocity equation for studying the pressure form stresses acting at layer interfaces.

36.4.3 Dynamic pressure and the Montgomery potential

The term $g\,\rho_{\mathrm{k}}\,z$ appearing in the layer pressures (36.81) has a zero horizontal gradient. Hence, it does not contribute to the horizontal pressure gradient acceleration acting on a layer. As a result, it is a "do nothing" pressure that motivates us to introduce the *shallow water dynamic pressure* (e.g., equation (3.44) of *Vallis* (2017))

$$p_{\mathrm{k}} + g\,\rho_{\mathrm{k}}\,z = p_{\mathrm{a}} + \rho_{\mathrm{ref}}\sum_{\mathrm{j}=0}^{\mathrm{k}-1} g^{\mathrm{r}}_{\mathrm{j}+1/2}\,\eta_{\mathrm{j}+1/2} \equiv p_{\mathrm{a}} + p^{\mathrm{dyn}}_{\mathrm{k}} \Longrightarrow \nabla p_{\mathrm{k}} = \nabla p_{\mathrm{a}} + \nabla p^{\mathrm{dyn}}_{\mathrm{k}}, \tag{36.87}$$

The term "dynamic" is motivated since $p^{\mathrm{dyn}}_{\mathrm{k}}$ gradients directly lead to accelerations. Notably, the dynamic pressure is depth independent within a layer, so that it has a jump moving across a layer interface. Also note that $p^{\mathrm{dyn}}_{\mathrm{k}}$ is related to the shallow water *Montgomery potential* via

$$M^{\mathrm{dyn}}_{\mathrm{k}} = \rho_{\mathrm{ref}}^{-1}\,p^{\mathrm{dyn}}_{\mathrm{k}} = \sum_{\mathrm{j}=0}^{\mathrm{k}-1} g^{\mathrm{r}}_{\mathrm{j}+1/2}\,\eta_{\mathrm{j}+1/2} \tag{36.88}$$

(e.g., Section 12.2 of *Cushman-Roisin and Beckers* (2011)), with the continuous Montgomery potential defined by equation (62.4). When studying the mechanical energy budget in Section 37.6, we find that $p^{\mathrm{dyn}}_{\mathrm{k}}$ naturally appears since the energy budget is derived using the pressure gradient body force. The difference of the dynamic pressure between two layers is given by

$$p^{\mathrm{dyn}}_{\mathrm{k}} - p^{\mathrm{dyn}}_{\mathrm{k}+1} = -\rho_{\mathrm{ref}}\,g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta_{\mathrm{k}+1/2} \Longleftrightarrow M^{\mathrm{dyn}}_{\mathrm{k}} - M^{\mathrm{dyn}}_{\mathrm{k}+1} = -g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta_{\mathrm{k}+1/2}, \tag{36.89}$$

which is an expression of the hydrostatic balance for shallow water layers.

We often find it useful to study pressure contributions to the momentum equation via the duality between the pressure gradient body force and the pressure contact force as when studying form stress in Chapter 29, and further applied to the shallow water in Section 37.4 and in Chapter 63. For those purposes, we do not use $p_{\mathrm{k}}^{\mathrm{dyn}}$ since it is not the hydrostatic pressure measured within a shallow water layer, so that $p_{\mathrm{k}}^{\mathrm{dyn}}$ cannot be directly used to convert the pressure gradient body force to the pressure contact force. Instead, we must use the pressure, p_{k}.

36.4.4 Properties of the vertical velocity

From Section 20.4.2 we know that

$$w = \frac{\mathrm{D}\eta}{\mathrm{D}t} \tag{36.90}$$

provides an expression for the vertical velocity of a fluid parcel at a point on an impermeable surface, $z = \eta(x, y, t)$. We made use of this equation in Section (36.2.7) when studying the surface kinematic boundary condition for a single shallow water layer. We make use of this relation to further our understanding of the vertical velocity in a shallow water model. In particular, we find that the jump in horizontal velocity across the interface leads to a jump in the vertical velocity.

Jump condition for the vertical velocity across a layer interface

Consider two shallow water layers labelled by k and k + 1 that are separated by an interface at $z = \eta_{\mathrm{k}+1/2}(x, y, t)$. Define the vertical velocity at the $z = \eta_{\mathrm{k}+1/2}$ interface according to the material kinematic condition

$$w^{(\mathrm{k})}(\eta_{\mathrm{k}+1/2}) = w^{(\mathrm{k})}_{\mathrm{k}+1/2} = (\partial_t + \boldsymbol{u}_{\mathrm{k}} \cdot \nabla)\, \eta_{\mathrm{k}+1/2}. \tag{36.91}$$

Evidently, $w^{(\mathrm{k})}_{\mathrm{k}+1/2}$ is the vertical velocity for a fluid parcel on the top side of the $z = \eta_{\mathrm{k}+1/2}$ interface. Similarly, define the vertical velocity for a fluid parcel on the lower side of the $z = \eta_{\mathrm{k}+1/2}$ interface according to

$$w^{(\mathrm{k}+1)}_{\mathrm{k}+1/2} = (\partial_t + \boldsymbol{u}_{\mathrm{k}+1} \cdot \nabla)\, \eta_{\mathrm{k}+1/2}. \tag{36.92}$$

Taking the difference leads to the jump condition

$$w^{(\mathrm{k})}(\eta_{\mathrm{k}+1/2}) - w^{(\mathrm{k}+1)}(\eta_{\mathrm{k}+1/2}) = (\boldsymbol{u}_{\mathrm{k}} - \boldsymbol{u}_{\mathrm{k}+1}) \cdot \nabla \eta_{\mathrm{k}+1/2} \neq 0. \tag{36.93}$$

As advertised, the vertical velocity has a jump across the interface that arises from the jump in the horizontal velocity. In Section 37.2.2 we derive the shallow water expression (37.9) for thermal wind balance maintained by geostrophic flow, known as the *Margules' relation*. In that special case there is no jump in the vertical velocity since $\hat{\boldsymbol{z}} \times (\boldsymbol{u}_{\mathrm{k}} - \boldsymbol{u}_{\mathrm{k}+1})$ is parallel to $\nabla \eta_{\mathrm{k}+1/2}$, so that $(\boldsymbol{u}_{\mathrm{k}} - \boldsymbol{u}_{\mathrm{k}+1}) \cdot \nabla \eta_{\mathrm{k}+1/2} = 0$. We thus conclude that the vertical velocity jump arises from ageostrophic contributions to the horizontal flow.

It is tempting to introduce a sub-region that smoothly connects the horizontal velocity between the layers, thus removing the jump condition for both $\boldsymbol{u}$ and w. Doing so enhances the realism of the stacked layers, since a physical realization of fluid layers will have a finite sized region that interpolates between the layer properties. However, adding this transition zone moves us beyond the stacked shallow water model, and so requires analysis that falls outside shallow water theory.

Preservation of the relative vertical position within a column

Following the approach from Section 36.2.8, we compute the vertical velocity within a layer by vertically integrating the non-divergence condition, $\nabla \cdot \boldsymbol{v} = 0$. For layer k we have

$$w^{(\mathrm{k})}(z) = w^{(\mathrm{k})}_{\mathrm{k}+1/2} - (z - \eta_{\mathrm{k}+1/2})\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}}, \tag{36.94}$$

where $w^{(\mathrm{k})}(z)$ is the vertical velocity at a vertical position, z, that is located within layer, k so that $\eta_{\mathrm{k}+1/2} \leq z \leq \eta_{\mathrm{k}-1/2}$. Equation (36.94) generalizes the single-layer equation (36.38), thus revealing that the vertical velocity within an arbitrary shallow water layer is a linear function of the vertical position. Now evaluate equation (36.94) at the upper interface for the layer, $z = \eta_{\mathrm{k}-1/2}$, in which case

$$w^{(\mathrm{k})}_{\mathrm{k}-1/2} = w^{(\mathrm{k})}_{\mathrm{k}+1/2} - h_{\mathrm{k}}\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}}, \tag{36.95}$$

where

$$h_{\mathrm{k}} = \eta_{\mathrm{k}-1/2} - \eta_{\mathrm{k}+1/2} \tag{36.96}$$

is the layer thickness. Eliminating the horizontal convergence between equations (36.94) and (36.95) renders

$$\frac{w^{(\mathrm{k})}_{\mathrm{k}-1/2} - w^{(\mathrm{k})}_{\mathrm{k}+1/2}}{h_{\mathrm{k}}} = \frac{w^{(\mathrm{k})}(z) - w^{(\mathrm{k})}_{\mathrm{k}+1/2}}{z - \eta_{\mathrm{k}+1/2}}. \tag{36.97}$$

Making use of the kinematic boundary condition at the two interfaces allows us to write

$$w^{(\mathrm{k})}_{\mathrm{k}-1/2} = \frac{\mathrm{D}^{(\mathrm{k})}\eta_{\mathrm{k}-1/2}}{\mathrm{D}t} = (\partial_t + \boldsymbol{u}_{\mathrm{k}} \cdot \nabla)\, \eta_{\mathrm{k}-1/2} \tag{36.98a}$$

$$w^{(\mathrm{k})}_{\mathrm{k}+1/2} = \frac{\mathrm{D}^{(\mathrm{k})}\eta_{\mathrm{k}+1/2}}{\mathrm{D}t} = (\partial_t + \boldsymbol{u}_{\mathrm{k}} \cdot \nabla)\, \eta_{\mathrm{k}+1/2}, \tag{36.98b}$$

which then brings equation (36.97) to the form

$$\frac{1}{h_{\mathrm{k}}}\frac{\mathrm{D}^{(\mathrm{k})}h_{\mathrm{k}}}{\mathrm{D}t} = \frac{1}{z - \eta_{\mathrm{k}+1/2}}\frac{\mathrm{D}^{(\mathrm{k})}(z - \eta_{\mathrm{k}+1/2})}{\mathrm{D}t} \Longrightarrow \frac{\mathrm{D}^{(\mathrm{k})}}{\mathrm{D}t}\left[\frac{z - \eta_{\mathrm{k}+1/2}}{h_{\mathrm{k}}}\right] = 0 \tag{36.99}$$

Just like for a single layer of shallow water fluid, vertical columns within each layer are stretched and squeezed in a manner that preserves the relative vertical position for a point within the column.

Averaged vertical velocity for a layer

Since the vertical velocity is a linear function of depth within a layer, its layer averaged value is the average of the vertical velocity at the upper and lower layer interfaces. It is a useful exercise

of the formalism to prove this result

$$\overline{w}_{\mathrm{k}} = \frac{1}{h_{\mathrm{k}}} \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} w^{(\mathrm{k})}(z)\, \mathrm{d}z \tag{36.100a}$$

$$= \frac{1}{h_{\mathrm{k}}} \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \left[w^{(\mathrm{k})}_{\mathrm{k}+1/2} - (z - \eta_{\mathrm{k}+1/2})\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}} \right] \mathrm{d}z \tag{36.100b}$$

$$= w^{(\mathrm{k})}_{\mathrm{k}+1/2} + \eta_{\mathrm{k}+1/2}\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}} - (1/h_{\mathrm{k}})\, (\eta^2_{\mathrm{k}-1/2} - \eta^2_{\mathrm{k}+1/2})\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}} \tag{36.100c}$$

$$= w^{(\mathrm{k})}_{\mathrm{k}+1/2} - (h_{\mathrm{k}}/2)\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}} \tag{36.100d}$$

$$= (w^{(\mathrm{k})}_{\mathrm{k}+1/2} + w^{(\mathrm{k})}_{\mathrm{k}-1/2})/2, \tag{36.100e}$$

where the final step made use of the identity (36.95). Note that we can also write the layer averaged vertical velocity as

$$\overline{w}_{\mathrm{k}} = (w^{(\mathrm{k})}_{\mathrm{k}+1/2} + w^{(\mathrm{k})}_{\mathrm{k}-1/2})/2 = \frac{\mathrm{D}^{(\mathrm{k})}\overline{\eta}_{\mathrm{k}}}{\mathrm{D}t}, \tag{36.101}$$

where

$$\overline{\eta}_{\mathrm{k}} = (\eta_{\mathrm{k}+1/2} + \eta_{\mathrm{k}-1/2})/2 \tag{36.102}$$

is the average of the interface height for the layer.

36.4.5 Rigid lid shallow water models

Throughout this section we formulated the equations for an N-layer shallow water model where $\eta_{1/2}$ is the undulating free surface. For some applications of large-scale oceanography, it is useful to remove the external gravity waves from the model, where these gravity waves are associated with linear fluctuations of the upper free surface.[8] To remove these gravity waves we can, by fiat, set the upper ocean interface to a rigid constant, conventionally taken as $\eta_{1/2} = 0$. This assumption is known as the *rigid lid*. There is good justification for this approximation given that undulations of the free surface are far smaller than undulations of interior interfaces, as seen for the reduced gravity model in Section 36.3.

If there is no applied pressure, $p_{\mathrm{a}} = 0$, then there is no horizontal pressure gradient in the upper layer, much like an inverted reduced gravity model (see Exercise 36.6). A dynamically more interesting case arises when there is an applied pressure, $p_{\mathrm{a}} \neq 0$, so that motion is generated in layer one, which in turn induces motion throughout all layers. Indeed, as seen when studying the horizontally non-divergent barotropic model in Chapter 39, there *must* be a nonzero applied surface pressure in order to constrain the free surface to be flat and fixed. This pressure is referred to as the *lid pressure*

A rigid lid constrains the depth integrated flow to be horizontally non-divergent. We see this property by summing the thickness equation over all of the shallow water layers

$$\partial_t \eta_{1/2} + \sum_{\mathrm{k}=1}^{N} \nabla \cdot (\boldsymbol{u}_{\mathrm{k}}\, h_{\mathrm{k}}) = 0 \quad \text{where} \quad \sum_{\mathrm{k}=1}^{N} \partial_t h_{\mathrm{k}} = \partial_t(\eta_{1/2} - \eta_{\mathrm{b}}) = \partial_t \eta_{1/2}. \tag{36.103}$$

[8] In Section 53.5 we study gravity waves in a single shallow water layer.

For the rigid lid, $\partial_t \eta_{1/2} = 0$, which then leads to the non-divergence condition

$$\sum_{\mathrm{k}=1}^{N} \nabla \cdot (\boldsymbol{u}_{\mathrm{k}}\, h_{\mathrm{k}}) = \nabla \cdot \sum_{\mathrm{k}=1}^{N} \boldsymbol{u}_{\mathrm{k}}\, h_{\mathrm{k}} = \nabla \cdot \boldsymbol{U} = 0 \quad \text{with} \quad \boldsymbol{U} = \sum_{\mathrm{k}=1}^{N} \boldsymbol{u}_{\mathrm{k}}\, h_{\mathrm{k}}. \tag{36.104}$$

Note that velocity in the upper layer remains horizontally divergent since the $\eta_{3/2}$ interface is not generally rigid. Even so, fixing $\eta_{1/2}$ to be rigid serves to remove the relatively fast external gravity waves from the stacked shallow water model. We return to the rigid lid assumption when discussing the horizontal non-divergent barotropic model in Chapter 39 (see in particular Section 39.4).

36.4.6 Comments on vanishing layers

Interior layer interfaces can intersect either the surface, referred to as *outcropping*, or the solid bottom, referred to as *incropping*. In this manner, any particular layer may only exist over a sub-region of the full horizontal domain. Treatment of such geometries is actually quite subtle when numerically discretizing the equations of motion, since it requires methods to allow for layers to vanish and appear as a function of time. The thickness weighted equations developed in this section offer one means to handle these situations. We also considered some of the related conceptual subtleties in Section 30.9 when studying available potential energy in a continuously stratified Boussinesq ocean. *Griffies et al.* (2020) present a primer on numerical methods that support vanishing layers.

36.5 Vector-invariant velocity equation

Following the discussion in Section 25.4 for a continuously stratified fluid, we here derive the vector-invariant form of the shallow water velocity equation. This formulation proves useful in the kinetic energy budget of Section 37.6.3 and for vorticity in Section 40.1.

36.5.1 Basic manipulations

The following manipulations hold for each shallow water layer, so it is convenient to drop layer indices to reduce clutter. To start, we introduce vorticity for the full velocity field

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} \tag{36.105a}$$
$$= \hat{\boldsymbol{x}}\,(\partial_y w - \partial_z v) + \hat{\boldsymbol{y}}\,(\partial_z u - \partial_x w) + \hat{\boldsymbol{z}}\,(\partial_x v - \partial_y u) \tag{36.105b}$$
$$= \hat{\boldsymbol{x}}\,\partial_y w - \hat{\boldsymbol{y}}\,\partial_x w + \hat{\boldsymbol{z}}\,(\partial_x v - \partial_y u) \tag{36.105c}$$
$$= -\hat{\boldsymbol{z}} \times \nabla w + \hat{\boldsymbol{z}}\,(\partial_x v - \partial_y u), \tag{36.105d}$$

where we set

$$\partial_z u = \partial_z v = 0 \tag{36.106}$$

holding for the horizontal velocity within a shallow water layer. We also find it convenient to introduce the vorticity associated with the horizontal velocity field

$$\boldsymbol{\omega}^* = \nabla \times \boldsymbol{u} = -\hat{\boldsymbol{x}}\,\partial_z v + \hat{\boldsymbol{y}}\,\partial_z u + \hat{\boldsymbol{z}}\,(\partial_x v - \partial_y u) = \hat{\boldsymbol{z}}\,(\partial_x v - \partial_y u). \tag{36.107}$$

The vertical component to vorticity is particularly important for geophysical flows, in which case we write

$$\zeta = \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega} = \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}^* = \partial_x v - \partial_y u. \tag{36.108}$$

The vector identity (see Section 2.3.4)

$$(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} = (1/2)\,\nabla(\boldsymbol{u}\cdot\boldsymbol{u}) - \boldsymbol{u}\times(\nabla\times\boldsymbol{u}) = (1/2)\,\nabla(\boldsymbol{u}\cdot\boldsymbol{u}) + \boldsymbol{\omega}^*\times\boldsymbol{u} \tag{36.109}$$

brings the inviscid shallow water velocity equation (36.85)

$$\frac{\partial\boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\rho_{\mathrm{ref}}^{-1}\,\nabla p \tag{36.110}$$

into its *vector invariant* form

$$\frac{\partial\boldsymbol{u}}{\partial t} + (f+\zeta)\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\nabla\left(p/\rho_{\mathrm{ref}} + \boldsymbol{u}\cdot\boldsymbol{u}/2\right). \tag{36.111}$$

Again, this equation holds separately for each layer, so that by reintroducing layer indices we have

$$\frac{\partial\boldsymbol{u}_{\mathrm{k}}}{\partial t} + (f+\zeta_{\mathrm{k}})\,\hat{\boldsymbol{z}}\times\boldsymbol{u}_{\mathrm{k}} = -\nabla(p_{\mathrm{k}}/\rho_{\mathrm{ref}} + \boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}/2). \tag{36.112}$$

36.5.2 Dynamical pressure and the Magnus acceleration

As in our discussion in Section 25.4 of the vector invariant velocity equation for continuously stratified flows, the velocity equation (36.112) exposes two physical processes that lend insight into the motion of a shallow water fluid column.

Dynamical pressure from kinetic energy per mass

The kinetic energy per mass, $\boldsymbol{u}\cdot\boldsymbol{u}/2$, adds a *dynamical pressure* to the mechanical pressure associated with the free surface undulations. Gradients in the kinetic energy thus drive accelerations towards regions of smaller kinetic energy; i.e., down the kinetic energy gradient.[9]

Magnus acceleration

As discussed in Sections 25.4 and 33.2.6, the Magnus acceleration is a body acceleration defined by the nonlinear term

$$\boldsymbol{A}_{\mathrm{magnus}} = -\boldsymbol{\omega}^*\times\boldsymbol{u} = \zeta\,(\boldsymbol{u}\times\hat{\boldsymbol{z}}), \tag{36.113}$$

appearing in the vector-invariant velocity equation (36.112). There is a non-zero Magnus acceleration when a shallow water fluid column spins while it moves, with this acceleration acting to deflect the spinning column perpendicular to its trajectory. As for the example in Figure 25.1, consider a shallow water fluid column moving zonally, in which case the Magnus acceleration is

$$\boldsymbol{A}_{\mathrm{magnus}} = u\,\zeta\,(\hat{\boldsymbol{x}}\times\hat{\boldsymbol{z}}) = -\hat{\boldsymbol{y}}\,u\,\zeta. \tag{36.114}$$

With a positive relative vorticity, $\zeta > 0$, the Magnus acceleration is directed to the right of the motion, which is in the same direction as the Coriolis acceleration in the northern hemisphere. For large-scale geophysical flows, the Magnus acceleration is sub-dominant to the Coriolis acceleration. However, the Magnus acceleration is a crucial facet of large (order unity or larger) Rossby number motions in which relative vorticity is sizable.

[9] The dynamical pressure afforded by the kinetic energy should not be confused with the shallow water dynamic pressure introduced by equation (36.87). They are distinct.

36.6 Exchanges between and within layers

Much of the focus on shallow water mechanics in this book concerns the inviscid and adiabatic case in which shallow water layers are immiscible and there are no frictional or boundary stresses within or between layers. Even so, we find occasion to consider the transfer of volume between layers via dia-surface fluxes, as well as momentum transfer associated with viscous friction and boundary stresses, and tracer transfer via diffusion. Such exchanges are basic to many applications of shallow water models. In this section we formulate the stacked shallow water equations that include such processes. The discussion offers a vertically discrete version of the continuous isopycnal model primitive equations detailed in Chapter 62.

36.6.1 Volume transfer across layer interfaces (dia-layer transport)

Consider the case of dia-surface transfer as occurs across the ocean surface through evaporation, precipitation, and river runoff, or as occurs for interior layers in the presence of irreversible mixing processes. Let $w^{(\dot\eta)}$ measure the volume per time per horizontal area of fluid crossing the surface interface of the shallow water layer, with $w^{(\dot\eta)}$ having dimensions of length per time. As shown in Figure 36.7, we choose a sign convention so that $w^{(\dot\eta)}_{\mathrm{k}-1/2} > 0$ means volume leaves shallow layer k through its upper interface, whereas $w^{(\dot\eta)}_{\mathrm{k}+1/2} > 0$ means that volume enters the layer through its lower interface.

Surface kinematic boundary condition for a single shallow water layer

The kinematic boundary condition (36.35) expresses the material nature of the free surface in the absence of boundary volume flux. In the presence of a non-zero boundary flux, $w^{(\dot\eta)} \neq 0$, we follow the formulation of the kinematic boundary condition for the ocean free surface with a mass flux (equation (20.79)), which renders the boundary condition

$$\frac{\mathrm{D}(z-\eta)}{\mathrm{D}t} = w^{(\dot\eta)} \qquad \text{at } z = \eta. \tag{36.115}$$

In effect, this relation defines the surface boundary flux, and this boundary condition can be written in the equivalent form

$$\frac{\mathrm{D}\eta}{\mathrm{D}t} = w(\eta) - w^{(\dot\eta)}. \tag{36.116}$$

Layer thickness equation for a single shallow water layer

Following through the derivation of the thickness equation in Section 36.2.5, we are trivially led to the following generalization in the presence of volume moving through the upper interface

$$\frac{\partial h}{\partial t} + \nabla \cdot (h\,\boldsymbol{u}) = -w^{(\dot\eta)}, \tag{36.117}$$

or equivalently

$$\frac{\mathrm{D}h}{\mathrm{D}t} = -h\,\nabla \cdot \boldsymbol{u} - w^{(\dot\eta)}. \tag{36.118}$$

As volume leaves the layer through its upper interface, $w^{(\dot\eta)} > 0$, equation (36.117) says that the layer thickness decreases, and conversely the layer thickness increases when volume is added via $w^{(\dot\eta)} < 0$.

FIGURE 36.7: Dia-surface transport across the upper interface, $w^{(\dot\eta)}_{k-1/2}$, and lower interface, $w^{(\dot\eta)}_{k+1/2}$, of shallow water layer k. The sign convention is that $w^{(\dot\eta)}_{k+1/2} > 0$ for fluid entering layer k through its lower interface, and $w^{(\dot\eta)}_{k-1/2} > 0$ for fluid leaving layer k through its upper interface. The evolution of layer thickness at a horizontal position is given by equation (36.119), with a thickness time tendency due to the convergence of horizontal thickness transport within a layer, and the net transport of fluid moving across the layer interfaces.

Thickness equation for a stacked shallow water model

It is straightforward to generalize the thickness equation (36.117) to the case of a stacked shallow water model, in which

$$\frac{\partial h_k}{\partial t} + \nabla \cdot (h_k \, \boldsymbol{u}_k) = -(w^{(\dot\eta)}_{k-1/2} - w^{(\dot\eta)}_{k+1/2}). \tag{36.119}$$

In this way, a positive volume flux coming through the lower layer interface, $w^{(\dot\eta)}_{k+1/2} > 0$, leads to an increase in h_k, whereas a positive flux leaving through the upper interface, $w^{(\dot\eta)}_{k-1/2} > 0$, decreases the layer thickness. The right hand side is written as the thickness weighted convergence of the cross-layer transport. Finally, the flux-form equation (36.119) takes on its material evolution form

$$\frac{D_k h_k}{Dt} = -h_k \, \nabla \cdot \boldsymbol{u}_k - (w^{(\dot\eta)}_{k-1/2} - w^{(\dot\eta)}_{k+1/2}). \tag{36.120}$$

Evidently, the material evolution of layer thickness is affected by the convergence of the horizontal flow as well as the transfer of volume across the layer interfaces.

Vanishing layers and transfer across the top and bottom of the stacked layers

A shallow water layer can vanish at any horizontal position, so that it need not be defined for all horizontal positions in the domain. Such vanishing layers are elegantly handled by working with the thickness weighted tracer and momentum budgets in the following, as doing so avoids dividing by a zero layer thickness when computing vertical transfer across layer interfaces. It also means that the transfer of material and momentum across the top and bottom of a stacked shallow water model occurs via the layer adjacent to these boundaries. That is, boundary fluxes are incorporated via cross-layer fluxes entering or leaving the layer that sits at the surface layer or bottom.

36.6.2 Subgrid scale advective volume tranport within layers

In the presence of subgrid scale processes, there can be an additional advective transport of volume within a layer beyond that arising from the resolved flow field, $\boldsymbol{u}$. Such *subgrid scale transport* from a velocity, $\boldsymbol{u}^{sgs}_k$, is commonly found when studying the effects of turbulent eddies

on ocean and atmospheric flows, with the papers by *Gent and McWilliams* (1990) and *Gent et al.* (1995) offering the canonical ocean example (see Section 66.3 for more on this topic). For present purposes, we are not concerned with how to compute this subgrid flow. Rather, we are concerned with how to account for this flow in a manner that conserves volume, tracer, and momentum. For the thickness equation the extra transport simply represents a term added to the resolved flow, so that the thickness equation takes on the form

$$\partial_t h_{\mathrm{k}} + \nabla \cdot [(h_{\mathrm{k}} \, (\boldsymbol{u}_{\mathrm{k}} + \boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}})] = -(w_{\mathrm{k}-1/2}^{(\dot{\eta})} - w_{\mathrm{k}+1/2}^{(\dot{\eta})}), \tag{36.121}$$

where $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$ is the subgrid scale flow. Volume for the layer is conserved in the presence of $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$ so long as $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$ satisfies the same no-flow kinematic boundary conditions as $\boldsymbol{u}$. Bringing the subgrid scale contribution to the right hand side renders

$$\partial_t h_{\mathrm{k}} + \nabla \cdot (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}) = -(w_{\mathrm{k}-1/2}^{(\dot{\eta})} - w_{\mathrm{k}+1/2}^{(\dot{\eta})}) - \nabla \cdot (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}). \tag{36.122}$$

As shown in the following sections, the presence of both the dia-surface transport and the subgrid scale along-layer transport lead to corresponding terms in the tracer and momentum equations, with such terms required for conservation of tracer and momentum.

36.6.3 Tracer equation

Tracer content is transferred into or out of layer k in the presence of a nonzero volume flux, $w_{\mathrm{k}\pm1/2}^{(\dot{\eta})} \neq 0$. Likewise, tracer is transferred within a layer due to advection by $\boldsymbol{u}_{\mathrm{k}} + \boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$. To formulate the tracer budget admitting such transfer, we work with the thickness weighted tracer equation so to work with an extensive quantity. Namely, the tracer content per horizontal area, $h_{\mathrm{k}} \, C_{\mathrm{k}}$, which satisfies a relatively straightforward budget.

Tracer equation with cross-layer transport and subgrid advection

We ensure self-consistency between the tracer equation and thickness equation (36.119) by writing the tracer budget, in the presence of cross-layer transfer and subgrid scale along-layer advection, as

$$\partial_t (h_{\mathrm{k}} \, C_{\mathrm{k}}) + \nabla \cdot (h_{\mathrm{k}} \, C_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}) = -[(w^{(\dot{\eta})} \, C)_{\mathrm{k}-1/2} - (w^{(\dot{\eta})} \, C)_{\mathrm{k}+1/2}], \tag{36.123}$$

where we introduced the shorthand for the effective flow

$$\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}} = \boldsymbol{u}_{\mathrm{k}} + \boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}. \tag{36.124}$$

The tracer fluxes on the right hand side, $(w^{(\dot{\eta})} \, C)_{\mathrm{k}\pm1/2}$, are evaluated at the layer interfaces. Evidently, a positive flux at the lower interface, $(w^{(\dot{\eta})} \, C)_{\mathrm{k}+1/2} > 0$, contributes to an increase in the tracer content for layer k, whereas $(w^{(\dot{\eta})} \, C)_{\mathrm{k}-1/2} > 0$ signals tracer leaving through the upper interface.

To estimate the tracer concentration at the layer interface, we make use of the *upwind advective flux*. For the flux $(w^{(\dot{\eta})} \, C)_{\mathrm{k}+1/2}$, the upwind method uses $C_{\mathrm{k}+1}$ if $w_{\mathrm{k}+1/2}^{(\dot{\eta})} > 0$, whereas the flux uses C_{k} if $w_{\mathrm{k}+1/2}^{(\dot{\eta})} < 0$

$$(w^{(\dot{\eta})} \, C)_{\mathrm{k}+1/2} = w_{\mathrm{k}+1/2}^{(\dot{\eta})} \left[\begin{array}{ll} C_{\mathrm{k}+1} & \text{if } w_{\mathrm{k}+1/2}^{(\dot{\eta})} > 0 \\ C_{\mathrm{k}} & \text{if } w_{\mathrm{k}+1/2}^{(\dot{\eta})} < 0, \end{array} \right. \tag{36.125}$$

with the same approach used for other interfaces. This method ensures that integrated tracer

content is conserved for the full domain, since the tracer content that enters one layer leaves an adjacent layer.

FIGURE 36.8: Depicting the tracer budget within a shallow water layer according to the thickness weighted tracer equation (36.123) and in the presence of dia-layer transport as in Figure 36.7. The cross-layer tracer fluxes, $(w^{(\dot\eta)}\, C)_{k\pm 1/2}$, are computed according to an upwind method (36.125).

Consistency of the thickness weighted tracer equation and tracer concentration equation

As a consistency check, note that the thickness weighted tracer equation (36.123) reduces to the thickness equation (36.121) upon setting the tracer concentration to a space-time constant. As a second consistency check, use the product rule in equation (36.123) to have

$$C_k\,[\partial_t h_k + \nabla\cdot(h_k\,\boldsymbol{u}^{\rm eff}_k)] + h_k\,(\partial_t C_k + \boldsymbol{u}^{\rm eff}_k\cdot\nabla C_k) = -[(w^{(\dot\eta)}\, C)_{k-1/2} - (w^{(\dot\eta)}\, C)_{k+1/2}]. \quad (36.126)$$

Use of the thickness equation (36.121) and rearrangement renders the advective form tracer concentration equation

$$h_k\,(\partial_t + \boldsymbol{u}^{\rm eff}_k\cdot\nabla)C_k = -\big[[(w^{(\dot\eta)}\, C)_{k-1/2} - C_k\, w^{(\dot\eta)}_{k-1/2}] - [(w^{(\dot\eta)}\, C)_{k+1/2} - C_k\, w^{(\dot\eta)}_{k+1/2}]\big]. \quad (36.127)$$

The tracer concentration equation (36.127) is self-consistent since both sides vanish when C_k is a space-time constant.

The particular case of $w^{(\dot\eta)}_{k-1/2} > 0$ and $w^{(\dot\eta)}_{k+1/2} > 0$, and use of upwind tracer fluxes (36.125), leads to the tracer concentration equation

$$h_k\,(\partial_t + \boldsymbol{u}^{\rm eff}_k\cdot\nabla)C_k = -w^{(\dot\eta)}_{k+1/2}\,(C_k - C_{k+1}). \quad (36.128)$$

Evidently, again with $w^{(\dot\eta)}_{k+1/2} > 0$, the tracer concentration in layer k increases if $C_{k+1} > C_k$ and decreases if $C_{k+1} < C_k$. This is the expected behavior, thus further supporting self-consistency of both the thickness weighted tracer equation and the tracer concentration equation.

Including tracer diffusion

The addition of a cross-layer diffusive flux, with a kinematic diffusivity $\kappa_{\rm cr} > 0$, and an along-layer diffusive flux, with a kinematic diffusivity $\kappa_{\rm al} > 0$, leads to the shallow water thickness-weighted advection-diffusion equation

$$\partial_t(h_{\rm k}\, C_{\rm k}) + \nabla \cdot [h_{\rm k}\, (C_{\rm k}\, \boldsymbol{u}_{\rm k}^{\rm eff} - \kappa_{\rm al} \nabla C_{\rm k})] \\ = -[(w^{(\dot\eta)}\, C - \kappa_{\rm cr}\, \partial_z C)_{\rm k-1/2} - (w^{(\dot\eta)}\, C - \kappa_{\rm cr}\, \partial_z C)_{\rm k+1/2}]. \quad (36.129)$$

In this equation, $(-\kappa_{\rm cr}\, \partial_z C)_{\rm k\pm 1/2}$ is the downgradient cross-layer diffusive tracer flux evaluated at the $\rm k \pm 1/2$ interface, and $-\kappa_{\rm al} \nabla C_{\rm k}$ is the downgradient along-layer diffusive flux within layer k. Both diffusivities, $\kappa_{\rm cr}$ and $\kappa_{\rm al}$, can be functions of space and time. Finally, notice that the diffusive fluxes arise from gradients in the tracer concentration, not gradients in the thickness weighted tracer. Consequently, the presence of tracer diffusion does not affect self-consistency with the thickness equation, since the diffusive fluxes all vanish when the tracer concentration is a space-time constant.

Thickness weighted tracer equation or tracer concentration equation?

As suggested at the start of this section, the thickness weighted tracer equation offers a straightforward means to ensure that tracer content is conserved when including further physical processes, such as cross-layer transport, along-layer subgrid scale advection, and tracer diffusion. The reason is that this equation provides a budget for the tracer content per horizontal area within the shallow water layer. In contrast, tracer concentration, as an intrinsic property, does not satisfy a budget equation. We thus recommend using the thickness weighted tracer budget as the foundation for self-consistently including new physical processes. The tracer concentration is then simply diagnosed through division

$$C_{\rm k} = \frac{(h_{\rm k}\, C_{\rm k})}{h_{\rm k}}. \quad (36.130)$$

Additionally, the thickness weighted tracer equation can be converted to the tracer concentration equation through use of the product rule and the thickness equation.

36.6.4 Viscous frictional stresses acting within the layer

As discussed in Chapter 26, accelerations from friction appear in the momentum equation via the divergence of the frictional stress tensor. For a shallow water fluid we may choose to include a frictional stress proportional to lateral shears within each layer, much like the friction operators discussed in Section 26.8. The thickness weighted velocity equation (36.86) is given for a layer in the form

$$\partial_t(h_{\rm k}\, \boldsymbol{u}_{\rm k}) + \nabla \cdot (h_{\rm k}\, \boldsymbol{u}_{\rm k} \otimes \boldsymbol{u}_{\rm k}) + f\, \hat{\boldsymbol{z}} \times h_{\rm k}\, \boldsymbol{u}_{\rm k} = -(h_{\rm k}/\rho_{\rm ref})\, \nabla p_{\rm k} + h_{\rm k}\, \boldsymbol{F}_{\rm k}, \quad (36.131)$$

where $\boldsymbol{F}_{\rm k}$ is an acceleration arising from viscous friction. For a Laplacian operator arising from within-layer strains, we make use of the generalized vertical coordinate discussion in Section 59.15.2 to write

$$h_{\rm k}\, \boldsymbol{F}_{\rm k} = \nabla \cdot (h_{\rm k}\, \nu_{\rm k}\, \nabla \boldsymbol{u}_{\rm k}), \quad (36.132)$$

where $\nu_{\rm k} > 0$ is the along-layer kinematic viscosity (dimensions $\rm L^2\, T^{-1}$), which can generally be a function of the flow. Notice how the thickness appears inside the divergence operator on the right hand side of equation (36.132). It accords with the treatment of along-layer tracer diffusion in

equation (36.129). Like for the tracer, we note that the friction arises from shears in the velocity, not shears in the thickness weighted velocity.[10]

Treatment of the Laplacian viscous operator (36.132) is directly analogous to treatment of Laplacian tracer diffusion in Section 36.6.3. However, when the viscosity is a function of space, the direct analog holds only for the Cartesian coordinates used here. More general coordinates (e.g., spherical) require a distinct treatment to ensure symmetries are respected by the friction operator so to conserve angular momentum as discussed in Section 26.4. *Griffies and Hallberg* (2000) and Part 5 of *Griffies* (2004) offer details for both the Laplacian and biharmonic friction operators.

36.6.5 Parameterized interfacial stresses

We now consider parameterized stresses at the layer interfaces. One application concerns the treatment of winds at the top of the shallow water column, and bottom friction at the interface with the solid-earth bottom. For this purpose, consider the Boussinesq form (Section 30.7.2) of the vertical stress divergence appearing in the momentum equation

$$\boldsymbol{F} = \frac{1}{\rho_0} \frac{\partial \boldsymbol{\tau}}{\partial z}, \tag{36.133}$$

where $\boldsymbol{\tau}$ is the horizontal stress vector acting on the layer interface. We discretize this stress divergence for the shallow water layer as

$$\boldsymbol{F}_{\mathrm{k}} = \frac{1}{\rho_{\mathrm{ref}}} \frac{\boldsymbol{\tau}_{\mathrm{k}-1/2} - \boldsymbol{\tau}_{\mathrm{k}+1/2}}{h_{\mathrm{k}}}. \tag{36.134}$$

In this expression, h_k is the layer thickness, $\boldsymbol{\tau}_{\mathrm{k}-1/2}$ is the stress at the upper layer interface and $\boldsymbol{\tau}_{\mathrm{k}+1/2}$ is the stress at the lower layer interface. Since a shallow water layer is homogeneous, the interface stress is, in effect, applied uniformly throughout the layer as a layer body stress.

Wind stress

Stress at the top interface of the top layer arises from winds, so that

$$\boldsymbol{\tau}_{k_{\mathrm{top}}} = \boldsymbol{\tau}_{\mathrm{wind}}, \tag{36.135}$$

where k_{top} is the index for the layer that sits at the top of the column at the particular horizontal position. We have $k_{\mathrm{top}} = 1$ for horizontal positions where that top layer exists. Yet it is possible for this layer to vanish, such as when a lower layer outcrops, in which case $k_{\mathrm{top}} \neq 1$. Furthermore, it is important to apply this boundary stress over a nontrivial layer thickness, which for thin upper layers can mean the boundary stress is applied to more than one layer. Doing so ensures that the boundary stress does not over-accelerate a layer that happens to be very thin.

Bottom drag

At the bottom interface of the lowest layer, $\mathrm{k} = k_{\mathrm{bot}}$, bottom drag is commonly applied as a means to include dissipation, in which case[11]

$$\boldsymbol{\tau}_{k_{\mathrm{bot}}} = \boldsymbol{\tau}_{\mathrm{bot}} = \rho_{\mathrm{ref}} C_{\mathrm{D}} \, |\boldsymbol{u}|_{k_{\mathrm{bot}}} \, \boldsymbol{u}_{k_{\mathrm{bot}}}, \tag{36.136}$$

[10] Placement of thickness in equation (36.132) is consistent with the continuum treatment of generalized vertical coordinates in Section 59.15.2.

[11] Be aware that the bottom drag coefficient, C_{D}, is distinct from tracer concentration, C_{k}.

where C_{D} is a dimensionless drag coefficient (typically with values on the order of 10^{-3}), and $\boldsymbol{u}_{k_{\mathrm{bot}}}$ is the velocity in the layer adjacent to the bottom. Generally we expect $k_{\mathrm{bot}} = \mathrm{K}$, yet it will differ in regions of incropping layers along the botton.

Viscous stress

Finally, we may wish to consider a viscous stress that acts between layers and takes on the form

$$\boldsymbol{\tau}_{\mathrm{k}\pm 1/2} = -\rho_{\mathrm{ref}} \, (\mu \, \partial_z \boldsymbol{u})_{\mathrm{k}\pm 1/2}, \tag{36.137}$$

where $\mu > 0$ is a vertical kinematic viscosity (dimensions $\mathrm{L}^2 \, \mathrm{T}^{-1}$) and $(\mu \, \partial_z \boldsymbol{u})_{\mathrm{k}\pm 1/2}$ is the viscous stress evaluated at the $\mathrm{k} \pm 1/2$ interface.

36.6.6 Transfer of horizontal momentum from inter-layer volume transfer

Along with tracer, a transfer of volume across the layer interface gives rise to a transfer of horizontal momentum. In a manner directly akin to the treatment of tracers in Section 36.6.3, we have the thickness weighted velocity equation given by

$$\begin{aligned} \partial_t (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}) + \nabla \cdot (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}} \otimes \boldsymbol{u}_{\mathrm{k}}) + f \, \hat{\boldsymbol{z}} \times h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}} &= -(h_{\mathrm{k}}/\rho_{\mathrm{ref}}) \, \nabla p_{\mathrm{k}} + \nabla \cdot (h_{\mathrm{k}} \, \nu_{\mathrm{k}} \, \nabla \boldsymbol{u}_{\mathrm{k}}) \\ &\quad - [(w^{(\dot{\eta})} \, \boldsymbol{u} - \mu \, \partial_z \boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})} \, \boldsymbol{u} - \mu \, \partial_z \boldsymbol{u})_{\mathrm{k}+1/2}] + \delta_{\mathrm{k},\mathrm{k}_{\mathrm{top}}} \, \boldsymbol{\tau}_{\mathrm{wind}} - \delta_{\mathrm{k},\mathrm{k}_{\mathrm{bot}}} \, \boldsymbol{\tau}_{\mathrm{bot}}. \end{aligned} \tag{36.138}$$

In this equation, $(w^{(\dot{\eta})} \, \boldsymbol{u})_{\mathrm{k}+1/2}$ is the transfer of horizontal momentum across the lower layer interface, and $(w^{(\dot{\eta})} \, \boldsymbol{u})_{\mathrm{k}-1/2}$ is the transfer across the upper layer interface. To estimate the horizontal velocity at the interface, we can take an upwind approach just as for the tracers in equation (36.125)

$$(w^{(\dot{\eta})} \, \boldsymbol{u})_{\mathrm{k}+1/2} = w^{(\dot{\eta})}_{\mathrm{k}+1/2} \left[\begin{array}{ll} \boldsymbol{u}_{\mathrm{k}+1} & \text{if } w^{(\dot{\eta})}_{\mathrm{k}+1/2} > 0 \\ \boldsymbol{u}_{\mathrm{k}} & \text{if } w^{(\dot{\eta})}_{\mathrm{k}+1/2} < 0, \end{array} \right. \tag{36.139}$$

Gent (1993) notes that some realizations of the shallow water equations in the presence of $w^{(\dot{\eta})} \neq 0$ fail to incorporate the transfer of horizontal momentum between the layers present in equation (36.138). As such, these realizations are not self-consistent and thus do not correspond to a discrete realization of a continuous isopycnal model.[12]

36.6.7 Inclusion of subgrid along-layer volume transport

In Section 36.6.2, we introduced a subgrid scale advective volume tranport within layers, and then included that transport in the tracer equation in Section 36.6.3. To see how to do so for the linear momentum equation, it is sufficient to focus on the case without friction or viscosity, Unlike the thickness weighted tracer equation (36.123), here we do not have a straightforward consistency check with the thickness equation (36.121) to determine a unique form for including the effects from $\boldsymbol{u}^{\mathrm{sgs}}_{\mathrm{k}}$ into the momentum equation. We thus consider the following formulations.

[12] We formulate the continuous isopycnal model equations in Chapter 62.

Absence of $\boldsymbol{u}_{\mathrm{k}}^{sgs}$ in the thickness weighted velocity equation

In this formulation we assume there is no appearance of $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$ in the thickness weighted velocity equation, so that

$$\partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\otimes\boldsymbol{u}_{\mathrm{k}}) + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}]. \quad (36.140)$$

Use of the product rule gives

$$h_{\mathrm{k}}\,[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}] + \boldsymbol{u}_{\mathrm{k}}\,[\partial_t h_{\mathrm{k}} + \nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}})] + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}], \quad (36.141)$$

with the thickness equation (36.122) then rendering

$$h_{\mathrm{k}}\,[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}] + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}] + \boldsymbol{u}_{\mathrm{k}}\,[\nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}) + w^{(\dot{\eta})}_{\mathrm{k}-1/2} - w^{(\dot{\eta})}_{\mathrm{k}+1/2}]. \quad (36.142)$$

This formulation is unsatisfying since the velocity is advected by the velocity, $\boldsymbol{u}_{\mathrm{k}}$, whereas tracer is advected by $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}$ as seen in equations (36.123) and (36.127).

Absence of $\boldsymbol{u}_{\mathrm{k}}^{sgs}$ in the velocity equation

As noted by *Janson et al.* (2024), certain layered ocean models, such as MOM6 *Adcroft et al.* (2019), are formulated with no appearance of $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$ in the velocity equation, so that

$$h_{\mathrm{k}}\,[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}\cdot\nabla)\boldsymbol{u}_{\mathrm{k}}] + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}]. \quad (36.143)$$

Use of the product rule and thickness equation (36.122) leads to the thickness weighted velocity equation

$$\partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\otimes\boldsymbol{u}_{\mathrm{k}}) + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}] - \boldsymbol{u}_{\mathrm{k}}\,[\nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}) + w^{(\dot{\eta})}_{\mathrm{k}-1/2} - w^{(\dot{\eta})}_{\mathrm{k}+1/2}]. \quad (36.144)$$

This equation is unsatisfying for the same reason as the velocity equation (36.142). Namely, both formulations have the advection of velocity determined by the velocity, $\boldsymbol{u}_{\mathrm{k}}$, whereas tracer is advected by $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}$, as seen in equations (36.123) and (36.127).

Advection by $\boldsymbol{u}_{\mathrm{k}}^{eff}$ in the velocity equation and thickness weighted velocity equation

Next consider the case where advection occurs with $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}$, just like for tracers as in equation (36.123), so that the thickness weighted velocity equation is written in the form

$$\partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \partial_i[h\,u_i^{\mathrm{eff}}\,\boldsymbol{u}]_{\mathrm{k}} + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}} - [(w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot{\eta})}\,\boldsymbol{u})_{\mathrm{k}+1/2}], \quad (36.145)$$

where we exposed the Cartesian tensor index, i, on the left hand side. The thickness equation (36.121) leads to the identity

$$\partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \partial_i[h\,u_i^{\mathrm{eff}}\,\boldsymbol{u}]_{\mathrm{k}} = h_{\mathrm{k}}\left[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}\right] + \boldsymbol{u}_{\mathrm{k}}\left[\partial_t h_{\mathrm{k}} + \nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}})\right] \tag{36.146a}$$

$$= h_{\mathrm{k}}\left[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}\right] - \boldsymbol{u}_{\mathrm{k}}\,(w^{(\dot\eta)}_{\mathrm{k}-1/2} - w^{(\dot\eta)}_{\mathrm{k}+1/2}), \tag{36.146b}$$

which, when inserted to equation (36.145), gives the velocity equation

$$h_{\mathrm{k}}\left[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}^{\mathrm{eff}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}\right] + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}}$$
$$- [(w^{(\dot\eta)}\,\boldsymbol{u})_{\mathrm{k}-1/2} - w^{(\dot\eta)}_{\mathrm{k}-1/2}\,\boldsymbol{u}_{\mathrm{k}}] + [(w^{(\dot\eta)}\,\boldsymbol{u})_{\mathrm{k}+1/2} - w^{(\dot\eta)}_{\mathrm{k}+1/2}\,\boldsymbol{u}_{\mathrm{k}}]. \tag{36.147}$$

This form for the velocity equation corresponds to the tracer concentration equation (36.127), with both equations having advection determined by the effective velocity, $\boldsymbol{u}^{\mathrm{eff}}$. Rearrangement renders the equivalent form

$$h_{\mathrm{k}}\left[\partial_t\boldsymbol{u}_{\mathrm{k}} + (\boldsymbol{u}_{\mathrm{k}}\cdot\nabla)\,\boldsymbol{u}_{\mathrm{k}}\right] + f\,\hat{\boldsymbol{z}}\times h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}})\,\nabla p_{\mathrm{k}}$$
$$- [(w^{(\dot\eta)}\,\boldsymbol{u})_{\mathrm{k}-1/2} - (w^{(\dot\eta)}\,\boldsymbol{u})_{\mathrm{k}+1/2}] + [w^{(\dot\eta)}_{\mathrm{k}-1/2} - w^{(\dot\eta)}_{\mathrm{k}+1/2} - h_{\mathrm{k}}\,(\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}\cdot\nabla)]\,\boldsymbol{u}_{\mathrm{k}}. \tag{36.148}$$

36.6.8 Further study

Elements of the discrete stacked shallow water model formulation given in this section are considered by *Janson et al.* (2024) for the case of a continuous vertical coordinate. As noted in that paper, in the presence of a subgrid scale velocity, $\boldsymbol{u}_{\mathrm{k}}^{\mathrm{sgs}}$, there is an consistency between the discrete velocity equation and that suggested by the considerations in this section (i.e., equation (36.145)).

36.7 Exercises

EXERCISE 36.1: RELATIONS FOR VERTICAL VELOCITY (EXERCISE (3.2) OF *Vallis* (2006))
Show that the vertical velocity within a shallow water system is given by

$$w = \left[\frac{z-\eta_{\mathrm{b}}}{h}\right]\frac{\mathrm{D}h}{\mathrm{D}t} + \frac{\mathrm{D}\eta_{\mathrm{b}}}{\mathrm{D}t}, \tag{36.149}$$

where η_{b} is the position of the bottom topography (see Figure 36.1). Interpret the result, showing that it gives sensible answers at the top and bottom of the fluid layer.

EXERCISE 36.2: STRETCHING OF A VERTICAL COLUMN WITH LAYER VOLUME EXCHANGE
Show that if there is transport across the surface interface of a single shallow water layer, as per the thickness equation (36.117), then the column stretching equation (36.42) becomes

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\ln\left(\frac{z-\eta_b}{h}\right)\right] = \frac{w^{(\dot\eta)}}{h}. \tag{36.150}$$

Evidently, in the presence of a surface boundary volume flux, a column of shallow water fluid no longer stretches or squeezes uniformly. Instead, for $w^{(\dot\eta)} < 0$, a fluid parcel moves down within the column as more fluid is added to the top of the layer, and conversely when volume leaves the layer.

EXERCISE 36.3: DERIVING THE SHALLOW WATER TRACER EQUATION (36.46)
Show all steps needed to derive equations (36.45a)-(36.45c) and then show the steps leading to the shallow water tracer equation (36.46). Hint: use the z independence of $\boldsymbol{u}$ and $\partial_z w$ within the shallow water layer.

EXERCISE 36.4: HYDRAULIC CONTROL
Consider the steady flow of a shallow water layer in a non-rotating reference frame where the flow is purely one-dimensional in the zonal direction, and with positive layer thickness, $h > 0$, throughout the domain.

(a) Show that the steady flow satisfies the balance

$$[1 - \mathrm{Fr}^2]\, \partial_x h = \partial_x \eta_{\mathrm{b}} \tag{36.151}$$

where η_{b} is the position of the bottom topography (see Figure 36.1), and where the local Froude number is given by

$$\mathrm{Fr} = \frac{u}{\sqrt{g\, h}}. \tag{36.152}$$

The Froude number is the local ratio of the speed for a fluid particle to the speed of a shallow water gravity wave.

(b) Discuss the case in which $\partial_x \eta_{\mathrm{b}} = 0$ yet $\partial_x h \neq 0$. This case is known as *hydraulic control*.

EXERCISE 36.5: SHALLOW WATER EQUATIONS WITH TIDES
In Chapter 35 we derive the equations for a primitive equation ocean in the presence of astronomical forcing that leads to tides. Specialize the general results from that chapter to derive the thickness and momentum equations for a single layer of shallow water fluid in the presence of astronomical tidal forcing. As in Section 35.4, assume the perturbation geopotential is depth independent.

EXERCISE 36.6: INVERTED REDUCED GRAVITY MODEL
Derive the shallow water equations for a single moving layer of fluid of density ρ_2 above a rigid floor, with this moving layer below a stagnant fluid of density ρ_1, with $\rho_1 < \rho_2$, and with the upper stagnant layer assumed to have infinite thickness (as per the upper ocean reduced gravity model in Figure 36.4). Assume $\nabla p_{\mathrm{a}} = 0$. Discuss the constraint placed on the interface $\eta_{1/2}$ to maintain a stagnant upper layer. Show that as $\rho_1/\rho_2 \to 0$ with $\rho_{\mathrm{ref}} = \rho_2$, then the single layer shallow water equations emerge. Make use of notation from the three-layer system shown in Figure 36.6. This model might be used to study flow in the atmosphere well above the boundary layer, or the abyssal ocean well below the pycnocline. Hint: invert the approach taken in Section 36.3 for the reduced gravity model of the upper ocean.

Chapter 37

Shallow water dynamics

In this chapter we further our dynamical understanding of the shallow water fluid model. The study includes geostrophy, thermal wind (as expressed by Margules' relation), momentum budgets, form stress, kinetic energy, gravitational potential energy, available potential energy, and mechanical energy. We also develop the following case studies to exemplify the fundamentals: the steady force balance in a zonally reentrant channel, and the angular momentum dynamics of a rotating tank of shallow water fluid. We offer many details to support those aiming to become nimble with the equations describing the momentum and energy dynamics of a stacked shallow water model.

READER'S GUIDE TO THIS CHAPTER

This chapter builds from the formulations in Chapter 36 as well as the geostrophic mechanics from Chapter 32 and the pressure form stress from Chapter 29. We make use of the dynamical results in this chapter for many of the subsequent chapters. Notationally, we follow the same convention for the gradient operator noted at the start of Chapter 36.

37.1 Loose threads

- Some more interpretation of the N-layer mechanical energy equations and their connections to the continuous case.
- More schematics
- Consider adding a diabatic term to the energy budgets in Sections 37.5 and 37.6.

37.2 Geostrophic balance and thermal wind

As described in Chapter 32, geostrophic balance arises from neglecting the material time derivative in the inviscid horizontal momentum equation, which is a sensible assumption when the Rossby number is small. The resulting balance between Coriolis and pressure accelerations constitutes the geostrophic balance. We consider here the implications of geostrophy for one and two-layer shallow water systems.

37.2.1 Geostrophy for a single layer

Ignoring atmospheric pressure ($p_{\mathrm{a}} = 0$) leads to the geostrophic balance for a single shallow water layer

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -g\,\nabla\eta \Longrightarrow f\,\boldsymbol{u}_{\mathrm{g}} = g\,\hat{\boldsymbol{z}} \times \nabla\eta, \tag{37.1}$$

or in component form

$$u_{\mathrm{g}} = -\frac{g}{f}\frac{\partial\eta}{\partial y} \qquad \text{and} \qquad v_{\mathrm{g}} = \frac{g}{f}\frac{\partial\eta}{\partial x}. \tag{37.2}$$

Consequently, the shallow water layer geostrophic current is balanced by the gradient of the free surface (sea level). In the northern hemisphere, where $f > 0$, geostrophic shallow water currents flow counter-clockwise around negative sea level anomalies (low pressure) and clockwise around positive sea level anomalies (high pressure). The opposite orientation holds in the southern hemisphere, where $f < 0$. Figure 37.1 shows a schematic of geostrophic balance for a single shallow water layer.

FIGURE 37.1: Side view of geostrophic balance for a single shallow water layer, here shown with two high pressure centers surrounding a low pressure center. The Coriolis force balances the pressure gradient force. In the northern hemisphere, where $f > 0$, geostrophic flow is counter-clockwise around a low pressure center and clockwise around a high pressure center.

37.2.2 Geostrophy and thermal wind for two layers

Now consider two shallow water layers as in Figure 36.6. Recall the layer pressure equations (36.62) and (36.63), which leads to the pressure difference

$$p_1 - p_2 = g\,\eta_{3/2}\,(\rho_1 - \rho_2) + g\,z\,(\rho_2 - \rho_1) = g^{\mathrm{r}}_{3/2}\,\rho_{\mathrm{ref}}\,(z - \eta_{3/2}), \tag{37.3}$$

where the reduced gravity is given by equation (36.68)

$$g^{\mathrm{r}}_{3/2} = g\,(\rho_2 - \rho_1)/\rho_{\mathrm{ref}} > 0, \tag{37.4}$$

where ρ_{ref} is the shallow water Boussinesq reference density (36.66). The density difference $\rho_2 - \rho_1$ is generally much smaller than either density, so that $g^{\mathrm{r}}_{3/2} \ll g$. For the Boussinesq shallow water system, the momentum equations are given by

$$\frac{\mathrm{D}^{(1)}\boldsymbol{u}_1}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_1 = -\rho_{\mathrm{ref}}^{-1}\,\nabla p_1 \tag{37.5a}$$

$$\frac{\mathrm{D}^{(2)}\boldsymbol{u}_2}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_2 = -\rho_{\mathrm{ref}}^{-1}\,\nabla p_2, \tag{37.5b}$$

where we introduced the material time derivatives for each layer (we introduced this notation in Section 36.4.4)

$$\frac{\mathrm{D}^{(\mathrm{k})}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{u}_{\mathrm{k}} \cdot \nabla. \tag{37.6}$$

Making use of the pressure difference (37.3) renders

$$\frac{\mathrm{D}_1\boldsymbol{u}_1}{\mathrm{D}t} - \frac{\mathrm{D}_2\boldsymbol{u}_2}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \Delta\boldsymbol{u} = -\rho_{\mathrm{ref}}^{-1}\,\nabla(p_1 - p_2) = g^{\mathrm{r}}_{3/2}\,\nabla\eta_{3/2}, \tag{37.7}$$

where

$$\Delta\boldsymbol{u} = \boldsymbol{u}_1 - \boldsymbol{u}_2 \tag{37.8}$$

is the vertical difference of the layer horizontal velocities. We see that the difference in the geostrophic velocities for the two layers is proportional to the slope of the interface between the two layers

$$f\,\hat{\boldsymbol{z}} \times \Delta \boldsymbol{u}_{\mathrm{g}} = g^{\mathrm{r}}_{3/2}\,\nabla \eta_{3/2} \Longrightarrow \Delta u_{\mathrm{g}} = +(g^{\mathrm{r}}_{3/2}/f)\,\partial_y \eta_{3/2} \quad \text{and} \quad \Delta v_{\mathrm{g}} = -(g^{\mathrm{r}}_{3/2}/f)\,\partial_x \eta_{3/2}. \tag{37.9}$$

These equations are known as the *Margules' relation*. It applies at any interface between two shallow water fluid layers. It says that the vertical difference between the layer geostrophic velocities is proportional to the interface slope. When the slope is large, the vertical difference in the geostrophic velocity is large. Also, the velocity difference is large when the reduced gravity is large; i.e., when the density difference is large. We illustrate this relation in Figure 37.2. The Margules relation is a discrete (two-layer) version of the thermal wind relation discussed in Section 32.5.6.

FIGURE 37.2: Illustrating Margules' relation for the northern hemisphere ($f > 0$). Here we show the interface between a two-layer shallow water model with a cold/heavy layer to the right and a warm/light layer to the left. The slope of the interface is positive, $\partial \eta_{3/2}/\partial y > 0$, thus leading to an increase in the eastward zonal geostrophic velocity moving upward, as depicted by the circles with a dot. This orientation corresponds to the northern hemisphere atmospheric jet stream, whereby the interface between cold/heavy air to the north and warm/light air to the south leads to a zonal thermal wind jet. This figure is directly comparable to the continuously stratified case shown in Figure 32.6.

37.2.3 Geostrophic transport within layers

We are often interested in computing the net volume transport within a layer of fluid in order to measure how much the fluid is moving across a particular region. For an N-layer shallow water fluid this transport is written

$$\boldsymbol{U} = \int \boldsymbol{u}\,\mathrm{d}z = \sum_{\mathrm{k}=1}^{N} \boldsymbol{u}_{\mathrm{k}}\,h_{\mathrm{k}}, \tag{37.10}$$

where $\boldsymbol{u}_{\mathrm{k}}$ is the layer horizontal velocity and h_{k} the layer thickness. For many purposes it is sufficient to compute the transport due to the geostrophic motion, in which case

$$\boldsymbol{u}_{\mathrm{k}} = (\rho_{\mathrm{ref}}\,f)^{-1}\,\hat{\boldsymbol{z}} \times \nabla p_{\mathrm{k}}, \tag{37.11}$$

so that the geostrophic transport is

$$\boldsymbol{U}_{\mathrm{g}} = \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u}_{\mathrm{g}}\,\mathrm{d}z = (\rho_{\mathrm{ref}}\,f)^{-1}\,\hat{\boldsymbol{z}} \times \sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}} \nabla p_{\mathrm{k}}. \tag{37.12}$$

For the pressure gradient we can make use of the expression (36.87)

$$\nabla p_{\mathrm{k}} = \nabla p_{\mathrm{a}} + \nabla p_{\mathrm{k}}^{\mathrm{dyn}} = \nabla p_{\mathrm{a}} + \rho_{\mathrm{ref}} \sum_{\mathrm{j}=1}^{\mathrm{k}} g_{\mathrm{j}-1/2}^{\mathrm{r}} \, \nabla \eta_{\mathrm{j}-1/2}, \tag{37.13}$$

thus revealing the cascade of contributions from each of the layer interfaces.

As an exercise, let us write the geostrophic transport for $N = 3$ layers (assuming $p_{\mathrm{a}} = 0$), in which the layer pressure gradients are

$$\nabla p_1 = \rho_{\mathrm{ref}} \, g \, \nabla \eta_{1/2} \tag{37.14a}$$

$$\nabla p_2 = \nabla p_1 + \rho_{\mathrm{ref}} \, g_{3/2}^{\mathrm{r}} \, \nabla \eta_{3/2} \tag{37.14b}$$

$$\nabla p_3 = \nabla p_1 + \nabla p_2 + \rho_{\mathrm{ref}} \, g_{5/2}^{\mathrm{r}} \, \nabla \eta_{5/2}. \tag{37.14c}$$

We see here the utility of setting

$$\rho_{\mathrm{ref}} = \rho_1, \tag{37.15}$$

in which case the geostrophic transport within the three layers is

$$h_1 \, \boldsymbol{u}_{1\mathrm{g}} = \frac{h_1}{f} \, \hat{\boldsymbol{z}} \times \nabla (g_{1/2}^{\mathrm{r}} \, \eta_{1/2}) \tag{37.16a}$$

$$h_2 \, \boldsymbol{u}_{2\mathrm{g}} = \frac{h_2}{f} \, \hat{\boldsymbol{z}} \times \nabla (g_{1/2}^{\mathrm{r}} \, \eta_{1/2} + g_{3/2}^{\mathrm{r}} \, \eta_{3/2}) \tag{37.16b}$$

$$h_3 \, \boldsymbol{u}_{3\mathrm{g}} = \frac{h_3}{f} \, \hat{\boldsymbol{z}} \times \nabla (g_{1/2}^{\mathrm{r}} \, \eta_{1/2} + g_{3/2}^{\mathrm{r}} \, \eta_{3/2} + g_{5/2}^{\mathrm{r}} \, \eta_{5/2}), \tag{37.16c}$$

in which case the depth integrated geostrophic transport is

$$\boldsymbol{U}_{\mathrm{g}} = f^{-1} \, \hat{\boldsymbol{z}} \times \Big[h_1 \nabla (g \, \eta) + h_2 \nabla (g \, \eta + g_{3/2}^{\mathrm{r}} \, \eta_{3/2}) + h_3 \nabla (g \, \eta + g_{3/2}^{\mathrm{r}} \, \eta_{3/2} + g_{5/2}^{\mathrm{r}} \, \eta_{5/2}) \Big]. \tag{37.17}$$

This expression for $\boldsymbol{U}_{\mathrm{g}}$ displays the cascade of contributions from each of the layer interfaces and their corresponding reduced gravities.

37.2.4 Flow within a geostrophic eddy

The ocean and atmosphere are highly turbulent fluids, with turbulent features extending from the small scales (millimeters) to large scales (hundreds to thousands of kilometers). The larger scale turbulent features feel the earth's rotation and thus maintain a force balance close to geostrophic.[1] We here outline some features of an ocean *geostrophic eddy* as idealized using the reduced gravity model of Section 36.3. Figure 37.3 shows a vertical-zonal slice through the upper portion of an ocean eddy in the middle latitude northern hemisphere ($f > 0$) ocean. The central region consists of a geostrophic eddy, sometimes also referred to as an *ocean mesoscale eddy*. The signature of the eddy is a depression in the free surface height and upward deformation of the pycnocline. The lateral scale of the eddy is on the order of the internal deformation scale (see Exercise 37.10).

The ocean eddy in Figure 37.3 is an anomalously dense cyclonic mesoscale eddy with the dense water causing the pycnocline to deviate upward. If density is dominated by temperature, as it typically is within the middle to lower latitude oceans, then the eddy is a *cold core eddy*, meaning

[1] As noted in Section 33.6, the gradient wind balance provides a more accurate approximation to flows in ocean and atmospheric eddies by also including the centrifugal acceleration associated with the curved motion. Even so, the geostrophic balance provides a sufficient approximation for many purposes and it will be used here, along with thermal wind.

FIGURE 37.3: Vertical-zonal slice through a northern hemisphere mid-latitude cold-core ocean eddy looking from the south to the north (north is into the page). The ocean free surface is depressed down in the middle so that geostrophic flow is cyclonic (counter-clockwise in north) within the upper portion of the eddy where $\rho = \rho_{\text{upper}}$. The pycnocline (region of enhanced vertical density gradient) is deformed upward, and the baroclinic flow implied by Margules' relation (37.9) is indicated, making use of the reduced gravity $g^r = g\,(\rho_{\text{lower}} - \rho_{\text{upper}})/\rho_{\text{ref}}$. Note that $\Delta v_g = v_{\text{upper}} - v_{\text{lower}}$, so that $\Delta v_g > 0$ means that the meridional flow increases in the $+\hat{\boldsymbol{y}}$-direction when moving from the lower to upper layer, and conversely when $\Delta v_g < 0$.

that the core of the eddy is cold. Under geostrophic balance, water circulates counter-clockwise in the northern hemisphere within the upper portion of the cold core eddy, in the region where the pressure gradient force is dominated by the free surface undulation. In this case we see say the eddy is cyclonic. According to the reduced gravity model from Section 36.3 (see in particular Figure 36.5), the ratio of the free surface undulation to the pynocline undulation scales like the reduced gravity, so that a meter undulation of the free surface corresponds to roughly 100 m undulation of the pynocline. The same ideas hold for a *warm core eddy*, such as that depicted in Figure 37.4, with undulations complementing those in the cold core and thus supporting anti-cyclonic thermal wind flow.

In presenting the idealized rendition of an ocean eddy in Figure 37.3, we are assuming a reduced gravity model is sufficient and that the atmosphere has no significant horizontal pressure gradients over the scale of the eddy. Under these assumptions, we make use of the Margules' relation (37.9) to deduce the thermal wind flow in the upper layer relative to the layer below; i.e., the vertical shear in the geostrophic flow. For the left side of the eddy, where $\partial \eta_{\text{interior}}/\partial x > 0$, the vertical shear in the meridional geostrophic velocity is southward, consistent with orientation of the flow implied by the sea surface gradient. Conversely, on the right side of the eddy, where $\partial \eta_{\text{interior}}/\partial x < 0$, the vertical shear in the meridional flow is northward.

FIGURE 37.4: Schematic of a warm core (light water) geostrophic ocean eddy as idealized by a reduced gravity model. The geostrophic/thermal wind flow is anti-cyclonic within the eddy, which contrasts to the cyclonic flow for a cold core eddy as depicted in Figure 37.3. The eddy is characterized by a slight expansion of the free surface (high pressure) and a relatively larger depression of the pycnocline.

37.3 Thickness weighted momentum equation

Throughout our discussion of the shallow water model, we made use of the prognostic equation for the velocity of a layer. Here, we study the momentum equation as determined by the velocity as depth integrated within a shallow water layer. This formulation proves particularly useful when studying forces acting on the layer, such as those from pressure form stresses. It is also of use for studies of rotating hydraulics such as pursued in the book by *Pratt and Whitehead* (2008).

For a shallow water model with just a single layer, the water column extends from the surface to the bottom of the layer (see Figure 37.5)

$$\int_{\eta_b}^{\eta} \boldsymbol{u}\, \mathrm{d}z = \boldsymbol{u}\, h, \tag{37.18}$$

so that the column momentum equals to $\boldsymbol{u}\, h\, \rho\, \mathrm{d}x\, \mathrm{d}y$. The resulting momentum equation is written in its flux form. In Section 37.7 we illustrate the momentum budget for a zonal channel. We also show in Section 37.4.2 that the N-layer equations are isomorphic to the single layer, thus allowing for concepts developed for a single layer to be readily extended to multiple layers.

FIGURE 37.5: Momentum of a column of a single layer shallow water fluid is affected by contact forces at the column boundaries (pressure and friction), as well as body forces acting throughout the column (Coriolis and gravity).

37.3.1 Single layer equations

Recall the velocity and thickness equations written using the material time operator

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -g \nabla \eta \qquad \text{and} \qquad \frac{\mathrm{D}h}{\mathrm{D}t} = -h\, \nabla \cdot \boldsymbol{u}. \tag{37.19}$$

Combining these two equations allows us to write the thickness weighted material acceleration as

$$h\, \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = h\, \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \boldsymbol{u} \left[\frac{\mathrm{D}h}{\mathrm{D}t} + h\, \nabla \cdot \boldsymbol{u} \right] = \frac{\partial (h\, \boldsymbol{u})}{\partial t} + \nabla \cdot [h\, \boldsymbol{u} \otimes \boldsymbol{u}], \tag{37.20}$$

so that the thickness weighted equation takes the vector form

$$\frac{\partial (h\, \boldsymbol{u})}{\partial t} + \nabla \cdot [h\, \boldsymbol{u} \otimes \boldsymbol{u}] + f\, \hat{\boldsymbol{z}} \times (h\, \boldsymbol{u}) = -g\, h\, \nabla \eta. \tag{37.21}$$

The Cartesian tensor form of the outer product is[2]

$$[\boldsymbol{u} \otimes \boldsymbol{u}]_{mn} = u_m \, u_n \qquad \text{for } m, n = 1, 2, \tag{37.22}$$

with $h \, \boldsymbol{u} \otimes \boldsymbol{u}$ the specialization to the shallow water system of the *kinetic stress* appearing in the continuously stratified momentum equation (26.56). The component form of the thickness weighted momentum equation (37.21) is

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2) + \partial_y(h\,u\,v) - v\,h\,f = -\,g\,h\,\partial_x\eta \tag{37.23a}$$

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2) + u\,h\,f = -\,g\,h\,\partial_y\eta. \tag{37.23b}$$

Note that when the bottom is flat then $\nabla h = \nabla\eta$ so that we have

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2 + g\,h^2/2) + \partial_y(h\,u\,v) - v\,h\,f = 0 \tag{37.24a}$$

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2 + g\,h^2/2) + u\,h\,f = 0. \tag{37.24b}$$

37.3.2 Geostrophic and ageostrophic contributions

Bringing the Coriolis terms to the right hand side of equations (37.23a) and (37.23b) renders

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2) + \partial_y(h\,u\,v) = h\,(-g\,\partial_x\eta + v\,f) \tag{37.25a}$$

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2) + u\,h\,f = h\,(-g\,\partial_y\eta - u\,f). \tag{37.25b}$$

In the absence of rotation, the right hand side has contributions only from the thickness weighted pressure gradient. For the case of rotation it sometimes proves useful to decompose velocity into its geostrophic and ageostrophic components

$$f\,u = f\,(u_{\mathrm{a}} + u_{\mathrm{g}}) = f\,u_{\mathrm{a}} - g\,\partial\eta/\partial y \tag{37.26a}$$

$$f\,v = f\,(v_{\mathrm{a}} + v_{\mathrm{g}}) = f\,v_{\mathrm{a}} + g\,\partial\eta/\partial x, \tag{37.26b}$$

in which case equations (37.25a) and (37.25b) become

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2) + \partial_y(h\,u\,v) = h\,f\,v_{\mathrm{a}} \tag{37.27a}$$

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2) = -h\,f\,u_{\mathrm{a}}. \tag{37.27b}$$

One should be careful *not* to take the $f = 0$ limit of these equations since one might spuriously conclude there is no free surface contribution. Instead, equations (37.25a) and (37.25b) should be the basis for the $f = 0$ limit.

37.3.3 Form stresses acting on a shallow water column

The kinetic stress contributes to momentum evolution in equations (37.23a) and (37.23b) via its divergence. In contrast, the pressure stress contributes as a thickness weighted pressure gradient

[2]Equation (37.22) is the only place in this chapter where a subscript refers to a tensor label. Otherwise, subscripts refer to a shallow water layer index as in Section 37.4.2.

body stress. In this subsection, and in all of Section 37.4, we formulate pressure as a contact stress, in which case it also contributes to momentum evolution as a divergence. In so doing, we provide a flux-form conservation law for momentum that supports analysis and interpretation.

Reintroducing atmospheric pressure to symmetrize the forces acting on the layer

To expose both the surface and bottom form stresses, we reintroduce the atmospheric pressure, p_a, and thus make use of the effective sea level (36.4)

$$\eta^\mathrm{eff} = \eta + p_\mathrm{a}/(\rho\, g) = \eta_\mathrm{b} + h + p_\mathrm{a}/(\rho\, g), \tag{37.28}$$

with the corresponding thickness weighted horizontal momentum equation

$$\frac{\partial(h\,\boldsymbol{u})}{\partial t} + \nabla\cdot[h\,\boldsymbol{u}\otimes\boldsymbol{u}] + f\,\hat{\boldsymbol{z}}\times(h\,\boldsymbol{u}) = -g\,h\,\nabla\eta^\mathrm{eff}. \tag{37.29}$$

Exposing the contact pressure stresses

The free surface height equals $\eta = \eta_\mathrm{b} + h$, in which case the momentum equation (37.29) is

$$\frac{\partial(h\,\boldsymbol{u})}{\partial t} + \nabla\cdot[h\,\boldsymbol{u}\otimes\boldsymbol{u}] + f\,\hat{\boldsymbol{z}}\times(h\,\boldsymbol{u}) = -(g/2)\nabla h^2 - g\,h\,\nabla[\eta_\mathrm{b} + p_\mathrm{a}/(\rho\, g)]. \tag{37.30}$$

To help interpret this equation it is convenient to write the boundary terms on the right hand side as

$$-g\,h\,\nabla[\eta_\mathrm{b} + p_\mathrm{a}/(\rho\, g)] = -\nabla(h\,p_\mathrm{a}/\rho) + (p_\mathrm{a}/\rho)\,\nabla(\eta-\eta_\mathrm{b}) - g\,h\,\nabla\eta_\mathrm{b} \tag{37.31a}$$

$$= -\nabla(h\,p_\mathrm{a}/\rho) + (p_\mathrm{a}/\rho)\,\nabla\eta - (g\,h + p_\mathrm{a}/\rho)\,\nabla\eta_\mathrm{b} \tag{37.31b}$$

$$= -\nabla(h\,p_\mathrm{a}/\rho) + \rho^{-1}\,(p_\mathrm{a}\nabla\eta - p_\mathrm{b}\nabla\eta_\mathrm{b}), \tag{37.31c}$$

so that

$$-(g/2)\nabla h^2 - g\,h\,\nabla[\eta_\mathrm{b} + p_\mathrm{a}/(\rho\, g)] = -\nabla[(g/2)\,h^2 + h\,p_\mathrm{a}/\rho] + \rho^{-1}\,(p_\mathrm{a}\nabla\eta - p_\mathrm{b}\nabla\eta_\mathrm{b}). \tag{37.32}$$

The first term on the right hand side is the gradient of the layer integrated hydrostatic pressure

$$P \equiv \int_{\eta_\mathrm{b}}^{\eta} [p_\mathrm{a} + \rho\, g\,(\eta - z)]\,\mathrm{d}z = h\,(\rho\, g\, h/2 + p_\mathrm{a}), \tag{37.33}$$

and the second term exposes the form stresses acting at the surface and bottom of the layer. With these expressions, the horizontal thickness weighted momentum equation (37.30) becomes

$$\frac{\partial(h\,\boldsymbol{u})}{\partial t} + \nabla\cdot[h\,\boldsymbol{u}\otimes\boldsymbol{u} + \mathbb{I}\,P/\rho] + f\,\hat{\boldsymbol{z}}\times(h\,\boldsymbol{u}) = (p_\mathrm{a}\nabla\eta - p_\mathrm{b}\nabla\eta_\mathrm{b})/\rho, \tag{37.34}$$

where $\mathbb{I}$ is the unit tensor. Exposing the zonal and meridional components renders

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2 + P/\rho) + \partial_y(h\,u\,v) - v\,h\,f = (p_\mathrm{a}\,\partial_x\eta - p_\mathrm{b}\,\partial_x\eta_\mathrm{b})/\rho \tag{37.35a}$$

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2 + P/\rho) + u\,h\,f = (p_\mathrm{a}\,\partial_y\eta - p_\mathrm{b}\,\partial_y\eta_\mathrm{b})/\rho. \tag{37.35b}$$

The horizontal pressure gradient appears as a continuous operator since we assumed an infinitesimal horizontal cross-sectional area for the fluid column. In contrast, the pressure form stresses

appear as a vertical finite difference across the layer interfaces, which results since we are integrating over the thickness of a finite layer. Furthermore, note how the depth integrated pressure contributions appear in a flux-form, which contrasts to the body force version that appears as thickness weighted pressure gradient.

Kinetic stresses and contact pressure stresses combined into a momentum flux

To anticipate the thickness weighted momentum equation for the stacked shallow water model in Section 37.4, write the finite difference of the form stresses as

$$p_{\mathrm{a}} \nabla \eta - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} = p_{1/2} \nabla \eta_{1/2} - p_{3/2} \nabla \eta_{3/2} \equiv \delta_{\mathrm{k}} (p_{\mathrm{k}-1/2} \nabla \eta_{\mathrm{k}-1/2}). \tag{37.36}$$

We here introduced the layer interface difference operator

$$\delta_{\mathrm{k}} (\Psi_{\mathrm{k}-1/2}) = \Psi_{\mathrm{k}-1/2} - \Psi_{\mathrm{k}+1/2} = -(\Psi_{\mathrm{k}+1/2} - \Psi_{\mathrm{k}-1/2}), \tag{37.37}$$

with the backward difference motivated since k increases downward whereas $\hat{\boldsymbol{z}}$ points upward. In the following, we choose to define the difference operator to only act on interface fields. Hence, any layer quantity, such as the layer thickness, commutes with the interface operator

$$\delta_{\mathrm{k}} (h \, A_{\mathrm{k}-1/2}) = h \, (A_{\mathrm{k}-1/2} - A_{\mathrm{k}+1/2}). \tag{37.38}$$

Also note that the thickness itself is the difference between the layer interfaces

$$h = \eta - \eta_{\mathrm{b}} = \delta_{\mathrm{k}} \eta_{\mathrm{k}-1/2}, \tag{37.39}$$

where $\eta_{1/2} = \eta$ and $\eta_{3/2} = \eta_{\mathrm{b}}$.

With the above notation, the component momentum equations (37.35a) and (37.35b) take on the matrix-vector form

$$\begin{bmatrix} \partial_t (h \, u) - h \, f \, v \\ \partial_t (h \, v) + h \, f \, u \end{bmatrix} = - \begin{bmatrix} \partial_x & \partial_y & h^{-1} \, \delta_{\mathrm{k}} \end{bmatrix} \begin{bmatrix} D_1^{(\mathrm{u})} & D_1^{(\mathrm{v})} & 0 \\ D_2^{(\mathrm{u})} & D_2^{(\mathrm{v})} & 0 \\ D_3^{(\mathrm{u})} & D_3^{(\mathrm{v})} & 0 \end{bmatrix}. \tag{37.40}$$

The 3×3 matrix is a second order tensor with the first and second columns consisting of the momentum fluxes

$$\boldsymbol{D}^{(\mathrm{u})} = (h \, u^2 + P/\rho) \, \hat{\boldsymbol{x}} + h \, u \, v \, \hat{\boldsymbol{y}} - (p_{\mathrm{k}-1/2} \, \partial_x \eta_{\mathrm{k}-1/2} / \rho) \, h \, \hat{\boldsymbol{z}} \tag{37.41a}$$

$$\boldsymbol{D}^{(\mathrm{v})} = h \, u \, v \, \hat{\boldsymbol{x}} + (h \, v^2 + P/\rho) \, \hat{\boldsymbol{y}} - (p_{\mathrm{k}-1/2} \, \partial_y \eta_{\mathrm{k}-1/2} / \rho) \, h \, \hat{\boldsymbol{z}}, \tag{37.41b}$$

where we suppressed unnecessary layer indices. The horizontal flux components are given by minus the thickness weighted kinetic stress, $h \, \boldsymbol{u} \otimes \boldsymbol{u}$, plus the depth integrated contact pressure acting on the vertical sides of the shallow water column. The vertical flux component contains the pressure form stresses acting on the top and bottom interfaces, with these interfacial form stresses leading to the vertical transfer of horizontal form stresses across the layer boundaries. These fluxes allow us to write the thickness weighted zonal and meridional momentum equations

as

$$\frac{\partial(h\,u)}{\partial t} - v\,h\,f = -(\hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,h^{-1}\delta_{\mathrm{k}}) \cdot \boldsymbol{D}^{(\mathrm{u})} \tag{37.42a}$$

$$\frac{\partial(h\,v)}{\partial t} + u\,h\,f = -(\hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,h^{-1}\delta_{\mathrm{k}}) \cdot \boldsymbol{D}^{(\mathrm{v})}. \tag{37.42b}$$

In this form of the momentum equation, contributions from contact stresses (kinetic stresses and form stresses) appear as the convergence of these stresses with the divergence operator built as combination of the continuous horizontal gradient operator along with a finite difference vertical operator. The third column of the tensor (37.40) is identically zero and so it can be readily dropped. However, we include it to connect with the *Eliassen-Palm flux tensor* as detailed by *Maddison and Marshall* (2013). We return to equations (37.42a) and (37.42b) in Section 37.4.9 for the stacked shallow water model.

37.3.4 Comments on the two pressure force formulations

The momentum equations (37.42a) and (37.42b) are written as a flux-form conservation law, with only the Coriolis force appearing as a body force. This formulation follows that for Cauchy's equation of motion as discussed in Section 25.2.3. We make use of these flux-form momentum equations in Section 37.7 when discussing force balances in a zonally periodic channel, as well as in Chapter 63 when formulating the thickness weighted averaged shallow water equations. Before doing so, we focus in Section 37.4 by further unpacking the contact force version of pressure as it appears in the shallow water model.

What has been gained by writing the momentum equation as the thickness weighted forms (37.42a) and (37.42b) versus the non-flux form velocity equation (37.19)? Indeed, the thickness weighted formulation is arguably less elegant and takes more effort to derive. A key reason we consider the thickness weighted equations is that they provide a venue to study how pressure contact forces alter momentum of a shallow water fluid column through interactions with the bottom, the surface, and adjacent vertical columns. We put this perspective to use in Section 37.7 when studying the force balances on a zonally reentrant channel. Additionally, in Section 37.4 we further pursue the contact force perspective by studying how pressure form stresses appear within a stacked shallow water model.

37.4 Contact pressure forces in shallow water layers

For a finite region of fluid, if the boundary area integrated contact pressure stress is nonzero, then pressure accelerates the region. In this section we study the physics and maths of contact pressure forces as they appear in the stacked shallow water model. As revealed by this study, the columnar motion of the shallow water fluid is fundamental to the analysis. Namely, the contact pressure approach is realized by studying the thickness weighted velocity equations of motion, which determine evolution of the momentum per horizontal area of a shallow water fluid column. We introduced the thickness weighted approach in Section 37.3 for a single shallow water layer, and it led to the flux-form momentum equations (37.42a) and (37.42b). The single layer results are reproduced here for the stacked shallow water model, yet only after furthering our understanding of how pressure forces act to move momentum through shallow water layers.

37.4.1 Pressure contact force and pressure body force

As discussed in Section 26.2.3, the connection between the body force and contact force expressions of the pressure force arise through an application of Gauss's divergence theorem to scalar fields (see Section 2.7.2)

$$\boldsymbol{F}^{\text{press}}_{\mathcal{R}} = -\int_{\mathcal{R}} \nabla p \, \mathrm{d}V = -\oint_{\partial\mathcal{R}} p \, \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{37.43}$$

The first expression on the right hand side is a volume integral of the pressure gradient over the fluid region, $\mathcal{R}$. This expression provides the body force version of the pressure force. The second expression is a surface area integral over the region boundary, $\partial\mathcal{R}$, whose outward normal is $\hat{\boldsymbol{n}}$. This second expression provides the contact force version of the pressure force. Neither expression is more or less fundamental. Instead, they offer complementary insights into how pressure acts to modify the momentum of a fluid, with general notions of this complementarity the topic of Chapter 29. We here pursue the contact force perspective as a means to understand the *pressure form stress* or *interfacial form stress* acting between layers of a shallow water fluid. There is also a pressure form stress acting between a fluid layer and the solid earth (topographic form stress), as well as between a fluid layer and the overlying atmosphere when the atmosphere has a non-zero mass (atmosphere form stress).

37.4.2 N-layer equations

Our starting point for the development in this section are the N-layer shallow water thickness and velocity equations derived in Section 36.4.2

$$\frac{\partial h_{\mathrm{k}}}{\partial t} + \nabla \cdot (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}) = 0 \quad \text{and} \quad [\partial_t + (\boldsymbol{u}_{\mathrm{k}} \cdot \nabla)]\boldsymbol{u}_{\mathrm{k}} + f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{k}} = -(1/\rho_{\mathrm{ref}}) \, \nabla p_{\mathrm{k}}, \tag{37.44}$$

where $\mathrm{k} = 1, N$ is the layer index with no implied summation over this index, ρ_{ref} is the the Boussinesq reference density (often chosen as $\rho_{\mathrm{ref}} = \rho_1$), and equation (36.81) gives the horizontal pressure gradient acceleration. Equations (37.44) are isomorphic to the single layer equations considered in Section 37.3.1. Hence, the thickness weighted velocity equation is a simple generalization of the single layer equation (37.21)

$$\frac{\partial (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}})}{\partial t} + \nabla \cdot [h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}} \otimes \boldsymbol{u}_{\mathrm{k}}] + f \, \hat{\boldsymbol{z}} \times (h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}) = -(h_{\mathrm{k}}/\rho_{\mathrm{ref}}) \, \nabla p_{\mathrm{k}}, \tag{37.45}$$

where, again, there is no implied summation over the layer index, k. We commonly refer to the thickness weighted equation (37.45) as the momentum equation since $\rho \, \mathrm{d}x \, \mathrm{d}y \, h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}}$ is the horizontal momentum of a shallow water fluid column,

37.4.3 Contact pressure force along vertical sides

We now build up our understanding of pressure form stresses acting in a stacked shallow water fluid, with the essence of this discussion following that encountered for the single layer in Section 37.3.3. Our interest concerns the pressure acting on the boundaries of a fluid column within a shallow water layer, such as shown in Figure 37.6.

The pressure at a vertical position within the shallow water layer-k is given by

$$p_{\mathrm{k}}(z) = \rho_{\mathrm{k}} \, g \, (\eta_{\mathrm{k}-1/2} - z) + p_{\mathrm{k}-1/2}. \tag{37.46}$$

FIGURE 37.6: A schematic of the contact pressure force per area acting on the boundaries of a vertical column region within a shallow water layer of density ρ_{k}. Since fluid moves as vertical columns in a shallow water layer, we focus on the pressure forces acting on this column. The horizontal cross-sectional area of the column is depth independent. The interface at the lower boundary is at the vertical position $z = \eta_{\text{k}+1/2}$, and the upper interface is at $z = \eta_{\text{k}-1/2}$. In accordance with Newton's third law, pressures are continuous across each of the $\eta_{\text{k}\pm 1/2}$ layer interfaces so that the pressure forces are equal in magnitude yet oppositely directed on the opposite sides to the interfaces. The layer thickness is the difference between the interface positions, $h_{\text{k}} = \eta_{\text{k}-1/2} - \eta_{\text{k}+1/2}$. The boundaries of the columnar region feel a contact pressure force from the surrounding fluid that acts inward. The left side of the column experiences a pressure p_L; the right side experiences p_R; the upper interface has a pressure $p_{\text{k}-1/2}$ acting between the layer $\text{k}-1$ and layer k, and the lower interface has a pressure $p_{\text{k}+1/2}$ acting between the layer $\text{k}+1$ and layer k. The net pressure acting on the column is computed as the area integral of the pressure acting around the full extent of the column boundaries. The horizontal components of the stress are known as *interfacial form stresses*. This figure is identical to Figure 29.5 used to discuss the general notions of pressure form stress.

Integrating this pressure over the layer thickness yields

$$P_{\text{k}} \equiv \int_{\eta_{\text{k}+1/2}}^{\eta_{\text{k}-1/2}} p_{\text{k}}(z)\,\mathrm{d}z \tag{37.47a}$$

$$= g\,\rho_{\text{k}}\left[\eta_{\text{k}-1/2}\,h_{\text{k}} - (1/2)\,(\eta^2_{\text{k}-1/2} - \eta^2_{\text{k}+1/2})\right] + p_{\text{k}-1/2}\,h_{\text{k}} \tag{37.47b}$$

$$= h_{\text{k}}\,(g\,\rho_{\text{k}}\,h_{\text{k}}/2 + p_{\text{k}-1/2}). \tag{37.47c}$$

Since pressure is a linear function of z within a layer, the vertically averaged hydrostatic pressure within a layer, $P_{\text{k}}/h_{\text{k}}$, equals to the pressure at the upper interface, $p_{\text{k}-1/2}$, plus one-half the weight per area of the layer, $g\,\rho_{\text{k}}\,h_{\text{k}}/2$.

The zonal pressure force acting on the column sides is the difference between the pressure integrated across the left and right zonal faces of the column. Assuming the fluid column to have

an infinitesimal horizontal cross-sectional area $\mathrm{d}x\,\mathrm{d}y$, we find the zonal pressure force is given by

$$\mathrm{d}y \int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} (p_L - p_R)\,\mathrm{d}z = -\mathrm{d}x\,\mathrm{d}y \left[(g/2)\,\rho_{\mathrm{k}}\,\frac{\partial h_{\mathrm{k}}^2}{\partial x} + \frac{\partial (h_{\mathrm{k}}\,p_{\mathrm{k}-1/2})}{\partial x} \right] \tag{37.48a}$$

$$= -\mathrm{d}x\,\mathrm{d}y\,\partial_x \left[(g/2)\,\rho_{\mathrm{k}}\,h_{\mathrm{k}}^2 + h_{\mathrm{k}}\,p_{\mathrm{k}-1/2} \right] \tag{37.48b}$$

$$= -\mathrm{d}x\,\mathrm{d}y\,\partial_x P_{\mathrm{k}}. \tag{37.48c}$$

The analogous result holds for the meridional direction, thus rendering the net contact pressure force acting on the vertical sides of the column

$$\boldsymbol{F}_{\text{sides}}^{\text{press}} = -\mathrm{d}x\,\mathrm{d}y\,\nabla P_{\mathrm{k}}. \tag{37.49}$$

Hence, the contact force on the vertical sides of the column is given by the gradient of the layer vertically integrated pressure, with the vertical integral given by equation (37.47c). It is notable that this semi-discrete exercise reveals no more information than already contained within the integral theorem (37.43). Nonetheless, it is useful to see how the integral theorem manifests within discrete shallow water layers.

37.4.4 Contact pressure force along the top and bottom interfaces

Now consider the contact pressure force acting on the top interface. This interface is generally sloped, so that the contact force has a component in both the vertical and horizontal directions. The vertical component to the pressure force maintains hydrostatic balance with the contact pressure at the lower boundary interface. The horizontal component provides a horizontal acceleration, with this acceleration (sign and magnitude) determined by the slope of the interface. Following our discussion in Section 29.3, we term the horizontal pressure acting on the sloped interface the *interfacial form stress*.

To mathematically characterize the pressure force on the top interface, $z = \eta_{\mathrm{k}-1/2}$, requires the outward normal

$$\hat{\boldsymbol{n}}_{\mathrm{k}-1/2} = \frac{\nabla\,(z - \eta_{\mathrm{k}-1/2})}{|\nabla\,(z - \eta_{\mathrm{k}-1/2})|} = \frac{\hat{\boldsymbol{z}} - \nabla \eta_{\mathrm{k}-1/2}}{\sqrt{1 + (\nabla \eta_{\mathrm{k}-1/2})^2}}. \tag{37.50}$$

Temporarily assume the interface slope to have a zero projection in the $\hat{\boldsymbol{y}}$ direction. In this case, the outward normal is

$$\hat{\boldsymbol{n}}_{\mathrm{k}-1/2} = \frac{\hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\partial_x \eta_{\mathrm{k}-1/2}}{\sqrt{1 + (\partial_x \eta_{\mathrm{k}-1/2})^2}} \tag{37.51a}$$

$$= \frac{\hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\tan \varphi_{\mathrm{k}-1/2}}{\sqrt{1 + \tan^2 \varphi_{\mathrm{k}-1/2}}} \tag{37.51b}$$

$$= (\hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\tan \varphi_{\mathrm{k}-1/2}) \cos \varphi_{\mathrm{k}-1/2}, \tag{37.51c}$$

where we defined the interface slope as

$$\frac{\partial \eta_{\mathrm{k}-1/2}}{\partial x} = \tan \varphi_{\mathrm{k}-1/2}, \tag{37.52}$$

with $\varphi_{\mathrm{k}-1/2}$ the angle between the horizontal plane and the interface. Trigonometry leads to an

expression for the area of the top of the column[3]

$$\mathrm{d}\mathcal{S}_{\mathrm{k}-1/2} = \frac{\mathrm{d}x\,\mathrm{d}y}{\cos\varphi_{\mathrm{k}-1/2}}, \tag{37.53}$$

so that the product of the area and the outward normal is given by

$$\hat{\boldsymbol{n}}_{\mathrm{k}-1/2}\,\mathrm{d}\mathcal{S}_{\mathrm{k}-1/2} = \mathrm{d}x\,\mathrm{d}y\,(\hat{\boldsymbol{z}} - \hat{\boldsymbol{x}}\,\partial_x\eta_{\mathrm{k}-1/2}). \tag{37.54}$$

This result generalizes to an interface slope that projects into both horizontal directions

$$\hat{\boldsymbol{n}}_{\mathrm{k}-1/2}\,\mathrm{d}\mathcal{S}_{\mathrm{k}-1/2} = \mathrm{d}x\,\mathrm{d}y\,(\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{k}-1/2}), \tag{37.55}$$

so that the contact pressure force acting on layer-k at its top interface is given by

$$\boldsymbol{F}^{\mathrm{press}}_{\mathrm{top}} = -\mathrm{d}x\,\mathrm{d}y\,(\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{k}-1/2})\,p_{\mathrm{k}-1/2}. \tag{37.56}$$

Analogous considerations lead to the contact pressure force acting on layer-k at the bottom of the column

$$\boldsymbol{F}^{\mathrm{press}}_{\mathrm{bot}} = \mathrm{d}x\,\mathrm{d}y\,(\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{k}+1/2})\,p_{\mathrm{k}+1/2}. \tag{37.57}$$

37.4.5 Form stress

As noted earlier, form stress is the horizontal projection of the contact pressure acting on the sloped top or bottom interface of the fluid column (Chapter 29). The corresponding forces acting on layer-k is the horizontal area element multiplied by the form stress

$$\boldsymbol{F}^{\text{form stress}}_{\text{top face}} = \mathrm{d}x\,\mathrm{d}y\,(p_{\mathrm{k}-1/2}\nabla\eta_{\mathrm{k}-1/2}) \tag{37.58}$$

$$\boldsymbol{F}^{\text{form stress}}_{\text{bot face}} = -\mathrm{d}x\,\mathrm{d}y\,(p_{\mathrm{k}+1/2}\nabla\eta_{\mathrm{k}+1/2}). \tag{37.59}$$

These forces render a mechanically reversible vertical exchange of horizontal momentum. This momentum exchange occurs without any exchange of matter. Rather, it an inviscid exchange that occurs according to Newton's third law principle of action/reaction.

For a specific case, consider a $\mathrm{k}-1/2$ interface that slopes upward in the $\hat{\boldsymbol{x}}$ direction (e.g., see Figure 37.6). Form stress acting at the interface provides a $+\hat{\boldsymbol{x}}$ directed acceleration on the column. For the $\mathrm{k}+1/2$ interface, a negatively sloped interface also experiences a $+\hat{\boldsymbol{x}}$ directed acceleration.

37.4.6 Net contact pressure force on a shallow water column

Summing the contact pressure forces (37.49), (37.56), and (37.57), and dividing by the horizontal area, leads to the net pressure force per horizontal area acting on a column within layer-k

$$\frac{\boldsymbol{F}^{\mathrm{press}}_{\mathrm{net,k}}}{\mathrm{d}x\,\mathrm{d}y} = -\nabla P_{\mathrm{k}} - (\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{k}-1/2})\,p_{\mathrm{k}-1/2} + (\hat{\boldsymbol{z}} - \nabla\eta_{\mathrm{k}+1/2})\,p_{\mathrm{k}+1/2} \tag{37.60a}$$

$$= \rho_{\mathrm{k}}\,g\,h_k\,\hat{\boldsymbol{z}} - \nabla P_{\mathrm{k}} + p_{\mathrm{k}-1/2}\nabla\eta_{\mathrm{k}-1/2} - p_{\mathrm{k}+1/2}\nabla\eta_{\mathrm{k}+1/2}. \tag{37.60b}$$

[3]Equation (37.53) was also found in Section 20.4.3 when developing the kinematic boundary condition for a material interface.

To reach this result we made use of the hydrostatic relation for the vertical pressure difference across a layer

$$p_{\mathrm{k}+1/2} - p_{\mathrm{k}-1/2} = \rho_{\mathrm{k}}\, g\, h_{\mathrm{k}}. \tag{37.61}$$

The vertical component of the net contact pressure force balances the weight of the column within the layer, which is expected since the shallow water fluid is in hydrostatic balance. The horizontal contact pressure force arises from a horizontal gradient plus the form stress at the surface and bottom interfaces. The gradient term is removed when integrating horizontally over the full domain given that the thickness of the layer vanishes upon reaching the coastlines (e.g., see Figure 29.6). The resulting net force on the full domain arises just from the weight of the fluid acting in the vertical, plus form stress at the surface and bottom. We discuss this point more in Section 37.4.7.

37.4.7 Contact pressure force summed over all layers

Summing the contact pressure force (37.60b) over all layers reveals the contact forces on the interior layer interfaces vanish, as per Newton's third law (see Section 29.1), thus leaving just the form stress at the surface and bottom and the contact pressure force acting on the vertical sides. Dividing by the horizonal area of the column leads to the net pressure force per area

$$\frac{1}{\mathrm{d}x\,\mathrm{d}y}\sum_{\mathrm{k}=1}^{N}\boldsymbol{F}^{\mathrm{press}}_{\mathrm{net,k}} = \hat{\boldsymbol{z}}\, g\sum_{\mathrm{k}=1}^{N}\rho_{\mathrm{k}}\, h_{\mathrm{k}} + p_{\mathrm{a}}\nabla\eta_{1/2} - p_{\mathrm{b}}\nabla\eta_{\mathrm{b}} - \sum_{\mathrm{k}=1}^{N}\nabla P_{\mathrm{k}} \tag{37.62a}$$

$$= (p_{\mathrm{b}} - p_{\mathrm{a}})\,\hat{\boldsymbol{z}} + p_{\mathrm{a}}\nabla\eta_{1/2} - p_{\mathrm{b}}\nabla\eta_{\mathrm{b}} - \sum_{\mathrm{k}=1}^{N}\nabla P_{\mathrm{k}}, \tag{37.62b}$$

where we wrote the total weight per area within the column as the difference between the bottom pressure and applied surface pressure

$$g\sum_{\mathrm{k}=1}^{N}\rho_{\mathrm{k}}\, h_{\mathrm{k}} = p_{\mathrm{b}} - p_{\mathrm{a}}. \tag{37.63}$$

The horizontal components to the applied and bottom pressure terms in equation (37.62b) arise from pressure form stresses applied to the interfaces at the top and bottom of the column. The vertical component arises from the net weight per area of the fluid. The summation term is the horizontal gradient of the depth integrated contact pressure applied along the vertical sides of the column.

37.4.8 Horizontal pressure force with potential energy gradients

There is another means to express the horizontal pressure force. Here, we expose the gravitational potential energy per horizontal area for a column of fluid within a shallow water layer

$$\mathscr{P}_{\mathrm{k}} = g\,\rho_{\mathrm{k}}\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} z\,\mathrm{d}z = (g\,\rho_{\mathrm{k}}/2)\,(\eta^2_{\mathrm{k}-1/2} - \eta^2_{\mathrm{k}+1/2}). \tag{37.64}$$

Use of the layer gravitational potential energy brings the layer vertical integral of the hydrostatic pressure from Section 37.4.3 into

$$\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} p_{\mathrm{k}}(z)\,\mathrm{d}z = g\,\rho_{\mathrm{k}}\, h_{\mathrm{k}}^2/2 + h_{\mathrm{k}}\, p_{\mathrm{k}-1/2} = \mathscr{P}_{\mathrm{k}} - g\,\rho_{\mathrm{k}}\, h_{\mathrm{k}}\,\eta_{\mathrm{k}+1/2} + h_{\mathrm{k}}\, p_{\mathrm{k}-1/2}. \tag{37.65a}$$

Making use of this result in equation (37.60b), along with a few lines of algebra, yields the net horizontal contact pressure force acting on a shallow water column

$$-\nabla P_{\rm k} + \delta_{\rm k}(p_{{\rm k}-1/2}\nabla\eta_{{\rm k}-1/2}) = -\nabla\mathscr{P}_{\rm k} - \delta_{\rm k}(\eta_{{\rm k}-1/2}\nabla p_{{\rm k}-1/2}). \tag{37.66}$$

To reach the identity (37.66) requires the hydrostatic relation, $p_{{\rm k}+1/2} - p_{{\rm k}-1/2} = g\,\rho_{\rm k}\,h_{\rm k}$, and the the layer thickness, $h_{\rm k} = \eta_{{\rm k}-1/2} - \eta_{{\rm k}+1/2}$. A consistency check notes that the curl of both sides to equation (37.66) are the same. The identity (37.66) suggests we define the form stress and its dual

$$\boldsymbol{F}^{\rm form} = p\nabla\eta \quad \text{and} \quad \boldsymbol{F}^{\rm dual\ form} = -\eta\nabla p, \tag{37.67}$$

with both $\boldsymbol{F}^{\rm form}$ and $\boldsymbol{F}^{\rm dual\ form}$ defined on layer interfaces. These two stresses have the same curl, and thus impart the same pressure torque on a column of fluid (Chapter 40)

$$\nabla\times(p\nabla\eta) = \nabla\times(-\eta\nabla p). \tag{37.68}$$

However, these stresses are distinct and as such cannot be arbitrarily interchanged.[4]

37.4.9 Momentum equation with contact pressure forces

Comparing the body force version and the contact force version

Recall that the thickness weighted velocity equation (37.45), as written in terms of the pressure gradient body force, is given by[5]

$$\frac{\partial(h_{\rm k}\,\boldsymbol{u}_{\rm k})}{\partial t} + \nabla\cdot[h_{\rm k}\,\boldsymbol{u}_{\rm k}\otimes\boldsymbol{u}_{\rm k}] + f\,\hat{\boldsymbol{z}}\times(h_{\rm k}\,\boldsymbol{u}_{\rm k}) = -(h_{\rm k}/\rho_{\rm ref})\,\nabla_z p_{\rm k}, \tag{37.69}$$

again with no implied summation over the layer label, k. Alternatively, we can make use of the net contact pressure force (37.60b) so that

$$\frac{\partial(h_{\rm k}\,\boldsymbol{u}_{\rm k})}{\partial t} + \nabla\cdot(h_{\rm k}\,\boldsymbol{u}_{\rm k}\otimes\boldsymbol{u}_{\rm k} + \mathbb{I}\,P_{\rm k}/\rho_{\rm ref}) + f\,\hat{\boldsymbol{z}}\times(h_{\rm k}\,\boldsymbol{u}_{\rm k}) = \delta_{\rm k}(p_{{\rm k}-1/2}\nabla\eta_{{\rm k}-1/2})/\rho_{\rm ref}, \tag{37.70}$$

where $\mathbb{I}$ is the identity tensor, $P_{\rm k}$ is the layer integrated pressure given by equation (37.47c), and $\delta_{\rm k}$ is the difference operator defined by equation (37.37). Choosing the contact pressure force as in equation (37.66) to expose the potential energy brings the momentum equation (37.70) into the alternative form

$$\frac{\partial(h_{\rm k}\,\boldsymbol{u}_{\rm k})}{\partial t} + \nabla\cdot[h_{\rm k}\,\boldsymbol{u}_{\rm k}\otimes\boldsymbol{u}_{\rm k} + \mathbb{I}\,\mathscr{P}_{\rm k}/\rho_{\rm ref}] + f\,\hat{\boldsymbol{z}}\times(h_{\rm k}\,\boldsymbol{u}_{\rm k}) = -\delta_{\rm k}(\eta_{{\rm k}-1/2}\nabla p_{{\rm k}-1/2})/\rho_{\rm ref}. \tag{37.71}$$

[4] As noted in Section 29.1.3, much of the literature refers to $-\eta\nabla p$ as the form stress rather than the dual form stress. This usage presumably originates from the common application of zonal averages for studying atmospheric motions, whereby $\overline{\eta\,\partial_x p}^x = -\overline{p\,\partial_x\eta}^x$. But this identity does not hold for arbitrary averaging operators, such as the ensemble averages commonly used for turbulence studies. So it is generally necessary to distinguish the form stress from the dual form stress.

[5] In equation (37.69) we wrote the gradient on the pressure as ∇_z since we are only interested in the horizontal gradient acting on $p_{\rm k}(x,y,z)$. All other objects in equation (37.69) are just a function of horizontal position within a layer, so that ∇ acting on them reduces to ∇_z. Hence, the subscript on the gradient operator, ∇_z, is exposed only when it acts on a function of z, such as for $p_{\rm k}(x,y,z)$. Since $p_{\rm k}(x,y,z)$ is a linear function of z, its horizontal gradient is depth independent within the layer, as illustrated in Figure 36.1.

Equations (37.69), (37.70), and (37.71) allow us to identify the body force and contact force versions of the thickness weighted horizontal pressure acceleration

$$-h_{\rm k}\nabla_z p_{\rm k} = -\nabla P_{\rm k} + \delta_{\rm k}(p_{\rm k-1/2}\nabla\eta_{\rm k-1/2}) = -\nabla\mathscr{P}_{\rm k} - \delta_{\rm k}(\eta_{\rm k-1/2}\nabla p_{\rm k-1/2}). \tag{37.72}$$

The balance of pressure torques acting on a shallow water column

A necessary (but not sufficient) check of the identity (37.72) can be found by verifying that the curl agrees for each expression

$$\begin{aligned}
-\nabla\times\delta_{\rm k}(\eta_{\rm k-1/2}\nabla p_{\rm k-1/2}) &= \nabla\times\delta_{\rm k}(p_{\rm k-1/2}\nabla\eta_{\rm k-1/2}) && (37.73a)\\
&= \delta_{\rm k}[\nabla\times(p_{\rm k-1/2}\nabla\eta_{\rm k-1/2})] && (37.73b)\\
&= \delta_{\rm k}[\nabla p_{\rm k-1/2}\times\nabla\eta_{\rm k-1/2}] && (37.73c)\\
&= \nabla p_{\rm k-1/2}\times\nabla\eta_{\rm k-1/2} - \nabla(p_{\rm k-1/2} + g\,\rho_{\rm k}\,h_{\rm k})\times\nabla\eta_{\rm k+1/2} && (37.73d)\\
&= \nabla p_{\rm k-1/2}\times\nabla h_{\rm k} - g\,\rho_{\rm k}\nabla h_{\rm k}\times\nabla\eta_{\rm k+1/2} && (37.73e)\\
&= \nabla(p_{\rm k-1/2} + g\,\rho_{\rm k}\,\eta_{\rm k+1/2})\times\nabla h_{\rm k} && (37.73f)\\
&= \nabla(p_{\rm k-1/2} - g\,\rho_{\rm k}\,h_{\rm k} + g\,\rho_{\rm k}\,\eta_{\rm k-1/2})\times\nabla h_{\rm k} && (37.73g)\\
&= \nabla_z[p_{\rm k-1/2} + g\,\rho_{\rm k}\,(\eta_{\rm k-1/2} - z)]\times\nabla h_{\rm k} && (37.73h)\\
&= \nabla_z p_{\rm k}\times\nabla h_{\rm k} && (37.73i)\\
&= -\nabla\times(h_{\rm k}\nabla_z p_{\rm k}), && (37.73j)
\end{aligned}$$

which concurs with the curl of the left hand side of equation (37.72). To reach this result we set $h_{\rm k} = \eta_{\rm k-1/2} - \eta_{\rm k+1/2}$ and used equation (37.46) for the pressure within a shallow water layer: $p_{\rm k}(z) = \rho_{\rm k}\,g\,(\eta_{\rm k-1/2} - z) + p_{\rm k-1/2}$.

Anticipating our discussion of vorticity for the shallow water fluid in Section 40.1, we observe that the identity derived above

$$\nabla\times\delta_{\rm k}(p_{\rm k-1/2}\nabla\eta_{\rm k-1/2}) = -\nabla\times(h_{\rm k}\nabla_z p_{\rm k}) \tag{37.74}$$

says that the difference in interfacial pressure torques acting on the top and bottom of a shallow water layer precisely balances minus the torque arising from the thickness weighted horizontal pressure gradient acting within the layer. This rather remarkable fine tuning of the interfacial and interior pressure torques is a direct consequence of assuming that the fluid motion is restricted to extensible vertical columns within each shallow water layer. This balance is not maintained within a three dimensional fluid, where fluid columns can generally tilt and bend (Chapter 41).

Layer summed momentum equation

Taking the vertical sum of the layer-k momentum equation (37.70) leads to the column integrated horizontal momentum equation

$$\frac{\partial\boldsymbol{U}}{\partial t} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{U} + \nabla\cdot\left[\sum_{\rm k=1}^{N}(h_{\rm k}\,\boldsymbol{u}_{\rm k}\otimes\boldsymbol{u}_{\rm k} + \mathbb{I}\,P_{\rm k}/\rho_{\rm ref})\right] = [p_a\nabla\eta_{1/2} - p_{\rm b}\nabla\eta_{\rm b}]/\rho_{\rm ref}, \tag{37.75}$$

where $\boldsymbol{U}$ is the depth integrated horizontal velocity given by equation (37.10). The same vertical sum for equation (37.71) leads to

$$\frac{\partial \boldsymbol{U}}{\partial t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{U} + \nabla \cdot \left[\sum_{\mathrm{k}=1}^{N} (h_{\mathrm{k}}\, \boldsymbol{u}_{\mathrm{k}} \otimes \boldsymbol{u}_{\mathrm{k}} + \mathbb{I}\, \mathscr{P}_{\mathrm{k}}/\rho_1) \right] = [-\eta_{1/2} \nabla p_a + \eta_{\mathrm{b}} \nabla p_{\mathrm{b}}]/\rho_{\mathrm{ref}}. \tag{37.76}$$

The right hand side of equation (37.75) exposes the pressure form stresses acting on the ocean surface and bottom, whereas the right hand side of equation (37.76) exposes the dual form stress acting on the ocean surface and bottom.

Decomposing into depth averaged and depth deviation velocities

For detailed analyses of the depth integrated (layer summed) momentum and vorticity budgets, it is of interest to introduce the depth averaged operator and its deviation

$$\overline{\Phi}^{\mathrm{z}} = \frac{\sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}}\, \Phi_{\mathrm{k}}}{\sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}}} \quad \text{and} \quad \Phi'_{\mathrm{k}} = \Phi_{\mathrm{k}} - \overline{\Phi}^{\mathrm{z}} \tag{37.77}$$

so that the depth integrated kinetic stress in equation (37.75) is

$$\sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}}\, \boldsymbol{u}_{\mathrm{k}} \otimes \boldsymbol{u}_{\mathrm{k}} = D\, [\overline{\boldsymbol{u}}^{\mathrm{z}} \otimes \overline{\boldsymbol{u}}^{\mathrm{z}} + \overline{\boldsymbol{u}' \otimes \boldsymbol{u}'}^{\mathrm{z}}] \quad \text{where } D = \textstyle\sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}}. \tag{37.78}$$

The velocity $\boldsymbol{u}'_{\mathrm{k}}$ is the deviation of the layer-k velocity from the depth average velocity, and we refer to it as the *internal velocity*, whereas the depth averaged velocity, $\overline{\boldsymbol{u}}^{\mathrm{z}}$, is the *external velocity*.[6] The identity (37.78) reveals that the depth integrated kinetic stress can be decomposed into a stress arising from internal-internal velocity interactions plus external-external velocity interactions. By construction, there are no cross-terms (i.e., no internal-external terms) appearing in this depth integrated stress.

Momentum fluxes

Following the single layer discussion in Section 37.3.3, we write the momentum equation (37.70) in the form

$$\frac{\partial (h\, u)}{\partial t} - v\, h\, f = -(\hat{\boldsymbol{x}}\, \partial_x + \hat{\boldsymbol{y}}\, \partial_y + \hat{\boldsymbol{z}}\, h^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{D}^{(\mathrm{u})} \tag{37.79a}$$

$$\frac{\partial (h\, v)}{\partial t} + u\, h\, f = -(\hat{\boldsymbol{x}}\, \partial_x + \hat{\boldsymbol{y}}\, \partial_y + \hat{\boldsymbol{z}}\, h^{-1} \delta_{\mathrm{k}}) \cdot \boldsymbol{D}^{(\mathrm{v})}, \tag{37.79b}$$

where we dropped the k label for brevity and introduced the layer momentum fluxes

$$\boldsymbol{D}^{(\mathrm{u})} = (h\, u^2 + P/\rho_{\mathrm{ref}})\, \hat{\boldsymbol{x}} + h\, u\, v\, \hat{\boldsymbol{y}} - (p_{\mathrm{k}-1/2}\, \partial_x \eta_{\mathrm{k}-1/2}/\rho_{\mathrm{ref}})\, h\, \hat{\boldsymbol{z}} \tag{37.80a}$$

$$\boldsymbol{D}^{(\mathrm{v})} = h\, u\, v\, \hat{\boldsymbol{x}} + (h\, v^2 + P/\rho_{\mathrm{ref}})\, \hat{\boldsymbol{y}} - (p_{\mathrm{k}-1/2}\, \partial_y \eta_{\mathrm{k}-1/2}/\rho_{\mathrm{ref}})\, h\, \hat{\boldsymbol{z}}. \tag{37.80b}$$

[6] It is also common in the oceanography literature to refer to $\boldsymbol{u}'_{\mathrm{k}}$ as the *baroclinic velocity* and $\overline{\boldsymbol{u}}^{\mathrm{z}}$ as the *barotropic velocity*.

Likewise, we can write the momentum equation (37.71) in the component form

$$\frac{\partial(h\,u)}{\partial t} - v\,h\,f = -(\hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,h^{-1}\delta_{\mathrm{k}})\cdot\boldsymbol{E}^{(\mathrm{u})} \tag{37.81a}$$

$$\frac{\partial(h\,v)}{\partial t} + u\,h\,f = -(\hat{\boldsymbol{x}}\,\partial_x + \hat{\boldsymbol{y}}\,\partial_y + \hat{\boldsymbol{z}}\,h^{-1}\delta_{\mathrm{k}})\cdot\boldsymbol{E}^{(\mathrm{v})}, \tag{37.81b}$$

where the dual layer momentum fluxes are given by

$$\boldsymbol{E}^{(\mathrm{u})} = (h\,u^2 + \mathscr{P}/\rho_{\mathrm{ref}})\,\hat{\boldsymbol{x}} + h\,u\,v\,\hat{\boldsymbol{y}} + (\eta_{\mathrm{k}-1/2}\,\partial_x p_{\mathrm{k}-1/2}/\rho_{\mathrm{ref}})\,h\,\hat{\boldsymbol{z}} \tag{37.82a}$$

$$\boldsymbol{E}^{(\mathrm{v})} = h\,u\,v\,\hat{\boldsymbol{x}} + (h\,v^2 + \mathscr{P}/\rho_{\mathrm{ref}})\,\hat{\boldsymbol{y}} + (\eta_{\mathrm{k}-1/2}\,\partial_y p_{\mathrm{k}-1/2}/\rho_{\mathrm{ref}})\,h\,\hat{\boldsymbol{z}}. \tag{37.82b}$$

Besides swapping the depth integrated pressure, P, for the potential energy, $\mathscr{P}$, the dual momentum fluxes, $\boldsymbol{E}^{(\mathrm{u})}$ and $\boldsymbol{E}^{(\mathrm{v})}$, make use of the dual form stress, $\eta_{\mathrm{k}-1/2}\,\nabla p_{\mathrm{k}-1/2}$, rather than the form stress, $-p_{\mathrm{k}-1/2}\,\nabla\eta_{\mathrm{k}-1/2}$. Upon performing an eddy-mean flow decomposition as in Section 63.6, the eddy correlation portion of the fluxes (37.82a) and (37.82b) lead to the shallow water *Eliassen-Palm* fluxes, which are rows in the Eliassen-Palm flux tensor.

37.4.10 Further reading

Ward and Hogg (2011) and *Barthel et al.* (2017) offer pedagogical treatments of the stacked shallow water equations in the context of idealized simulations that lend insight into the dynamical balances. *Maddison and Marshall* (2013) study the Eliassen-Palm flux tensor for continously stratified quasi-geostrophy as well as the Boussinesq hydrostatic equations.

37.5 Energetics for a single layer

In this section we develop budgets for gravitational potential energy, kinetic energy, and mechanical energy for a single shallow water layer sitting on top of a non-flat bottom. Since the shallow water model has no internal energy, the total energy of the fluid is just that arising from the mechanical energy of the macroscopic motion. As part of this discussion we also consider the available potential energy (APE).

Motion within a shallow water layer occurs in vertical columns, so that we consider the energy of the layer integrated motion. The gravitational potential energy of a shallow water column is affected by vertical movement of the top and bottom of the column within the gravitational field. The kinetic energy is affected by pressure work, which, as we have seen in Sections 37.3 and 37.4, can be expressed either as a gradient body force or a contact force. Furthermore, pressure work leading to vertical motion manifests as buoyancy work. Our goal in this section is to study these energetic transformations and their mathematical expressions. We then extend the energetic analysis from the single layer to multiple layers in Section 37.6, though note that much of our work for the single layer is sufficient for multiple layers.

Before diving into details, we note that shallow water energetics can be derived from a layer integration of the continuously stratified Boussinesq energy equations from Section 30.6. That approach offers a somewhat more telescopic presentation than given here. However, we choose to present the derivations in a manner that supports skills in manipulating the shallow water equations, and further exposes the physical concepts arising from the motion of shallow water fluid columns.

37.5.1 Gravitational potential energy

The gravitational potential energy per horizontal area of a shallow water fluid is given by[7]

$$\mathscr{P}^{\text{sw}} = g\,\rho \int_{\eta_{\text{b}}}^{\eta} z\,\text{d}z = \frac{g\,\rho}{2}\,(\eta^2 - \eta_{\text{b}}^2) = \rho\,g\,h\,\overline{\eta}, \tag{37.83}$$

where the final equality introduced the layer thickness, h, and average of the layer interface heights

$$h = \eta - \eta_{\text{b}} \quad \text{and} \quad \overline{\eta} = (\eta + \eta_{\text{b}})/2. \tag{37.84}$$

Notice how the gravitational potential energy vanishes when $\eta^2 = \eta_{\text{b}}^2$. For the case $\eta = \eta_{\text{b}}$, there is no fluid in the column and so we expect the potential energy to vanish. For the case $\eta = -\eta_{\text{b}} > 0$, there is the same amount of fluid above $z = 0$ as below, in which case the potential energy for the column vanishes since we are computing it relative to the $z = 0$ reference state. Furthermore, in the flat bottom case, $\eta_{\text{b}} = 0$ so that $h = \eta - \eta_{\text{b}} = \eta$, in which case the potential energy (37.83) reduces to $\mathscr{P}^{\text{sw}}_{\text{flat}} = g\,\rho\,\eta^2/2$.

Material time derivative of gravitational potential energy

Taking the material time derivative of the gravitational potential energy in equation (37.83) yields

$$\frac{\text{D}\mathscr{P}^{\text{sw}}}{\text{D}t} = g\,\rho\left[\eta\,\frac{\text{D}\eta}{\text{D}t} - \eta_{\text{b}}\,\frac{\text{D}\eta_{\text{b}}}{\text{D}t}\right] \tag{37.85a}$$

$$= g\,\rho\,[\eta\,w(\eta) - \eta_{\text{b}}\,w(\eta_{\text{b}})] \tag{37.85b}$$

$$= g\,\rho\,h\,[w(\eta_{\text{b}}) - \eta\,\nabla\cdot\boldsymbol{u}] \tag{37.85c}$$

$$= g\,\rho\,h\,[w(\eta) - \eta_{\text{b}}\,\nabla\cdot\boldsymbol{u}], \tag{37.85d}$$

where we used equations for the vertical velocity component from Section 36.2.8, and for the final equality we used equation (36.95) to write

$$w(\eta) - w(\eta_{\text{b}}) = -h\,\nabla\cdot\boldsymbol{u}. \tag{37.86}$$

Evidently, the potential energy changes according to how the thickness of the layer increases through vertical motion along the top and bottom interfaces, and as weighted by the position of these interfaces relative to $z = 0$. Finally, it is useful to write equation (37.85d) in its flux-form, which is given by

$$\partial_t\mathscr{P}^{\text{sw}} + \nabla\cdot(\boldsymbol{u}\,\mathscr{P}^{\text{sw}}) = \mathscr{P}^{\text{sw}}\,\nabla\cdot\boldsymbol{u} + g\,\rho\,h\,[w(\eta) - \eta_{\text{b}}\,\nabla\cdot\boldsymbol{u}]. \tag{37.87}$$

The source term on the right hand side can be written as a buoyancy work term, which we show next.

[7] We include the "sw" superscript to distinguish the shallow water energetic terms, which we consider in their thickness weighted form so their dimensions are energy per area. In other areas of this book, we consider the energy per mass, such as in Chapters 27 and 30.

Exposing the role of buoyancy work

An alternative expression for the potential energy evolution is found by working with the final expression for potential energy in equation (37.83), whose material time derivative is

$$\frac{\mathrm{D}\mathscr{P}^{\mathrm{sw}}}{\mathrm{D}t} = g\,\rho\,\overline{\eta}\,\frac{\mathrm{D}h}{\mathrm{D}t} + g\,\rho\,h\,\frac{\mathrm{D}\overline{\eta}}{\mathrm{D}t} = -\mathscr{P}^{\mathrm{sw}}\,\nabla\cdot\boldsymbol{u} + \rho\,g\,h\,\overline{w}, \tag{37.88}$$

where we introduced the averaged vertical velocity for the layer according to equation (36.101)

$$\overline{w} = \frac{\mathrm{D}\overline{\eta}}{\mathrm{D}t} = \frac{1}{2}\,\frac{\mathrm{D}(\eta+\eta_{\mathrm{b}})}{\mathrm{D}t}. \tag{37.89}$$

The flux-form version of the potential energy equation (37.88) thus takes on the form

$$\partial_t\mathscr{P}^{\mathrm{sw}} + \nabla\cdot(\boldsymbol{u}\,\mathscr{P}^{\mathrm{sw}}) = g\,\rho\,h\,\overline{w}. \tag{37.90}$$

This equation is the shallow water analog to the gravitational potential energy budget (27.5) for in a continuously stratified fluid. In particular, we see that the buoyancy work term, $g\,\rho\,h\,\overline{w}$, alters potential energy when there is vertical motion through the gravity field. As a check on the manipulations, we verify that the potential energy budgets (37.87) and (37.90) are indeed self-consistent by noting that

$$\mathscr{P}^{\mathrm{sw}}\,\nabla\cdot\boldsymbol{u} + \rho\,g\,h\,[w(\eta) - \eta_{\mathrm{b}}\,\nabla\cdot\boldsymbol{u}] = \rho\,g\,h\,[(\overline{\eta}-\eta_{\mathrm{b}})\,\nabla\cdot\boldsymbol{u} + w(\eta)] \tag{37.91a}$$

$$= \rho\,g\,h\,[(h/2)\,\nabla\cdot\boldsymbol{u} + w(\eta)] \tag{37.91b}$$

$$= \rho\,g\,h\,[-(1/2)\,\mathrm{D}h/\mathrm{D}t + w(\eta)] \tag{37.91c}$$

$$= \rho\,g\,h\,\overline{w}. \tag{37.91d}$$

37.5.2 Kinetic energy and work from pressure gradients

The kinetic energy per horizontal area is

$$\mathscr{K}^{\mathrm{sw}} = \frac{1}{2}\int_{\eta_{\mathrm{b}}}^{\eta}\rho\,\boldsymbol{u}\cdot\boldsymbol{u}\,\mathrm{d}z = \frac{1}{2}\,\rho\,h\,\boldsymbol{u}\cdot\boldsymbol{u}. \tag{37.92}$$

Its material time derivative is given by

$$\frac{\mathrm{D}\mathscr{K}^{\mathrm{sw}}}{\mathrm{D}t} = \rho\,h\,\boldsymbol{u}\cdot\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \frac{1}{2}\,\rho\,\boldsymbol{u}\cdot\boldsymbol{u}\,\frac{\mathrm{D}h}{\mathrm{D}t} \tag{37.93a}$$

$$= -h\,\boldsymbol{u}\cdot\nabla p + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F} + \frac{\mathscr{K}^{\mathrm{sw}}}{h}\,\frac{\mathrm{D}h}{\mathrm{D}t} \tag{37.93b}$$

$$= -h\,\boldsymbol{u}\cdot\nabla p + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F} - \mathscr{K}^{\mathrm{sw}}\,\nabla\cdot\boldsymbol{u}, \tag{37.93c}$$

where we made use of the velocity equation (36.9) along with the addition of a frictional acceleration, $\boldsymbol{F}$ (see Section 36.6.5), and we used the thickness equation (36.20). Rearrangement of equation (37.93c) leads to the flux-form budget for layer integrated kinetic energy

$$\partial_t\mathscr{K}^{\mathrm{sw}} + \nabla\cdot(\boldsymbol{u}\,\mathscr{K}^{\mathrm{sw}}) = -h\,\boldsymbol{u}\cdot\nabla p + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.94}$$

The first term on the right hand side is the projection of the horizontal velocity onto the horizontal pressure gradient acceleration, thus indicating that kinetic energy for the fluid column increases if the velocity has a component that is directed down the horizontal pressure gradient. This term arises from the work done by the horizontal pressure gradient force acting on the moving fluid

columns. The second right hand side term is the projection of the velocity onto the thickness weighted horizontal friction, which accounts for work done by friction and/or boundary stresses on the moving fluid.

For a slight modification to the budget equation (37.94), write the layer pressure as

$$p = p_{\mathrm{a}} + \rho\, g\, (\eta - z) = \rho\, g\, (\eta^{\mathrm{eff}} - z), \tag{37.95}$$

where we introduced the effective free surface from equation (36.4)

$$\eta^{\mathrm{eff}} = \eta + p_{\mathrm{a}}/(\rho\, g). \tag{37.96}$$

The thickness weighted pressure work thus takes the form

$$-h\, \boldsymbol{u} \cdot \nabla p = -h\, \rho\, g\, \boldsymbol{u} \cdot \nabla \eta^{\mathrm{eff}}, \tag{37.97}$$

so that the kinetic energy equation (37.94) becomes

$$\partial_t \mathcal{K}^{\mathrm{sw}} + \nabla \cdot [\boldsymbol{u}\, (\mathcal{K}^{\mathrm{sw}} + \rho\, g\, h\, \eta^{\mathrm{eff}})] = \rho\, g\, \eta^{\mathrm{eff}}\, \nabla \cdot (h\, \boldsymbol{u}) + \rho\, h\, \boldsymbol{u} \cdot \boldsymbol{F}. \tag{37.98}$$

37.5.3 Kinetic energy and buoyancy work

Following the second formulation of gravitational potential energy in Section 37.5.1, we here expose the buoyancy work that is contained in the term $\rho\, g\, \eta^{\mathrm{eff}}\, \nabla \cdot (h\, \boldsymbol{u})$ appearing in equation (37.98). For this purpose, make use of the thickness equation, $\partial_t h = -\nabla \cdot (\boldsymbol{u}\, h)$, to write

$$\rho\, g\, \eta^{\mathrm{eff}}\, \nabla \cdot (h\, \boldsymbol{u}) = -\rho\, g\, \eta^{\mathrm{eff}}\, \partial_t h = -\rho\, g\, \eta^{\mathrm{eff}}\, \partial_t(\delta_{\mathrm{k}} \eta_{\mathrm{k}-1/2}) = -\delta_{\mathrm{k}}(\rho\, g\, \eta^{\mathrm{eff}}\, \partial_t \eta_{\mathrm{k}-1/2}). \tag{37.99}$$

For the final two equations we introduced the layer index, with $\mathrm{k} = 1$ for the single layer and with the layer interfaces $\eta_{1/2} = \eta$ and $\eta_{3/2} = \eta_{\mathrm{b}}$. Additionally, δ_{k} is the finite difference operator (37.37) so that

$$h = \eta - \eta_{\mathrm{b}} = \eta_{1/2} - \eta_{3/2} = \delta_{\mathrm{k}} \eta_{\mathrm{k}-1/2}. \tag{37.100}$$

We inserted $\rho\, g\, \eta^{\mathrm{eff}}$ into the difference operator in equation (37.99) since this term is depth independent across the layer.

For the next step, we make use of equation (37.95) for the layer pressure, $p = \rho\, g\, (\eta^{\mathrm{eff}} - z)$, in which case[8]

$$-\delta_{\mathrm{k}}(\rho\, g\, \eta^{\mathrm{eff}}\, \partial_t \eta_{\mathrm{k}-1/2}) = -\delta_{\mathrm{k}}[(p + \rho\, g\, z)\, \partial_t \eta_{\mathrm{k}-1/2}] \tag{37.101a}$$

$$= -\delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\, \partial_t \eta_{\mathrm{k}-1/2}) - \delta_{\mathrm{k}}(\rho\, g\, \eta_{\mathrm{k}-1/2}\, \partial_t \eta_{\mathrm{k}-1/2}). \tag{37.101b}$$

This step is somewhat subtle since we replaced $\rho\, g\, \eta^{\mathrm{eff}}$, which is depth independent within a layer, with the sum $p + \rho\, g\, z$, where both p and $\rho\, g\, z$ are functions of depth. For equation (37.101b) we replaced p and z with their interface values since the argument of the difference operator is evaluated on the layer interfaces. Observe that $\partial_t \eta_{\mathrm{b}} = 0$, and yet it is convenient to carry this term through the manipulations to retain symmetry of the equations, and to anticipate the same formulation for the stacked shallow water energetics in Section 37.6.

We now make use of the potential energy in Section 37.5.1 by writing

$$-\delta_{\mathrm{k}}(\rho\, g\, \eta_{\mathrm{k}-1/2}\, \partial_t \eta_{\mathrm{k}-1/2}) = -(\rho\, g/2)\, \partial_t(\eta^2 - \eta_{\mathrm{b}}^2) = -\partial_t \mathcal{P}^{\mathrm{sw}} = \nabla \cdot (\boldsymbol{u}\, \mathcal{P}^{\mathrm{sw}}) - g\, \rho\, h\, \overline{w}, \tag{37.102}$$

where the final step used the potential energy equation (37.90). As advertised, this formulation

[8] Equations (37.101a) and (37.101b) are inspired by some unpublished notes from Christopher Wolfe.

exposes the buoyancy work term, $-g\,\rho\,h\,\overline{w}$, which then allows us to bring the kinetic energy equation (37.98) to the form

$$\partial_t \mathcal{K}^{\mathrm{sw}} + \nabla\cdot[\boldsymbol{u}\,(\mathcal{K}^{\mathrm{sw}} - \mathscr{P}^{\mathrm{sw}} + \rho\,g\,h\,\eta^{\mathrm{eff}})] + \delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\,\partial_t\eta_{\mathrm{k}-1/2}) = -g\,\rho\,h\,\overline{w} + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.103}$$

We can simplify the advective flux by writing

$$-\mathscr{P}^{\mathrm{sw}} + \rho\,g\,h\,\eta^{\mathrm{eff}} = -\rho\,g\,h\,\overline{\eta} + \rho\,g\,\eta + h\,p_{\mathrm{a}} = h\,(\rho\,g\,h/2 + p_{\mathrm{a}}) = P, \tag{37.104}$$

where the final equality introduced the layer integrated pressure

$$P = \int_{\eta_{\mathrm{b}}}^{\eta} p(z)\,\mathrm{d}z = \rho\,g\int_{\eta_{\mathrm{b}}}^{\eta}(\eta^{\mathrm{eff}} - z)\,\mathrm{d}z = h\,(\rho\,g\,h/2 + p_{\mathrm{a}}). \tag{37.105}$$

The kinetic energy equation (37.103) thus takes the form

$$\partial_t \mathcal{K}^{\mathrm{sw}} + \nabla\cdot[\boldsymbol{u}\,(\mathcal{K}^{\mathrm{sw}} + P)] + \delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\,\partial_t\eta_{\mathrm{k}-1/2}) = -g\,\rho\,h\,\overline{w} + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.106}$$

The term $\delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\,\partial_t\eta_{\mathrm{k}-1/2})$ on the left hand side is a vertical transfer that, as seen in Section 37.5.4, arises in part from pressure form stresses acting on the boundary of the fluid column.

37.5.4 Kinetic energy and pressure form stress

As a final form of the kinetic energy equation, we recombine the vertical transfer term and the buoyancy work term in equation (37.106) to have

$$-g\,\rho\,h\,\overline{w} - \delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\,\partial_t\eta_{\mathrm{k}-1/2}) = -g\,\rho\,h\,\overline{w} - p_{\mathrm{a}}\,[w(\eta) - \boldsymbol{u}\cdot\nabla\eta] + p_{\mathrm{b}}\,[w(\eta_{\mathrm{b}}) - \boldsymbol{u}\cdot\nabla\eta_{\mathrm{b}}]. \tag{37.107}$$

Introducing the bottom pressure and depth integrated pressure

$$p_{\mathrm{b}} = p_{\mathrm{a}} + \rho\,g\,h \quad\text{and}\quad P = h\,(p_{\mathrm{a}} + \rho\,g\,h/2), \tag{37.108}$$

leads to

$$\begin{aligned}
-g\,\rho\,h\,\overline{w} - \delta_{\mathrm{k}}(p_{\mathrm{k}-1/2}\,\partial_t\eta_{\mathrm{k}-1/2}) &= (P/h)\,[w(\eta_{\mathrm{b}}) - w(\eta)] + \boldsymbol{u}\cdot(p_{\mathrm{a}}\,\nabla\eta - p_{\mathrm{b}}\,\nabla\eta_{\mathrm{b}}) && (37.109\mathrm{a})\\
&= \frac{P}{h}\,\frac{\mathrm{D}(\eta_{\mathrm{b}} - \eta)}{\mathrm{D}t} + \boldsymbol{u}\cdot(p_{\mathrm{a}}\,\nabla\eta - p_{\mathrm{b}}\,\nabla\eta_{\mathrm{b}}) && (37.109\mathrm{b})\\
&= -\frac{P}{h}\,\frac{\mathrm{D}h}{\mathrm{D}t} + \boldsymbol{u}\cdot(p_{\mathrm{a}}\,\nabla\eta - p_{\mathrm{b}}\,\nabla\eta_{\mathrm{b}}) && (37.109\mathrm{c})\\
&= P\,\nabla\cdot\boldsymbol{u} + \boldsymbol{u}\cdot(p_{\mathrm{a}}\,\nabla\eta - p_{\mathrm{b}}\,\nabla\eta_{\mathrm{b}}), && (37.109\mathrm{d})
\end{aligned}$$

so that the kinetic energy equation (37.106) can be written

$$\partial_t \mathcal{K}^{\mathrm{sw}} + \nabla\cdot(\boldsymbol{u}\,\mathcal{K}^{\mathrm{sw}}) = \boldsymbol{u}\cdot(-\nabla P + p_{\mathrm{a}}\,\nabla\eta - p_{\mathrm{b}}\,\nabla\eta_{\mathrm{b}}) + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.110}$$

We have thus exposed the work done by pressure form stresses acting on the vertical side of an expanding or contracting shallow water column, plus those form stresses acting on the top and bottom layer interfaces. A direct way to derive equation (37.110) is to return to the kinetic energy equation (37.94) and make use of the identity (37.72). This identity equates the thickness weighted horizontal pressure gradient acting on a shallow water column, to the pressure form stresses acting over the boundary of the column, and for a single shallow water layer this identity

is

$$-h\,\nabla p = -\nabla P + p_{\rm a}\,\nabla\eta - p_{\rm b}\,\nabla\eta_{\rm b}. \tag{37.111}$$

Nonetheless, we chose the more tedious derivation as it provides a check on the correctness of the transfer term and the buoyancy work term in the kinetic energy budget (37.106).

37.5.5 Mechanical energy budget

The mechanical energy per horizontal area for the shallow water layer is given by

$$\mathcal{M}^{\rm sw} = \mathcal{K}^{\rm sw} + \mathcal{P}^{\rm sw} = (\rho/2)\,[h\,\boldsymbol{u}\cdot\boldsymbol{u} + g\,(\eta^2 - \eta_{\rm b}^2)] = \rho\,h\,(\boldsymbol{u}\cdot\boldsymbol{u}/2 + g\,\overline{\eta}). \tag{37.112}$$

To form a budget equation for the mechanical energy we simply add the budgets for the gravitational potential energy and kinetic energy.

Summary of the potential and kinetic energy budgets

We here summarize the flux-form budgets for potential energy and kinetic energy (equations (37.90), (37.94), (37.98), (37.106), and (37.110)):

$$\partial_t\mathcal{P}^{\rm sw} + \nabla\cdot(\boldsymbol{u}\,\mathcal{P}^{\rm sw}) = g\,\rho\,h\,\overline{w} \tag{37.113a}$$

$$\partial_t\mathcal{K}^{\rm sw} + \nabla\cdot(\boldsymbol{u}\,\mathcal{K}^{\rm sw}) = -h\,\boldsymbol{u}\cdot\nabla p + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.113b}$$

$$\partial_t\mathcal{K}^{\rm sw} + \nabla\cdot[\boldsymbol{u}\,(\mathcal{K}^{\rm sw} + \rho\,g\,h\,\eta^{\rm eff})] = \rho\,g\,\eta^{\rm eff}\,\nabla\cdot(h\,\boldsymbol{u}) + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.113c}$$

$$\partial_t\mathcal{K}^{\rm sw} + \nabla\cdot[\boldsymbol{u}\,(\mathcal{K}^{\rm sw} + P)] + \delta_{\rm k}(p_{\rm k-1/2}\,\partial_t\eta_{\rm k-1/2}) = -g\,\rho\,h\,\overline{w} + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F} \tag{37.113d}$$

$$\partial_t\mathcal{K}^{\rm sw} + \nabla\cdot(\boldsymbol{u}\,\mathcal{K}^{\rm sw}) = \boldsymbol{u}\cdot(-\nabla P + p_{\rm a}\,\nabla\eta - p_{\rm b}\,\nabla\eta_{\rm b}) + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.113e}$$

Example forms of the mechanical energy budget

Adding equations (37.113a) and (37.113b) leads to the mechanical energy budget

$$\partial_t\mathcal{M}^{\rm sw} + \nabla\cdot(\boldsymbol{u}\,\mathcal{M}^{\rm sw}) = g\,\rho\,h\,\overline{w} - h\,\boldsymbol{u}\cdot\nabla p + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}, \tag{37.114}$$

whereas the sum of equations (37.113a) and (37.113d) leads to

$$\partial_t\mathcal{M}^{\rm sw} + \nabla\cdot[\boldsymbol{u}\,(\mathcal{M}^{\rm sw} + P)] + \delta_{\rm k}(p_{\rm k-1/2}\,\partial_t\eta_{\rm k-1/2}) = \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.115}$$

As we discuss in Section 37.6, equations (37.114) and (37.115) hold also for the mechanical energy in a N-layer shallow water model.

Specializing to the single layer

Making use of the identity (see equation (37.104))

$$\mathcal{M}^{\rm sw} + P = \rho\,h\,(\boldsymbol{u}\cdot\boldsymbol{u}/2 + g\,\eta^{\rm eff}), \tag{37.116}$$

brings the mechanical energy budget (37.115) to the form

$$\partial_t\mathcal{M}^{\rm sw} + \nabla\cdot[h\,\boldsymbol{u}\,(\rho\,\boldsymbol{u}\cdot\boldsymbol{u}/2 + \rho\,g\,\eta + p_{\rm a})] + \delta_{\rm k}(p_{\rm k-1/2}\,\partial_t\eta_{\rm k-1/2}) = \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.117}$$

Further note that $\partial_t\eta_{\rm b} = 0$ so that

$$\nabla\cdot(h\,\boldsymbol{u}\,p_{\rm a}) + \delta_{\rm k}(p_{\rm k-1/2}\,\partial_t\eta_{\rm k-1/2}) = \nabla\cdot(h\,\boldsymbol{u}\,p_{\rm a}) + p_{\rm a}\,\partial_t\eta = h\,\boldsymbol{u}\cdot\nabla p_{\rm a}, \tag{37.118}$$

where $\partial_t \eta + \nabla \cdot (h\,\boldsymbol{u}) = 0$. We are thus led to single layer mechanical energy budget

$$\partial_t \mathcal{M}^{\mathrm{sw}} + \nabla \cdot [h\,\boldsymbol{u}\,(\boldsymbol{u}\cdot\boldsymbol{u}/2 + g\,\eta)] = -h\,\boldsymbol{u}\cdot\nabla p_{\mathrm{a}} + \rho\,h\,\boldsymbol{u}\cdot\boldsymbol{F}. \tag{37.119}$$

which proves of use when studying the mechanical energy of shallow water waves in Section 53.3.2.

Shallow water form of the Bernoulli theorem

It is notable that in the steady state of an unforced perfect shallow water fluid (so with $p_{\mathrm{a}} = 0$ and $\boldsymbol{F} = 0$), equation (37.117) becomes

$$\boldsymbol{u}\cdot\nabla(\boldsymbol{u}\cdot\boldsymbol{u} + g\,h) = 0, \tag{37.120}$$

which is an expression of the Bernoulli theorem (Section 27.9) for steady shallow water flow.

Domain integrated mechanical energy

The budget equations (37.114) or (37.115) have already been layer integrated. So to study the domain integrated energetics requires only an area integral. The budget equation (37.115) is ideally suited for this purpose since all terms, except the non-conservative acceleration, are written as a flux divergence and so they represent transfer processes. The domain integral of the flux-form mechanical energy equation (37.115) is

$$\int \partial_t \mathcal{M}^{\mathrm{sw}}\,\mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{S}} (\mathcal{M}^{\mathrm{sw}} + P)\,\boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}l + \int_{\mathcal{S}} (-p_{\mathrm{a}}\,\partial_t\eta + h\,\rho\,\boldsymbol{u}\cdot\boldsymbol{F})\,\mathrm{d}\mathcal{S}, \tag{37.121}$$

where we set $\partial_t \eta_{\mathrm{b}} = 0$. The boundary integral on the right hand side is computed as a line integral around the edge of the layer. We consider three options for the layer geometry as illustrated in Figure 29.6. First, the thickness vanishes at the edge of the domain as in the case of shorelines, in which case the boundary integral vanishes since each term in the integral is thickness weighted. Second, we assume the layer is bounded by vertical sidewalls, in which case $\boldsymbol{u}\cdot\hat{\boldsymbol{n}} = 0$ at the sidewall boundaries. Third, the domain has periodicity in one or both directions (e.g., a zonal channel), in which case the boundary integral again vanishes in the periodic directions.

Evidently, for either of the three types of domain boundaries considered above, the boundary integral in equation (37.121) vanishes, in which case the domain integrated mechanical energy budget reduces to

$$\int_{\mathcal{S}} \partial_t \mathcal{M}^{\mathrm{sw}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{S}} (-p_{\mathrm{a}}\,\partial_t\eta + h\,\rho\,\boldsymbol{u}\cdot\boldsymbol{F})\,\mathrm{d}\mathcal{S} = -\int_{\mathcal{S}} h\,\boldsymbol{u}\cdot(\nabla p_{\mathrm{a}} - \rho\,\boldsymbol{F})\,\mathrm{d}\mathcal{S}. \tag{37.122}$$

To reach the second equality we wrote

$$-\int_{\mathcal{S}} p_{\mathrm{a}}\,\partial_t\eta\,\mathrm{d}\mathcal{S} = \int_{\mathcal{S}} p_{\mathrm{a}}\,\nabla\cdot(h\,\boldsymbol{u})\,\mathrm{d}\mathcal{S} = -\int_{\mathcal{S}} h\,\boldsymbol{u}\cdot\nabla p_{\mathrm{a}}\,\mathrm{d}\mathcal{S}, \tag{37.123}$$

where we set

$$\int \nabla\cdot(p_{\mathrm{a}}\,h\,\boldsymbol{u})\,\mathrm{d}\mathcal{S} = 0, \tag{37.124}$$

which follows from the same reasoning used for the boundary integral in equation (37.121). Evidently, there is a nonzero domain integrated atmospheric pressure work only if there is a nonzero time tendency for the layer thickness. Furthermore, if p_{a} is a spatial constant, volume conservation

for the full layer means that

$$\int_{\mathcal{S}} \partial_t \eta \, \mathrm{d}\mathcal{S} = - \int_{\mathcal{S}} \nabla \cdot (h \, \boldsymbol{u}) \, \mathrm{d}\mathcal{S} = 0, \tag{37.125}$$

in which case we find that equation (37.122) is indeed self-consistent.

If the domain is bounded by sloping sides, then the mechanical energy vanishes at the horizontal boundaries, so that the time derivative acting on $\mathcal{M}^{\mathrm{sw}}$ commutes with the area integral on the left hand side of equation (37.121). Alternatively, if the layer is bounded by fixed vertical walls, or is periodic in one or both directions, then the horizontal domain boundaries are static, again meaning that the time derivative commutes with the horizontal integral. In each case we can write the domain integrated mechanical energy equation as

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_{\mathcal{S}} \mathcal{M}^{\mathrm{sw}} \, \mathrm{d}\mathcal{S} = - \int_{\mathcal{S}} h \, \boldsymbol{u} \cdot (\nabla p_{\mathrm{a}} - \rho \, \boldsymbol{F}) \, \mathrm{d}\mathcal{S}. \tag{37.126}$$

In the absence of work on the layer from atmospheric pressure, then the total mechanical energy is affected only via non-conservative forces, such as those from viscous friction or boundary stresses. It then follows that for a perfect and unforced shallow water fluid, then the domain integrated mechanical energy remains constant, in which case there is an exact exchange between the domain integrated gravitational potential and kinetic energies.

37.5.6 Available potential energy

As discussed in Section 30.9, a huge portion of the gravitational potential energy is not realizable as kinetic energy, merely because the minimum potential energy state is when the fluid is at rest with some fluid parcels sitting above others. Available potential energy measures the gravitational potential energy that can be converted to kinetic energy through a reversible rearrangement of the fluid. We here display the available potential energy for a single shallow water layer in a simply connected domain, thus specializing the more general discussion given in Section 30.9 for a continuously stratified Boussinesq ocean.

Taking $z = 0$ as the reference level, the domain integrated gravitational potential energy for a single shallow water layer is

$$\int \mathcal{P}^{\mathrm{sw}} \, \mathrm{d}\mathcal{S} = g \, \rho \int \mathrm{d}\mathcal{S} \int_{\eta_b}^{\eta} z \, \mathrm{d}z = \frac{g \, \rho}{2} \int (\eta^2 - \eta_b^2) \, \mathrm{d}\mathcal{S}. \tag{37.127}$$

We define a background or reference state potential energy as the potential energy contained in the fluid at rest, so that the free surface interface has its uniform area average value. Write the area average free surface height as

$$\langle \eta \rangle = \frac{1}{A} \int \eta \, \mathrm{d}\mathcal{S}, \tag{37.128}$$

where

$$A = \int \mathrm{d}\mathcal{S} \tag{37.129}$$

is the horizontal area integral over the full domain of the fluid. Hence, the reference state gravitational potential energy is realized when the surface height is flat at $z = \langle \eta \rangle$, so that

$$\int \mathcal{P}^{\mathrm{sw}}_{\mathrm{ref}} \, \mathrm{d}\mathcal{S} = \frac{g \, \rho}{2} \int (\langle \eta \rangle^2 - \eta_b^2) \, \mathrm{d}\mathcal{S}. \tag{37.130}$$

The available potential energy is defined by the difference

$$E_{\rm APE} = \int (\mathscr{P}^{\rm sw} - \mathscr{P}^{\rm sw}_{\rm ref})\, {\rm d}\mathcal{S} = \frac{g\,\rho}{2} \int (\eta^2 - \langle \eta \rangle^2)\, {\rm d}\mathcal{S} = \frac{g\,\rho}{2} \int (\eta')^2\, {\rm d}\mathcal{S} \geq 0, \tag{37.131}$$

where

$$\eta' = \eta - \langle \eta \rangle \tag{37.132}$$

is the anomalous free surface. Note how the bottom topography cancelled out from $E_{\rm APE}$ since $\eta_{\rm b}^2$ appears in both $\mathscr{P}^{\rm sw}$ and $\mathscr{P}^{\rm sw}_{\rm ref}$. Also note that to reach the final equality in equation (37.131) required the identity

$$\int (\eta - \langle \eta \rangle)^2\, {\rm d}\mathcal{S} = \int (\eta^2 - 2\,\langle \eta \rangle\, \eta + \langle \eta \rangle^2)\, {\rm d}\mathcal{S} \tag{37.133a}$$

$$= \int \eta^2\, {\rm d}\mathcal{S} + A\,\langle \eta \rangle^2 - 2\,\langle \eta \rangle \int \eta\, {\rm d}\mathcal{S} \tag{37.133b}$$

$$= \int \eta^2\, {\rm d}\mathcal{S} - \langle \eta \rangle^2\, A \tag{37.133c}$$

$$= \int (\eta^2 - \langle \eta \rangle^2)\, {\rm d}\mathcal{S}. \tag{37.133d}$$

Equation (37.131) shows that the available potential energy is non-negative for the shallow water layer. That is, any slope to the shallow water layer represents a store of positive available potential energy. We derive the available potential energy in Section 37.6.1 for the N-layer shallow water model, showing that it too is non-negative.

37.6 Energetics for N layers

We here generalize the single layer mechanical energy analysis from Section 37.5 to N-layers, making use of the N-layer equations from Section 36.4.

37.6.1 Potential energy and available potential energy

Here we develop the equation for potential energy in a form that naturally leads to the expression for the available potential energy.

Potential energy for N-layers

To derive the gravitational potential energy per horizontal area in a stacked shallow water model, first consider the case with $N = 3$ (Figure 36.6), in which the potential energy per horizontal area is

$$\mathscr{P}^{\rm sw} = g \int_{\eta_{\rm b}}^{\eta} z\, \rho\, {\rm d}z = g\,\rho_3 \int_{\eta_{\rm b}}^{\eta_{5/2}} z\, {\rm d}z + g\,\rho_2 \int_{\eta_{5/2}}^{\eta_{3/2}} z\, {\rm d}z + g\,\rho_1 \int_{\eta_{3/2}}^{\eta} z\, {\rm d}z, \tag{37.134}$$

which then leads to

$$2\,\mathscr{P}^{\rm sw} = g\,\rho_3\,(\eta_{5/2}^2 - \eta_{\rm b}^2) + g\,\rho_2\,(\eta_{3/2}^2 - \eta_{5/2}^2) + g\,\rho_1\,(\eta^2 - \eta_{3/2}^2) \tag{37.135a}$$

$$= g\,\eta_{5/2}^2\,(\rho_3 - \rho_2) + g\,\eta_{3/2}^2\,(\rho_2 - \rho_1) + g\,\eta_{1/2}^2\,\rho_1 - g\,\rho_3\,\eta_{\rm b}^2 \tag{37.135b}$$

$$= \rho_{\rm ref}\,(g_{5/2}^{\rm r}\,\eta_{5/2}^2 + g_{3/2}^{\rm r}\,\eta_{3/2}^2 + g_{1/2}^{\rm r}\,\eta_{1/2}^2) - g\,\rho_3\,\eta_{\rm b}^2, \tag{37.135c}$$

where $g^{\mathrm{r}}_{1/2} = g$ and $\eta_{1/2} = \eta$. Generalizing this expression to an arbitrary number of layers leads to

$$\mathscr{P}^{\mathrm{sw}} = \frac{1}{2}\left[-g\,\rho_N\,\eta_{\mathrm{b}}^2 + \rho_{\mathrm{ref}}\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta^2_{\mathrm{k}+1/2}\right], \tag{37.136}$$

with $\eta_{N+1/2} = \eta_{\mathrm{b}}$ (see Figure 36.6). The first term is a constant and so does not contribute to time changes of the potential energy, and so it is commonly ignored in the literature.

Available potential energy for N-layers

The transient terms in equation (37.136) are positive definite, so that potential energy increases when the reduced gravity increases and/or the layer interfaces deviate in either direction from their resting values. This behavior motivates us to introduce the available potential energy by decomposing the layer interface heights into their area mean and deviations, just as for the single layer in Section 37.5.6

$$\eta'_{\mathrm{k}\pm1/2} = \eta_{\mathrm{k}\pm1/2} - \langle\eta_{\mathrm{k}\pm1/2}\rangle. \tag{37.137}$$

Volume conservation for each layer implies that the area mean, $\langle\eta_{\mathrm{k}-1/2}\rangle$, is a space and time constant. Substitution into equation (37.136) leads to

$$\begin{aligned}\mathscr{P}^{\mathrm{sw}} = \frac{1}{2}&\left[-g\,\rho_N\,\eta_{\mathrm{b}}^2 + \rho_{\mathrm{ref}}\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\langle\eta_{\mathrm{k}+1/2}\rangle^2\right]\\ &+\frac{\rho_{\mathrm{ref}}}{2}\left[2\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\langle\eta_{\mathrm{k}+1/2}\rangle\,\eta'_{\mathrm{k}+1/2} + \sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,(\eta'_{\mathrm{k}+1/2})^2\right].\end{aligned} \tag{37.138}$$

The first bracketed term is a constant in time, and it mesures the potential energy of the system when all interfaces sit at their area mean values, for which $\eta'_{\mathrm{k}1/2} = 0$. When performing an area integral over the full domain, the term with $\langle\eta_{\mathrm{k}+1/2}\rangle\,\eta'_{\mathrm{k}+1/2}$ vanishes since the area integral of $\eta'_{\mathrm{k}+1/2}$ vanishes. We thus define the available potential energy for the N-layer shallow water fluid

$$E_{\mathrm{APE}} = \frac{\rho_{\mathrm{ref}}}{2}\int\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,(\eta'_{\mathrm{k}+1/2})^2\,\mathrm{d}\mathcal{S} \geq 0. \tag{37.139}$$

This expression generalizes the single layer form given by equation (37.131). As expected, the available potential energy increases whether a layer interface moves up or down, and it vanishes when all interfaces heights equal to their area mean values.

Time evolution of the potential energy

To derive an evolution equation for the potential energy, we take the time derivative of equation (37.136)

$$\partial_t\mathscr{P}^{\mathrm{sw}} = \rho_{\mathrm{ref}}\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta_{\mathrm{k}+1/2}\,\partial_t\eta_{\mathrm{k}+1/2} = \rho_{\mathrm{ref}}\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta_{\mathrm{k}+1/2}\sum_{\mathrm{j}=\mathrm{k}+1}^{N}\partial_t h_{\mathrm{j}}, \tag{37.140}$$

where the second equality made use of equation (36.79) to relate the interface height and the layer thickness. We can collapse the double sum through the following identities

$$\sum_{\mathrm{k}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{k}+1/2}\,\eta_{\mathrm{k}+1/2} \sum_{\mathrm{j}=\mathrm{k}+1}^{N} \partial_t h_{\mathrm{j}} = \partial_t h_N \sum_{\mathrm{j}=0}^{N-1} g^{\mathrm{r}}_{\mathrm{j}+1/2}\,\eta_{\mathrm{j}+1/2} + \partial_t h_{N-1} \sum_{\mathrm{j}=0}^{N-2} g^{\mathrm{r}}_{\mathrm{j}+1/2}\,\eta_{\mathrm{j}+1/2} + \ldots + \partial_t h_1\, g^{\mathrm{r}}_{1/2}\,\eta_{1/2}. \quad (37.141)$$

The product of reduced gravity and interface height can be written in terms of the shallow water dynamic pressure from equation (36.87)

$$p^{\mathrm{dyn}}_{\mathrm{k}} = \rho_{\mathrm{ref}} \sum_{\mathrm{j}=0}^{\mathrm{k}-1} g^{\mathrm{r}}_{\mathrm{j}+1/2}\,\eta_{\mathrm{j}+1/2}, \quad (37.142)$$

in which case we have the potential energy budget

$$\partial_t \mathscr{P}^{\mathrm{sw}} = \sum_{\mathrm{k}=1}^{N} p^{\mathrm{dyn}}_{\mathrm{k}}\,\partial_t h_{\mathrm{k}} = -\sum_{\mathrm{k}=1}^{N} p^{\mathrm{dyn}}_{\mathrm{k}}\,\nabla\cdot(\boldsymbol{u}_{\mathrm{k}}\,h_{\mathrm{k}}), \quad (37.143)$$

where the second equality made use of the layer thickness equation (36.78a). Rearrangement brings this equation to its flux-form expression

$$\partial_t \mathscr{P}^{\mathrm{sw}} + \nabla\cdot\sum_{\mathrm{k}=1}^{N} p^{\mathrm{dyn}}_{\mathrm{k}}\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}} = \sum_{\mathrm{k}=1}^{N} h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\nabla p^{\mathrm{dyn}}_{\mathrm{k}}. \quad (37.144)$$

37.6.2 Potential energy and buoyancy work

Potential energy for N-layers

Following the method for the single layer in Section 37.5.1, we write the gravitational potential energy for a column of shallow water fluid as

$$\mathscr{P}^{\mathrm{sw}} = g\int_{\eta_{\mathrm{b}}}^{\eta} z\,\rho\,\mathrm{d}z = g\sum_{\mathrm{k}=1}^{N}\rho_{\mathrm{k}}\,h_{\mathrm{k}}\,\overline{\eta}_{\mathrm{k}} = \sum_{\mathrm{k}=1}^{N}\mathscr{P}^{\mathrm{sw}}_{\mathrm{k}}, \quad (37.145)$$

where, again,

$$h_{\mathrm{k}} = \eta_{\mathrm{k}-1/2} - \eta_{\mathrm{k}+1/2} \quad \text{and} \quad \overline{\eta}_{\mathrm{k}} = (\eta_{\mathrm{k}-1/2} + \eta_{\mathrm{k}+1/2})/2 \quad (37.146)$$

makes use of the layer thickness, h_{k}, and the average interface height, $\overline{\eta}_{\mathrm{k}}$. We can think of equation (37.145) as building the potential energy using layer properties, whereas the alternative expression (37.136) is built using interface properties.

Time evolution of the potential energy

Taking the time derivative of the potential energy (37.145) leads to

$$\partial_t \mathcal{P}_{\mathrm{k}}^{\mathrm{sw}} = g\,\rho_{\mathrm{k}}\,\partial_t(h_{\mathrm{k}}\,\overline{\eta}_{\mathrm{k}}) \tag{37.147a}$$
$$= g\,\rho_{\mathrm{k}}(\partial_t h_{\mathrm{k}}\,\overline{\eta}_{\mathrm{k}} + h_{\mathrm{k}}\,\partial_t\overline{\eta}_{\mathrm{k}}) \tag{37.147b}$$
$$= g\,\rho_{\mathrm{k}}\,[-\overline{\eta}_{\mathrm{k}}\,\nabla\cdot(\boldsymbol{u}_{\mathrm{k}}\,h_{\mathrm{k}}) + h_{\mathrm{k}}\,(\overline{w}_{\mathrm{k}} - \boldsymbol{u}_{\mathrm{k}}\cdot\nabla\overline{\eta}_{\mathrm{k}})] \tag{37.147c}$$
$$= g\,\rho_{\mathrm{k}}\,h_{\mathrm{k}}\,\overline{w}_{\mathrm{k}} - g\,\nabla\cdot(\rho_{\mathrm{k}}\,\overline{\eta}_{\mathrm{k}}\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) \tag{37.147d}$$
$$= g\,\rho_{\mathrm{k}}\,h_{\mathrm{k}}\,\overline{w}_{\mathrm{k}} - \nabla\cdot(\boldsymbol{u}_{\mathrm{k}}\,\mathcal{P}_{\mathrm{k}}^{\mathrm{sw}}), \tag{37.147e}$$

so that the flux-form budget is given by

$$\partial_t \mathcal{P}_{\mathrm{k}}^{\mathrm{sw}} + \nabla\cdot(\boldsymbol{u}\,\mathcal{P}_{\mathrm{k}}^{\mathrm{sw}}) = g\,\rho_{\mathrm{k}}\,h_{\mathrm{k}}\,\overline{w}_{\mathrm{k}}. \tag{37.148}$$

This budget is identical to equation (37.90) that we discussed for a single layer, with the buoyancy work term exposed on the right hand side.

37.6.3 Kinetic energy

Kinetic energy and work from pressure gradients

Following our treatment in Section 37.5.2, consider the kinetic energy per horizontal area contained in a shallow water layer

$$\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} = \frac{1}{2}\int_{\eta_{\mathrm{k}+1/2}}^{\eta_{\mathrm{k}-1/2}} \rho_{\mathrm{ref}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}\,\mathrm{d}z = \frac{1}{2}\,\rho_{\mathrm{ref}}\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}. \tag{37.149}$$

Note that we set the density equal to the reference density as per the Boussinesq ocean, whereby the inertial mass is determined by the reference density (Section 30.1).

To derive an evolution equation for kinetic energy, multiply the thickness equation (36.78a) by $\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}$, and take the dot product of the vector-invariant velocity equation (36.112) with $h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}$,

$$(\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}})\,\partial_t h_{\mathrm{k}} = -(\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}})\,\nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) \tag{37.150a}$$
$$h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\partial_t\boldsymbol{u}_{\mathrm{k}} = -h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\nabla(p_{\mathrm{k}}/\rho_{\mathrm{ref}} + \boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}/2) + h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{F}_{\mathrm{k}}, \tag{37.150b}$$

where we included an acceleration, $\boldsymbol{F}_{\mathrm{k}}$, arising from friction or boundary stresses, as discussed in Section 36.6.5. Making use of these expressions leads to the time derivative of the kinetic energy per area, $\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} = \rho_{\mathrm{ref}}\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}/2$, of a shallow water layer

$$(2/\rho_{\mathrm{ref}})\,\partial_t\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} = \partial_t(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}) \tag{37.151a}$$
$$= (\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}})\,\partial_t h_{\mathrm{k}} + 2\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\partial_t\boldsymbol{u}_{\mathrm{k}} \tag{37.151b}$$
$$= -(\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}})\,\nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) - 2\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\nabla(p_{\mathrm{k}}/\rho_{\mathrm{ref}} + \boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{u}_{\mathrm{k}}/2) + 2\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{F}_{\mathrm{k}} \tag{37.151c}$$
$$= -2\,\nabla\cdot[\boldsymbol{u}_{\mathrm{k}}\,\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}}/\rho_{\mathrm{ref}}] - 2\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\nabla(p_{\mathrm{k}}/\rho_{\mathrm{ref}}) + 2\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{F}_{\mathrm{k}}, \tag{37.151d}$$

which then leads to the equivalent forms for the layer integrated kinetic energy budget

$$\partial_t\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} + \nabla\cdot(\boldsymbol{u}_{\mathrm{k}}\,\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}}) = -h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot[\nabla p_{\mathrm{k}} - \rho_{\mathrm{ref}}\,\boldsymbol{F}_{\mathrm{k}}], \tag{37.152a}$$
$$\partial_t\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} + \nabla\cdot[\boldsymbol{u}_{\mathrm{k}}\,(\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} + h_{\mathrm{k}}\,p_{\mathrm{k}})] = p_{\mathrm{k}}\,\nabla\cdot(h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}) + \rho_{\mathrm{ref}}\,h_{\mathrm{k}}\,\boldsymbol{u}_{\mathrm{k}}\cdot\boldsymbol{F}_{\mathrm{k}}. \tag{37.152b}$$

Recall that the pressure gradient is given by equation (36.87)

$$\nabla p_{\mathrm{k}} = \nabla p_{\mathrm{a}} + \nabla p_{\mathrm{k}}^{\mathrm{dyn}} = \nabla p_{\mathrm{a}} + \rho_{\mathrm{ref}} \, \nabla M_{\mathrm{k}}^{\mathrm{dyn}} \tag{37.153}$$

which arises from gradients in the applied atmospheric pressure plus the dynamic pressure, and where $M_{\mathrm{k}}^{\mathrm{dyn}} = \rho_{\mathrm{ref}} \, p_{\mathrm{k}}^{\mathrm{dyn}}$ is the Montgomery potential from Section 36.4.3. The budget equation (37.152b) corresponds to the single layer equation (37.98), where we identify the dynamic pressure for shallow water model with just a single layer

$$p_{\mathrm{k}=1}^{\mathrm{dyn}} = \rho \, g \, \eta^{\mathrm{eff}} = p_{\mathrm{a}} + \rho \, g \, \eta. \tag{37.154}$$

Kinetic energy and buoyancy work

The single layer discussion in Section 37.5.3 fully anticipated the N-layer case, so that we can immediately translate equation (37.106) to an arbitrary layer

$$\partial_t \mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} + \nabla \cdot [\boldsymbol{u} \, (\mathcal{K}_{\mathrm{k}}^{\mathrm{sw}} + P_{\mathrm{k}})] + \delta_{\mathrm{k}}(p_{\mathrm{k}-1/2} \, \partial_t \eta_{\mathrm{k}-1/2}) = -g \, \rho_{\mathrm{k}} \, h_{\mathrm{k}} \, \overline{w}_{\mathrm{k}} + \rho_{\mathrm{k}} \, h_{\mathrm{k}} \, \boldsymbol{u}_{\mathrm{k}} \cdot \boldsymbol{F}_{\mathrm{k}}. \tag{37.155}$$

37.6.4 Comments and further study

The discussion of mechanical energy for the single shallow water layer in Section 37.5.5 directly transfers to the N-layer case, thus making it unnecessary for us to develop the theory any further.

Elements of the discussion in this section are motivated by the energetic analysis of *Loose et al.* (2022), who detail the mechanical energy in a stacked shallow water model and decompose the energy budget into mean and transient eddy contributions.

37.7 Steady momentum balance in a zonal channel

In this section we study the depth integrated steady momentum budget for a single shallow water layer of density ρ in a zonally re-entrant channel, such as depicted in Figure 37.7. Such shallow water models have been used to garner insights into adiabatic aspects of Southern Ocean circulation, and we keep this application in mind for the following (so that $f < 0$). We are particularly interested in the force balances required to reach a steady flow in the presence of a prescribed constant wind stress acceleration, $\boldsymbol{\tau}/\rho$. The channel has arbitrary topography, including northern and southern bounds with sloping shelves and shorelines. Applying a zonal surface stress inserts zonal momentum to the fluid through the ocean surface. For simplicity we set the atmospheric pressure to zero, $p_{\mathrm{a}} = 0$, so that the bottom pressure is $p_{\mathrm{b}} = \rho \, g \, h$, and there is no form stress acting on the layer's upper surface.

A similar analysis was presented in Section 29.5 for the depth integrated axial angular momentum budget in a continuously stratified fluid. Following from that analysis, we ignore the role of internal viscous friction. However, we consider bottom frictional stresses written as a quadratic bottom drag

$$\boldsymbol{F}^{\mathrm{drag}} = -C_{\mathrm{d}} \, \boldsymbol{u} \, |\boldsymbol{u}|, \tag{37.156}$$

where $C_{\mathrm{d}} > 0$ is a dimensionless bottom drag coefficient.

The horizontal areal extent of the domain is a function of space and time since the shallow water layer rises up and down the northern and southern shorelines as motion occurs. Even so, since layer thickness vanishes at the shoreline edge, the horizontal boundary conditions for the shallow water layer are easy to apply when working with the thickness weighted equations. That is, all thickness weighted fields vanish at the shoreline edge merely since the thickness vanishes at the

edge. Indeed, working with thickness weighted fields allows us to handle any degree of vanishing layer thicknesses, including if the topography in the center of the channel becomes an island rather than a submerged seamount. We also made use of this property of thickness weighted budgets in Section 29.5 where we also considered sloping sides rather than the commonly considered, yet less realistic, vertical sides.

FIGURE 37.7: A zonally periodic/re-entrant southern hemisphere channel with northern and southern shelves and arbitrary seamount topography. Flow that leaves either the east or west boundary is assumed to re-enter the other side, so that the topology is periodic zonally. Left panel: horizontal (plan) view, showing the contours of the shelves and the topography, with flow leaving one of the zonal ends re-entering the other. The arbitrary dark solid contour extends across the zonal extent of the channel and is periodic, with a unit vector, $\hat{\boldsymbol{n}}$, depicted normal to a point along the contour. In a steady state, the net fluid transport crossing this contour vanishes: $\oint h\,\boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s = 0$, meaning that there is no accumulation of fluid within any region of the channel. Right panel: meridional-depth view through an arbitrary longitude, along with a sample vertical column of water extending from the bottom to the surface. The shoreline edges occur where the layer thickness vanishes on the northern and southern shelves. So although the position of the shoreline edge is a function of space and time (since the fluid moves up and down the shoreline slope), the vanishing layer thickness found at the edge renders a simple treatment of boundary conditions for the thickness weighted equations.

37.7.1 Volume transport for steady flow

Before considering the steady force balance, we establish a constraint based on volume conservation by considering the steady thickness equation

$$\nabla\cdot(h\,\boldsymbol{u}) = 0. \tag{37.157}$$

As discussed for incompressible flow in Chapter 22, this non-divergence condition means that there is zero net steady transport crossing any simply connected closed contour in the fluid. A particularly interesting closed contour is one that is periodic and extends across the full zonal extent of the channel (see Figure 37.7), in which case

$$\oint h\,\boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}s = 0, \tag{37.158}$$

where $\oint$ denotes a periodic line integral across the zonal extent of the channel, $\hat{\boldsymbol{n}}$ is a unit vector normal to the contour, and $\mathrm{d}s$ is the arc-length line element along the contour. The constraint (37.158) reflects the inability of the steady flow to build up or deplete the fluid on one region of the channel at the expense of another. In particular, if the contour follows a constant latitude line, then we see that for a steady state there is no net meridional transport across a latitude

circle

$$\oint h\,\boldsymbol{u}\cdot\hat{\boldsymbol{y}}\,\mathrm{d}x = \oint h\,v\,\mathrm{d}x = 0 \qquad \text{steady flow.} \tag{37.159}$$

This result means that the depth weighted Coriolis acceleration appearing in the zonal momentum equation vanishes when integrated zonally

$$\oint f\,h\,v\,\mathrm{d}x = f\oint h\,v\,\mathrm{d}x = 0 \qquad \text{steady flow.} \tag{37.160}$$

We make use of this result in Section 37.7.3.

37.7.2 Steady meridional balances

Consider the thickness weighted meridional momentum equation (37.35b) in the presence of a wind stress and bottom drag

$$\frac{\partial(h\,v)}{\partial t} + \partial_x(h\,u\,v) + \partial_y(h\,v^2 + g\,h^2/2) + u\,h\,f = -(p_\mathrm{b}/\rho)\,\partial_y\eta_\mathrm{b} + \tau^y/\rho - C_\mathrm{d}\,v\,|\boldsymbol{u}|. \tag{37.161}$$

Integrating zonally over the channel removes the zonal transport term, $\partial_x(h\,u\,v)$, due to periodicity

$$\oint\left[\frac{\partial(h\,v)}{\partial t} + \partial_y(h\,v^2 + g\,h^2/2) + u\,h\,f\right]\mathrm{d}x = \oint\left[-(p_\mathrm{b}/\rho)\,\partial_y\eta_\mathrm{b} + \tau^y/\rho - C_\mathrm{d}\,v\,|\boldsymbol{u}|\right]\mathrm{d}x. \tag{37.162}$$

We can pull the time derivative outside of the zonal integral since the domain is zonally periodic, in which case the time changes to the net meridional transport across a latitude circle are given by

$$\frac{\mathrm{d}}{\mathrm{d}t}\oint v\,h\,\mathrm{d}x = \oint\left[-\partial_y(h\,v^2 + g\,h^2/2) - u\,h\,f - (p_\mathrm{b}/\rho)\,\partial_y\eta_\mathrm{b} + \tau^y/\rho - C_\mathrm{d}\,v\,|\boldsymbol{u}|\right]\mathrm{d}x. \tag{37.163}$$

Correspondingly, a steady state along a latitude circle is realized by the balance

$$\oint\left[\partial_y(h\,v^2 + g\,h^2/2) + u\,h\,f\right]\mathrm{d}x = \oint\left[-(p_\mathrm{b}/\rho)\,\partial_y\eta_\mathrm{b} + \tau^y/\rho - C_\mathrm{d}\,v\,|\boldsymbol{u}|\right]\mathrm{d}x. \tag{37.164}$$

The right hand side represents forcing by the topographic form stress, meridional wind stress, and bottom drag. That forcing, integrated over a latitude circle, balances the left hand side, which is the Coriolis acceleration arising from zonal motion, plus the meridional divergence of meridional momentum advection plus layer integrated pressure.

We can eliminate the nonlinear term on the left hand side of the balance (37.164) by integrating meridionally across the channel. Since $h = 0$ at the shoreline edges we know that $h\,v^2 + g\,h^2/2$ vanishes at the boundaries, thus leaving

$$\int\left[\oint u\,h\,f\,\mathrm{d}x\right]\mathrm{d}y = \int\left[\oint\left[-(p_\mathrm{b}/\rho)\,\partial_y\eta_\mathrm{b} + \tau^y/\rho - C_\mathrm{d}\,v\,|\boldsymbol{u}|\right]\mathrm{d}x\right]\mathrm{d}y. \tag{37.165}$$

This is a balance between the integrated meridional Coriolis force on the left hand side with pressure form stress, winds, and bottom drag on the right hand side.

37.7.3 Steady zonal balance

Now consider the thickness weighted zonal momentum equation (37.35a), here with bottom drag and wind stress contributions

$$\frac{\partial(h\,u)}{\partial t} + \partial_x(h\,u^2 + g\,h^2/2) + \partial_y(h\,u\,v) - v\,h\,f = -(p_\mathrm{b}/\rho)\,\partial_x\eta_\mathrm{b} + \tau^x/\rho - C_\mathrm{d}\,u\,|\boldsymbol{u}|. \tag{37.166}$$

Assuming a steady state and integrating along a latitude circle leads to

$$\rho \oint \partial_y(h\,u\,v)\mathrm{d}x = \oint [-p_\mathrm{b}\,\partial_x\eta_\mathrm{b} + \tau^x - C_\mathrm{d}\,\rho\,u\,|\boldsymbol{u}|]\,\mathrm{d}x, \tag{37.167}$$

where we dropped the Coriolis acceleration as per volume conservation in equation (37.160). For flows that are quasi-linear, the nonlinear term $\partial_y(h\,u\,v)$ will be subdominant to the wind stress and topographic form stress, thus leading to the approximate balance along each latitude circle

$$\oint p_\mathrm{b}\,\partial_x\eta_\mathrm{b}\,\mathrm{d}x \approx \oint [\tau^x - C_\mathrm{d}\,\rho\,u\,|\boldsymbol{u}|]\,\mathrm{d}x \qquad \text{nonlinear term small.} \tag{37.168}$$

We realize an exact balance over the full channel domain by meridionally integrating the latitude balance (37.167), in which the nonlinear term $\partial_y(h\,u\,v)$ drops out since $h = 0$ at the northern and southern shoreline edges

$$\int \left[\oint \tau^x\,\mathrm{d}x\right]\mathrm{d}y = \int \left[\oint [p_\mathrm{b}\,\partial_x\eta_\mathrm{b} + C_\mathrm{d}\,\rho\,u\,|\boldsymbol{u}|]\,\mathrm{d}x\right]\mathrm{d}y. \tag{37.169}$$

Again, this is an exact steady state balance realized by integrating the zonal thickness weighted momentum equation over the full domain channel. It is a balance between the zonal momentum input from the winds (left hand side) to the full domain, and the integrated bottom form stress plus bottom frictional drag (right hand side).

37.7.4 The role of frictional bottom drag

Consider a flat bottom channel, in which case the area integrated balance (37.169) is between winds and bottom drag

$$\int \left[\oint \tau^x\,\mathrm{d}x\right]\mathrm{d}y = \int \left[\oint C_\mathrm{d}\,\rho\,u\,|\boldsymbol{u}|\,\mathrm{d}x\right]\mathrm{d}y \Longrightarrow \rho^{-1}\,\langle\tau^x\rangle = C_\mathrm{d}\,\langle u\,|\boldsymbol{u}|\rangle, \tag{37.170}$$

where the angle brackets denote a channel area mean. Typical empirical values for the dimensionless bottom drag coefficient are

$$C_\mathrm{d} \approx 2\times 10^{-3}. \tag{37.171}$$

An area mean eastward zonal wind stress of $\langle\tau^x\rangle = 0.1$ N m^{-2} leads to a root-mean-square zonal velocity of

$$\sqrt{\langle u\,|\boldsymbol{u}|\rangle} \approx \sqrt{\langle u^2\rangle} \approx 0.2 \text{ m s}^{-1}, \tag{37.172}$$

where the first approximation follows from assuming the zonal velocity dominates over the meridional velocity. How realistic is this number for the Southern Ocean? Field measurements from the Southern Ocean suggest that depth and area averaged velocities are far smaller than this value. Furthermore, if this value occurred in a channel 4000 m deep and 2000 km wide (a rough idealization of the Antarctic Circumpolar Current), then this depth averaged velocity would yield a zonal volume transport of $\approx 1500\times 10^6$ m^3 s^{-1}, which is about ten times larger than the measured

transport through the Drake Passage.

Munk and Palmén (1951) identified the problematic aspect of assuming a bottom frictional stress balance for the Southern Ocean. In brief, the field measurements do not support a frictional balance, either from bottom drag or from internal turbulent viscous friction. By inference, they proposed that topographic form stress is the dominant term that balances wind stress in the Southern Ocean. They supported that inference through estimates based on topographic features encountered by the Antarctic Circumpolar Current in its transit of the Southern Ocean. Subsequent studies, using theory, field measurements, and numerical models, support their conclusion. Indeed, in numerical models one finds that so long as there is only a modest degree of bottom slope, the bottom topographic form stress dominates over bottom drag. Given these considerations, we dispense with bottom drag for the remainder of this section.

37.7.5 Correlation between surface height and topographic slope

Given the minor role for bottom drag in establishing a steady channel flow in the Southern Ocean, the balance (37.169) says that an eastward wind stress must be balanced, in the area integral over the channel, by a westward topographic form stress

$$\int \left[\oint \tau^x \, \mathrm{d}x \right] \mathrm{d}y = \int \left[\oint p_\mathrm{b} \, \partial_x \eta_\mathrm{b} \mathrm{d}x \right] \mathrm{d}y. \tag{37.173}$$

What is required to establish a westward topographic form stress? Quite simply, in the area mean, there must be an anomalously large bottom pressure in regions where $\partial_x \eta_\mathrm{b} > 0$ and an anomalously small bottom pressure in regions where $\partial_x \eta_\mathrm{b} < 0$. Bottom pressure in a shallow water layer is determined by the column thickness. Hence, to establish the anomalous bottom pressures requires an anomalously thick fluid column upstream of topographic bumps and thin fluid column downstream. This situation is illustrated in Figure 37.8 described in Section 37.7.7.

To further reveal the correlation between surface height and bottom topography, write $p_\mathrm{b} = \rho \, g \, h$ and use $\eta = h + \eta_\mathrm{b}$ so that

$$p_\mathrm{bot} \, \partial_x \eta_\mathrm{b} = \rho \, g \, (\eta - \eta_\mathrm{b}) \, \partial_x \eta_\mathrm{b} = \rho \, g \, \eta \, \partial_x \eta_\mathrm{b} - (g \, \rho / 2) \, \partial_x \eta_\mathrm{b}^2. \tag{37.174}$$

The balance (37.173) thus becomes

$$\langle \tau^x \rangle = \rho \, g \langle \eta \, \partial_x \eta_\mathrm{b} \rangle. \tag{37.175}$$

Furthermore, due to zonal periodicity, it is only the zonal anomalies in η and η_b that contribute so that

$$\langle \tau^x \rangle = \rho \, g \langle \eta' \, \partial_x \eta_\mathrm{b}' \rangle, \tag{37.176}$$

where

$$\eta = \eta' + L^{-1} \oint \eta \, \mathrm{d}x \qquad \text{and} \qquad \eta_\mathrm{b} = \eta_b' + L^{-1} \oint \eta_\mathrm{b} \, \mathrm{d}x, \tag{37.177}$$

with $L = \oint \mathrm{d}x$ the zonal length of the channel. With $\langle \tau^x \rangle > 0$, we see that surface height anomalies must be positively correlated with the bottom slope, $\int \eta' \, \partial_x \eta_\mathrm{b}' \, \mathrm{d}x \, \mathrm{d}y > 0$. That is, the surface height is high where topography slopes are positive and low where topography slopes are negative.

As noted above, we must have a positive correlation between surface height anomalies and topographic slope, as in equation (37.176). It follows that a nonzero zonal integrated topographic form stress requires a nonzero phase shift between surface height anomalies and the bottom topography anomalies. That is, if the surface height and bottom topography were perfectly

aligned along a latitude circle, then $\oint \eta' \, \partial_x \eta'_{\rm b} \, {\rm d}x = 0$, in which case there is a zero zonal integrated topographic form stress along that latitude. The required phase shift between the free surface and bottom topography has the free surface shifted ahead (i.e., to the west) of the topography. We consider an explicit example in Section 37.7.7 to help in our understanding.

37.7.6 Connection to meridional geostrophic transport

Zonal periodicity allows us to swap the zonal derivative in the balance (37.176) so that

$$\langle \tau^x \rangle = -\rho \, g \langle \partial_x \eta' \, \eta'_{\rm b} \rangle \tag{37.178}$$

For the large scale flows under consideration here, we can assume that $g \, \partial_x \eta'$ is associated with an anomalous meridional geostrophic velocity

$$g \, \partial_x \eta' = f \, v'_{\rm g} \tag{37.179}$$

so that the balance (37.178) is

$$\langle \tau^x \rangle = -\rho \, \langle f \, v'_{\rm g} \, \eta'_{\rm b} \rangle . \tag{37.180}$$

Hence, the steady balance is realized with anomalous meridional geostrophic transport correlated with topographic anomalies. Note that periodicity means that the steady meridional geostrophic transport has a zero zonal integral

$$\oint v'_{\rm g} \, {\rm d}x = (g/f) \oint \partial_x \eta' \, {\rm d}x = 0, \tag{37.181}$$

which follows from the steady volume balance discussed in Section 37.7.1.

37.7.7 Sinusoidal example

To help further our understanding of the balance (37.176), and the phase shift required to develop nonzero zonal integrated topographic form stress, consider a sinusoidal topography that is a function only of the zonal direction. Also assume that the free surface has a sinusoidal shape (though we do not specify the dynamical mechanism for it to reach this shape). With these assumptions the anomalous surface height and bottom topography can be written

$$\eta' = \eta_o \sin(\kappa \, x + \varphi) \qquad \text{and} \qquad \eta'_{\rm b} = D \sin(\kappa \, x) \tag{37.182}$$

where $\eta_o > 0$ is a constant amplitude for the free surface undulations, $D > 0$ is the constant amplitude for the bottom undulations, $\kappa = 2 \, \pi \, n / L$ is the wavenumber for the undulations, $n > 0$ is an integer, L is the size of the zonal channel, and φ is a phase shift between the topography and the free surface. The corresponding meridional geostrophic flow is given by

$$f \, v'_{\rm g} = g \, \partial_x \eta' = g \, \kappa \, \eta_o \cos(\kappa \, x + \varphi). \tag{37.183}$$

Plugging into the balance (37.176) leads to

$$\sin \varphi = \left[\frac{L \, \langle \tau^x \rangle}{D \, \rho \, g \, \eta_o \, \pi \, n} \right] . \tag{37.184}$$

For $\langle \tau^x \rangle > 0$ we see that the free surface undulations are, as expected, shifted to the west of the bottom topography undulations. As an explicit example from an idealized channel configuration,

set

$$L = 10^7 \text{ m} \qquad D = 10^3 \text{ m} \qquad \eta_o = 1 \text{ m} \qquad \tau^x = 1 \text{ N m}^{-2}, \tag{37.185}$$

in which case

$$\sin\varphi \approx (\pi\, n)^{-1}. \tag{37.186}$$

For $n = 1$, which corresponds to just one topographic bump, then we have a phase shift of $\varphi \approx 18°$, and this case is depicted in Figure 37.8 for the southern hemisphere. If there are two bumps, then the phase shift is reduced to $\varphi \approx 9°$ since each bump shares half the burden of balancing the wind stress.

FIGURE 37.8: Zonal-depth view of the wind stress and bottom pressure acting on a steady state layer of shallow water fluid flowing over a sinusoidal bump (north is directed into the page and east is to the right). The eastward surface stress acts in the $+\hat{\boldsymbol{x}}$ direction and it is balanced by a westward topographic form stress. To establish this form stress when integrated over the zonal extent of the channel requires the sea surface undulations to be phase shifted to the west of the bottom topography undulations, with the phase shift, φ, given by equation (37.184). To better visualize the sea surface, the surface undulations are in units of cm whereas the bottom topography undulations are in units of m. In general, for the topographic form stresss to balance the wind stress, the bottom pressure must be anomalously large where $\partial\eta_b/\partial x > 0$ and small where $\partial\eta_b/\partial x < 0$, thus leading to the anomalously thick fluid column upstream of the bump and thin column downstream. This correlation also leads to a corresponding meridional geostrophic flow as shown here by the green curve for the southern hemisphere where $f < 0$, with $v_g > 0$ (northward) when shown above the horizontal line and $v_g < 0$ (southward) when below the line. Compare this figure to the analogous schematic in Figure 29.8.

Summarizing the dependencies

We here highlight the various dependencies in the phase equation (37.184).

- The phase shift increases with both larger wind stress and larger zonal extent to the domain. This dependency arises since with enhanced wind stress and an enhanced zonal *fetch* (distance over which the winds blow), there is an increase in zonal momentum inserted

to the ocean that must be absorbed by the bottom. The larger phase shift increases this topographic form stress, thus enabling the balance.

- Conversely, the phase shift decreases for larger topography D, and larger undulations in the free surface, η_o, in which case the free surface becomes more aligned with the topographic ridges. This result follows since the topographic form stress is larger for larger topography, thus requiring less phase shift in the surface wave patterns to affect a bottom pressure anomaly.

- Phase shifts decrease when there are more topographic bumps in the channel, with n the parameter setting the number of bumps. For the Southern Ocean, *Munk and Palmén* (1951) identified around four or five large-scale topographic features that provide the dominant balance for the zonal wind stress.

- What if the parameters are such that the right hand side of equation (37.184) has a magnitude larger than unity (e.g., huge winds, very long fetch, small topography, small surface height amplitude)? This situation signals that topographic form stress is insufficient to balance the winds. In a numerical model, one can merely increase the topograhic wavenumber, n, to increase the topographic form stress. Yet where topography is fixed, such as in Nature, then bottom frictional stresses come into play to help reach a force balance (see Section 37.7.4).

Distinguishing steady motion from zero motion

Why is the phase shift (37.184) independent of the fluid depth? One might suspect that to reach a force balance would require more form stress if there is more fluid. Instead, the force balance, as reflected in the phase shift, depends on the zonal anomalies of the surface height and bottom topography. The depth of the fluid is absent.

The answer to this question is that we are seeking a force balance. When forces are balanced there is no acceleration and thus, as per Newton's second law, the fluid maintains a constant velocity relative to the laboratory reference frame. If we instead wished to stop the fluid, then we would need to decelerate all fluid elements to zero velocity. Determining the forces needed to stop the fluid requires the total fluid mass and thus its depth (as well as the time over which the fluid is to stop). If the fluid is in motion, then halting the motion requires a net force, and that is a very different consideration than the case of zero net force. So in brief, a steady state refers to the absence of time dependence in the fluid from the perspective of an Eulerian (laboratory) observer, with a steady state *not* necessarily a static state.

37.7.8 Comments and further study

Gyres and channels

The dominance of topographic form stress for the steady Southern Ocean balance contrasts to many of the frictional theories for gyre circulations, such as the classic solutions discussed in Section 40.7. In those theories, based on flat bottom and vertical side configurations, the curl of the wind stress is balanced by torques created by friction.[9] One is thus led to conclude that zonally re-entrant channels exhibit a fundamentally distinct steady force balance from gyres. However, as discussed in Section 29.5.11, *Hughes and de Cueves* (2001) showed how topographic form stresses associated with sloping sides can lead to an inviscid balance for gyres. That is, friction is not needed so long as the bottom can support topographic torques. In this manner,

[9] We will encounter such balances in Chapter 40 when studying vorticity.

gyres and channels share much in common so long as they both contain topography and sloping sides.

The case with vertical stratification

The analysis of a single shallow water layer has direct relevance to flow in a stratified fluid. The reason is that when integrating over the full depth of the fluid, internal interfacial form stresses cancel pairwise.[10] The resulting net balance for contact forces is concerned with just those acting on the boundaries at the surface and the bottom. This property of contact forces was also implicit in in Section 29.5 where we developed the angular momentum budget for a continously stratified fluid. In that discussion we encountered the correlation between bottom pressure and bottom topography slope for steady flow in a channel as realized by a balance between wind stress and bottom form stress (see Figure 29.8). This correlation also holds for the single shallow water layer.

Although the single layer provides a direct connection to the depth integrated momentum in a continuously stratified fluid, the direct connection between undulations in the sea surface height and bottom pressure is more nuanced when allowing for stratification. We here outline some of the considerations that arise with flow in a stratified channel with a topographic bump. Our presentation is rather incomplete, with a more thorough analysis supported by numerical simulations.

Following the analysis of Section 28.2, we decompose the horizontal gradient of bottom pressure according to equation (28.48)

$$\nabla_z p_{\mathrm{b}} = \underbrace{\nabla_z p_{\mathrm{a}} + g\,\rho(\eta)\,\nabla_z \eta}_{\text{external contribution}} \; - \; \underbrace{\rho_0 \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z b \,\mathrm{d}z'}_{\text{internal contribution}} \equiv \nabla_z p_{\mathrm{bext}} + \nabla_z p_{\mathrm{bint}}, \tag{37.187}$$

where $b = -g\,(\rho - \rho_0)/\rho_0$ is the Archimedean buoyancy from Chapter 31. The external pressure gradient is all that is available for a single shallow water layer, so that there is a direct correlation between bottom topography and surface pressure in the steady channel flow where bottom form stress balances wind stress. In contrast, for a continously stratified fluid, or for a stacked shallow water fluid, the internal contribution to the pressure gradient is nonzero since buoyancy generally has a horizontal gradient.

As discussed in Section 16.4 of *Olbers et al.* (2012), watermasses in the Southern Ocean generally align themselves with lighter water on the upstream side of topographic features (to the west), and heavy water on the downstream side. This configuration means that the internal pressure is lower upstream of a topographic bump and higher downstream, thus leading to a westward internal pressure gradient force. To realize a steady flow with a balance between bottom pressure form stress and wind stress requires the external contribution to the bottom pressure gradient to counteract the internal contribution. Hence, the free surface height must have larger undulations in the presence of vertical stratification than without, with high values upstream of the bump and low values downstream. We depict this configuration in Figure 37.9, with the caption offering further details. *Zhang et al.* (2024) further detail the facets of the dynamical balances, including transient adjustments towards the steady balances discussed here. They offer a particularly clear distinction between the barotropic dynamics (as realized by a single shallow water layer) and baroclinic dynamics. Furthermore, they emphasize the central role of the barotropic dynamics for maintaining the momentum balance even for stratified fluid.

[10] We discussed this property of interfacial form stresses in Sections 26.2, 29.3, and 37.4.

FIGURE 37.9: A schematic of steady flow in a two-layer zonally periodic channel with a topographic bump and with bottom pressure form stress balancing zonal wind stress. To realize this balance requires anomalously high bottom pressure on the upstream side of the bump and anomalously low bottom pressure on the downstream side, where anomalies are relative to the zonal mean. Such anomalous bottom pressure is just as for a single shallow water layer. However, for a stratified fluid the bottom pressure is established by the sum of effects from the external and internal pressure fields. The internal pressure field arises from density, here shown with anomalously light water on the upstream side of the bump and heavy water downstream, such as occurs in the Southern Ocean. This density field leads to a westward contribution to the bottom pressure gradient force; i.e., anomalously low bottom pressure on the upstream side of the bump and high bottom pressure on the downstream. The external pressure field arises from the free surface undulations (red line), with a high upstream of the bump and low downstream. This free surface field leads to an eastward contribution to the bottom pressure gradient force; i.e., anomalously high bottom pressure on the upstream side of the bump and low bottom pressure on the downstream. For the bottom pressure form stress to balance the wind stress, we must have the external pressure gradient dominate the internal pressure gradient. Note that undulations of the free surface height are roughly 100-300 times smaller than those of the density field, with the relative undulations set according to the reduced gravity as described in Section 36.3.

Meridional overturning circulation

The balances in this section are modified when allowing for the vertical transfer of volume between the layers as required to admit a meridional-depth overturning circulation. In this case, there can be net meridional motion along a latitude circle to thus add the Coriolis force to the steady force balance, including an Ekman transport (balance between Coriolis and surface stress as in Section 34.1) for the layer feeling the zonal surface stress. Section 21.7 of *Vallis* (2017) as well as Chapter 16 of *Olbers et al.* (2012) provide pedagogical discussions of flow in the Antarctic Circumpolar Current, in which interfacial pressure form stress developed from baroclinic eddies provides a mechanism for vertically redistributing horizontal momentum. The studies from *Webb and de Cueves* (2007) and *Zhang et al.* (2024) detail how the barotropic dynamics, which act over days and weeks, continue to play the dominant role in balancing the surface wind stress and topographic form stress, even in the case of a stratified ocean with eddy form stresses, which have a time scale of years.

37.8 Angular momentum in a rotating tank

As our second case study for this chapter, we study angular momentum for a layer of shallow water fluid in a rotating cylindrical tank. This system was first discussed in Section 28.4, where

we developed the horizontal equation of motion

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\left(p/\rho + g_{\mathrm{e}}\,z - \Omega^2\,r^2/2\right), \tag{37.188}$$

where $r^2 = x^2 + y^2$ is the radial distance from the rotational axis,

$$\Omega = f/2 \tag{37.189}$$

is the constant angular rotation rate, and the vertical component to the right hand side is the hydrostatic balance, $\partial p/\partial z = -\rho\,g_{\mathrm{e}}$. Where convenient, we make use of the polar coordinates (see Chapter 10.3) in the following, whereby

$$x = r\,\cos\vartheta \tag{37.190a}$$

$$y = r\,\sin\vartheta, \tag{37.190b}$$

with the polar angle ϑ measured counter-clockwise from the positive x-axis.

37.8.1 Angular momentum for a column of shallow water fluid

The angular momentum for a column of shallow water fluid, computed with respect to the vertical rotational axis, is given by (see Sections 14.6 and 25.7)

$$L^z = \delta M\,[\boldsymbol{x} \times (\boldsymbol{u} + \boldsymbol{U}_{\mathrm{rigid}})] \cdot \hat{\boldsymbol{z}}, \tag{37.191}$$

where $\boldsymbol{x} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}} = r\,\hat{\boldsymbol{r}}$ is the position vector relative to the rotational axis, $\delta M = \rho\,h\,\delta A$ is the constant mass for the fluid column, and the rigid-body rotation velocity is

$$\boldsymbol{U}_{\mathrm{rigid}} = (f/2)\,\hat{\boldsymbol{z}} \times \boldsymbol{x} = r\,\Omega\,\hat{\boldsymbol{\vartheta}}, \tag{37.192}$$

where $\hat{\boldsymbol{z}} \times \hat{\boldsymbol{r}} = \hat{\boldsymbol{\vartheta}}$ is the azimuthal unit vector pointing counter-clockwise around the origin.

We can further massage the expression for the angular momentum by writing

$$\boldsymbol{x} \times \boldsymbol{u} = (x\,v - y\,u)\,\hat{\boldsymbol{z}} = r^2\dot{\vartheta}\,\hat{\boldsymbol{z}}, \tag{37.193}$$

where $\dot{\vartheta} = \mathrm{D}\vartheta/\mathrm{D}t$ is the angular velocity. Likewise, we have

$$\boldsymbol{x} \times \boldsymbol{U}_{\mathrm{rigid}} = r^2\,\Omega\,\hat{\boldsymbol{z}}, \tag{37.194}$$

so that the angular momentum can be written

$$L^z = \delta M\,[\boldsymbol{x} \times (\boldsymbol{u} + \boldsymbol{U}_{\mathrm{rigid}})] \cdot \hat{\boldsymbol{z}} = \delta M\,r^2\,(\dot{\vartheta} + \Omega). \tag{37.195}$$

37.8.2 Material time evolution of the angular momentum

The material time evolution for the angular momentum is given by

$$\frac{\mathrm{D}L^z}{\mathrm{D}t} = \delta M\,[\boldsymbol{u} \times (\boldsymbol{u} + \boldsymbol{U}_{\mathrm{rigid}})] \cdot \hat{\boldsymbol{z}} + \delta M\left[\boldsymbol{x} \times \left(\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + \frac{\mathrm{D}\boldsymbol{U}_{\mathrm{rigid}}}{\mathrm{D}t}\right)\right] \cdot \hat{\boldsymbol{z}}. \tag{37.196}$$

Note that we set

$$\frac{\mathrm{D}(\delta M)}{\mathrm{D}t} = \rho\,\mathrm{D}(\mathrm{h}\,\delta\mathrm{A})\mathrm{D}t = 0 \tag{37.197}$$

since the shallow water fluid columns each have constant volume as they move with the horizontal flow (Section 36.2.5). Using the rigid-body rotation velocity given by equation (37.192), and with a constant rotation rate, yields

$$\boldsymbol{u} \times \boldsymbol{U}_{\text{rigid}} + \boldsymbol{x} \times \frac{\mathrm{D}\boldsymbol{U}_{\text{rigid}}}{\mathrm{D}t} = \boldsymbol{u} \times (\boldsymbol{\Omega} \times \boldsymbol{x}) + \boldsymbol{x} \times (\boldsymbol{\Omega} \times \boldsymbol{u}) \tag{37.198a}$$

$$= (\boldsymbol{x} \cdot \boldsymbol{u})\, f\, \hat{\boldsymbol{z}}. \tag{37.198b}$$

Making use of the material evolution of the horizontal velocity given by equation (37.188) renders

$$\left[\boldsymbol{x} \times \frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t}\right] \cdot \hat{\boldsymbol{z}} = \left(\boldsymbol{x} \times \left[-f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} - \nabla\left(p/\rho + g_{\mathrm{e}}\, z - \Omega^2\, r^2/2\right)\right]\right) \cdot \hat{\boldsymbol{z}} \tag{37.199a}$$

$$= -f\, (\boldsymbol{x} \cdot \boldsymbol{u}) - (\boldsymbol{x} \times g\, \nabla\eta) \cdot \hat{\boldsymbol{z}}. \tag{37.199b}$$

The centrifugal term dropped out since

$$\boldsymbol{x} \times \nabla r^2 = 2\, \boldsymbol{x} \times r\, \hat{\boldsymbol{r}} = 2\, \boldsymbol{x} \times \boldsymbol{x} = 0. \tag{37.200}$$

The gravitational term dropped out since

$$(\boldsymbol{x} \times \nabla z) \cdot \hat{\boldsymbol{z}} = (\boldsymbol{x} \times \hat{\boldsymbol{z}}) \cdot \hat{\boldsymbol{z}} = 0, \tag{37.201}$$

as does the vertical component to the pressure gradient. We are thus left with

$$\frac{1}{\delta M}\, \frac{\mathrm{D}L^z}{\mathrm{D}t} = -g\, (\boldsymbol{x} \times \nabla\eta) \cdot \hat{\boldsymbol{z}}. \tag{37.202}$$

Consequently, the axial angular momentum for a fluid column is modified by the torque from the horizontal pressure gradient caused by undulations in the free surface height. Note how there is no contribution from the Coriolis acceleration, so that the evolution of angular momentum is the same whether viewed in the laboratory frame or rotating frame.

We can bring the expression (37.202) into a more transparent form by switching to polar coordinates

$$\boldsymbol{x} \times \nabla\eta = r\, \hat{\boldsymbol{r}} \times \left[\hat{\boldsymbol{r}}\, \frac{\partial\eta}{\partial r} + \hat{\boldsymbol{\vartheta}}\, \frac{1}{r}\, \frac{\partial\eta}{\partial\vartheta}\right] = \frac{\partial\eta}{\partial\vartheta}\, \hat{\boldsymbol{z}}, \tag{37.203}$$

so that

$$\frac{1}{\delta M}\, \frac{\mathrm{D}L^z}{\mathrm{D}t} = -g\, \frac{\partial\eta}{\partial\vartheta}. \tag{37.204}$$

This result is directly analogous to the angular momentum evolution for a fluid moving around a sphere as derived in Section 25.7. Namely, in the presence of angular pressure gradients, the fluid experiences a torque that in turn leads to a change in the angular momentum relative to the vertical rotation axis.

37.8.3 Materially invariant angular momentum

The angular momentum for a fluid column is materially invariant (i.e., a constant on a material fluid parcel) if

$$\frac{\mathrm{D}L^z}{\mathrm{D}t} = 0 \Longleftrightarrow \frac{\partial\eta}{\partial\vartheta} = 0. \tag{37.205}$$

For a flat bottom, equation (28.95) says that the free surface takes on a radial parabolic shape when the fluid is in rigid-body rotation. In this case, $\nabla\eta$ is in the radial direction, in which case

$\boldsymbol{x} \times \nabla\eta = 0$. Consequently, when the fluid is in rigid-body rotation, the angular momentum for each fluid column remains materially constant.

37.8.4 Comments

The material evolution equation (37.202) also holds for a fluid on the f-plane tangent to a sphere. The f-plane formulation is slightly simpler than the tank since the centrifugal term is absorbed into the geopotential (see Section 13.10.4). However, the tank is arguably more pedagogical as it is simpler to visualize and to conduct laboratory experiments. See Section 6.6.4 of *Marshall and Plumb* (2008) for more discussion of rotating tank experiments. Also, we return to this physical system in Section 55.3 when studying centrifugal instability of cyclostrophically balanced flow.

37.9 Exercises

EXERCISE 37.1: POTENTIAL TEMPERATURE SLOPES IN ATMOSPHERE AND OCEAN
Use the two-layer thermal wind relations from Section 37.2.2, also known as Margules' relation, to estimate the slope of the potential temperature surfaces in the atmosphere and ocean. This question is based on exercise 3.2 of *Vallis* (2006).

(a) Model the atmosphere as two immiscible shallow water layers of different density stacked one above the other. Using reasonable values for any required physical parameters, estimate the vertical displacement of the interfacial surface associated with a pole-to-equator temperature difference of 40K. You may wish to consult *Wallace and Hobbs* (2006) or *Marshall and Plumb* (2008) for physical scales.

(b) Estimate a vertical interfacial displacement in the ocean thermocline associated with a temperature difference of 20K over a horizontal distance of 4000 km. The interface between the two shallow water layers offers a crude representation of the main oceanic thermocline. Ignore salinity effects so that temperature and density are directly proportional.

Double-check your results by examining some atmosphere and ocean latitude-height profiles for potential temperature (e.g., Figure 5.8 of *Marshall and Plumb* (2008)).

EXERCISE 37.2: CIRCULAR STEADY GEOSTROPHIC FLOW
Consider a single layer of shallow water fluid in steady geostrophic balance on a f-plane so that

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -g\,\nabla\eta. \tag{37.206}$$

Assume $f > 0$ and that the free surface has a circular Gaussian shape

$$\eta = \eta_0\, e^{-r^2/(2\,\sigma^2)} \tag{37.207}$$

where $r^2 = x^2 + y^2$ is the squared radial position and σ is the standard deviation of the Gaussian.

(a) Determine the horizontal geostrophic velocity components corresponding to this free surface undulation. Write the solution in both Cartesian coordinates and polar coordinates. Is the flow oriented cyclonic or anti-cyclonic?

(b) Determine the streamlines for the flow. Hint: recall the discussion in Section 18.11.2. What is the geometric shape of a streamline?

EXERCISE 37.3: STEADY STATE MOMENTUM AND GEOSTROPHY
Consider a single layer of shallow water fluid with zero boundary mass fluxes through the surface. Assume the lateral boundaries are solid. All boundaries are thus material. The domain integrated horizontal momentum (within the rotating reference frame) is defined by

$$\boldsymbol{P} = \int \rho\, \boldsymbol{u}\, \mathrm{d}V = \int \rho\, h\, \boldsymbol{u}\, \mathrm{d}\mathcal{S}. \tag{37.208}$$

Show that for tangent plane motion (Section 25.5)

$$\frac{\mathrm{d}\boldsymbol{P}}{\mathrm{d}t} = 0 \tag{37.209}$$

can be realized either by (A) zero flow everywhere, (B) flow that is in geostrophic balance at each point, or (C) flow that is in geostrophic balance as a global integral.

EXERCISE 37.4: THICKNESS WEIGHTED MOMENTUM FOR TWO LAYERS
Following the methods from Section 37.3, derive the thickness weighted momentum equation for an inviscid two-layer stacked shallow water fluid. That is, derive the evolution equation for $h_1\, \boldsymbol{u}_1 + h_2\, \boldsymbol{u}_2$, thus providing the two-layer version of equation (37.21).

EXERCISE 37.5: CONTACT PRESSURE FORCE ON A SINGLE LAYER
As a check on our calculation of the contact pressure force (37.60b), consider a single shallow water layer under a massless atmosphere. Show that the contact pressure force per mass is given by

$$\frac{\boldsymbol{F}^{\text{press}}_{\text{net}}}{M} = g\, \hat{\boldsymbol{z}} - g \nabla \eta. \tag{37.210}$$

As expected, the horizontal component of this force equals to the pressure gradient body force per mass detailed in Section 36.2.1. The vertical pressure force balances the weight of the fluid as per the hydrostatic balance.

EXERCISE 37.6: TOPOGRAPHIC FORM STRESS FOR A RIDGE
As in Section 37.7, apply a constant eastward zonal wind to a zonally reentrant channel with a single shallow water layer. Let the layer flow over a topographic ridge of height H above the surrounding flat bottom, and let the ridge be a function just of zonal position, $\eta'_{\text{b}}(x)$. Furthermore, assume the ridge has a constant slope on both the upstream (west) side, S_{up}, and downstream (east) side, S_{dn}. An example is depicted in Figure 37.10. Following the force balance (37.176), derive an expression for the free surface height zonally averaged over the upstream side of the ridge, minus the free surface height zonally averaged over the downstream sides of the ridge,

$$\Delta\eta' = (\overline{\eta'})_{\text{up}} - (\overline{\eta'})_{\text{dn}}, \tag{37.211}$$

where

$$(\overline{\eta'})_{\text{up}} = \frac{\int_{x_{\text{up}}}^{x_0} \eta'\, \mathrm{d}x}{L_{\text{up}}} \qquad \text{and} \qquad (\overline{\eta'})_{\text{dn}} = \frac{\int_{x_0}^{x_{\text{dn}}} \eta'\, \mathrm{d}x}{L_{\text{dn}}}. \tag{37.212}$$

Show that the expression for $\Delta\eta'$ is independent of the two slopes. Instead, the only geometric property that determines $\Delta\eta'$ is the ridge height, H. Discuss this result.

EXERCISE 37.7: GEOSTROPHIC TRANSPORT
Consider a zonal-vertical section of shallow water flow in the middle latitude northern hemisphere. Let the section be 1000 m deep and away from side and bottom boundaries. Assume the sea level is 1 cm higher at the eastern end of the section than the western end. Estimate the mass transport (kg/sec) of constant density seawater going through the section. What direction is the transport?

FIGURE 37.10: Zonal-vertical view of a single layer of shallow water fluid moving in a zonally re-enetrant channel for use in Exercise 37.6. The domain has a topographic ridge that is a function just of the zonal direction and has constant slopes on its western and eastern sides. There is a constant eastward zonal wind stress.

Hint: Assume geostrophic balance; choose a representative constant seawater density; and note that the zonal width of the section cancels out so it is not needed.

EXERCISE 37.8: APE FOR TWO SHALLOW WATER LAYERS
Compute the APE for two shallow water layers using the notation from Figure 36.6 with nontrivial bottom topography, $z = \eta_{\rm b}(x, y)$. Show that the APE is non-negative. Assume the domain is simply connected. Hint: The answer is given by specializing the arbitrary N results in equation (37.139) to the special case of the $N = 2$. However, for this exercise you should not merely quote that result. Instead, show all steps starting from the potential energy for an $N = 2$ layer model.

EXERCISE 37.9: RATIO OF KE TO APE FOR SINGLE LAYER f-PLANE GEOSTROPHY
Consider a single layer of shallow water fluid in geostrophic balance on an f-plane with a flat bottom. Show that the ratio of kinetic energy to available potential energy scales like

$$\frac{E_{\rm KE}}{E_{\rm APE}} \sim \left[\frac{L_{\rm d}^{\rm ext}}{L}\right]^2 . \tag{37.213}$$

In this equation, L is the horizontal length scale for the fluctuation of the free surface η (i.e., $\nabla\eta \sim \eta'/L$), and

$$L_{\rm d}^{\rm ext} = \frac{\sqrt{g\,H}}{f} \tag{37.214}$$

is the external deformation radius. The scaling (37.213) means that for scales larger than the external deformation radius, $L_{\rm d}$, the available potential energy is larger than the kinetic energy. The converse holds for scales smaller than $L_{\rm d}$.

EXERCISE 37.10: RATIO OF KE TO APE FOR 1.5 LAYER f-PLANE GEOSTROPHY
Consider a reduced gravity system (Section 36.3) in geostrophic balance on an f-plane. Show that the ratio of kinetic energy to available potential energy scales like

$$\frac{E_{\rm KE}}{E_{\rm APE}} \sim \left[\frac{L_{\rm d}^{\rm int}}{L}\right]^2 . \tag{37.215}$$

In this equation, L is the horizontal length scale for the fluctuation of the internal interface $\eta_{3/2}$

(i.e., $\nabla\eta_{3/2} \sim \eta'_{3/2}/L$), and

$$L_{\mathrm{d}}^{\mathrm{int}} = \frac{\sqrt{g^{\mathrm{r}}_{3/2}\,\overline{h}}}{f} \tag{37.216}$$

is the internal deformation radius with $g^{\mathrm{r}}_{3/2} = g\,(\rho_2 - \rho_1)/\rho_{\mathrm{ref}}$ the reduced gravity and $h = A^{-1}\int(\eta_{1/2} - \eta_{3/2})\,\mathrm{d}\mathcal{S}$ the area averaged layer thickness (see Figure 36.4). The scaling (37.215) means that for scales larger than the internal deformation radius, $L_{\mathrm{d}}^{\mathrm{int}}$, the available potential energy is larger than the kinetic energy, and conversely for scales smaller than $L_{\mathrm{d}}^{\mathrm{int}}$.

To solve this exercise you must make use of the following.

- Derive the APE for two layers with a flat bottom.
- Assume the contribution to the APE from free surface undulations, is much smaller than from the interior interface. So that the APE is roughly due just to undulations of the interior interface. This assumption follows from Figure 36.5.
- The scaling (37.215) is identical to that found for the quasi-geostrophic system in Section 46.8.4. However, to solve this exercise it is <u>not</u> sufficient to merely reproduce the scaling discussed in Section 46.8.4. Instead, use here the expressions for APE and KE appropriate for the shallow water system.

EXERCISE 37.11: NON-DIMENSIONALIZED LINEAR SHALLOW WATER EQUATIONS

For the linear equations (53.137a)-(53.137b), introduce

$$\boldsymbol{x} = L\,\hat{\boldsymbol{x}}, \quad \boldsymbol{u}' = U\,\hat{\boldsymbol{u}}, \quad t = \frac{L\,\hat{t}}{U}, \quad f = \hat{f}\,T^{-1}, \quad \eta' = H\,\hat{\eta}, \tag{37.217}$$

where L is a horizontal length scale, $T = L/U$ is an advective time scale, U is a velocity scale, and $H \ll L$ is the resting layer thickness. All variables with hats are non-dimensional and not to be confused with unit vectors. Substitute into equations (53.137a)-(53.137b) and identify the non-dimensional ratio of the advective velocity scale to the non-rotating gravity wave speed

$$\mathrm{Fr} \equiv \frac{U}{\sqrt{g\,H}}. \tag{37.218}$$

This non-dimensional number is known as the *Froude number*. When the Froude number is larger than unity, the fluid can experience an instability known as an *hydraulic jump*, with some elements of jumps discussed in Exercise 36.4.

Part VII

Vorticity and potential vorticity

Vorticity locally measures the spin of a fluid element. For geophysical flows, external forces, ultimately due to differential heating over the planet, resupply vorticity in the face of dissipation. The addition of planetary vorticity, arising from motion on a rotating spherical planet, also renders a nonzero vorticity to geophysical fluids even when the fluid is at rest in the rotating earth reference frame. Vorticity thus plays a central role in characterizing geophysical fluid motions, even for relatively sluggish and laminar flow, since motion on a rotating planet always involves vorticity.

Besides offering a key method for flow characterization, vorticity evolution and its steady balances provide the means to mechanically understand how flows respond under changes to forces. Surprisingly, it does so even without needing to directly compute forces acting on the fluid. We thus encounter examples where vorticity mechanics offers a more direct and focused explanation for flow behavior than momentum or energy mechanics. This practical feature of vorticity mechanics represents the central reason it is so essential to the theoretical machinery of geophysical fluid mechanics.

Potential vorticity is a strategically chosen component of vorticity whose evolution is simpler than the full vorticity vector, thus helping to identify key facets of geophysical flows, their forcing, and constraints. Indeed, under certain assumptions of balance (considered in Part VIII), knowledge of potential vorticity offers the means to deduce all prognostic information about the flow. For these and other reasons explored in this part of the book, potential vorticity has found great use for understanding and predicting geophysical fluid flows. Indeed, the central importance of potential vorticity for the study of atmospheric and oceanic flows helps to distinguish geophysical fluid mechanics from other areas of fluid mechanics.

OUTLINE FOR THIS PART OF THE BOOK

We start this part of the book by introducing vorticity and circulation in Chapter 38, making use of Stokes' Theorem to show that the area integral of vorticity over a finite region yields the circulation around the region's boundary. In Chapter 39 we study vorticity in a horizontal flow that is non-divergent, thus leading to the study of non-divergent barotropic flow. This flow is fully described by the vorticity field, and it offers many insights into large-scale vortical flows in the atmosphere and ocean. Chapter 40 then introduces the mechanics of vorticity and potential vorticity within a shallow water fluid. It was for the shallow water system that *Rossby* (1940) revealed the power of potential vorticity conservation for understanding geophysical fluid flow patterns.

In Chapter 41 we fully dive into the fundamentals of vorticity and circulation. It is here that we encounter Kelvin's circulation theorem, which identifies the materially conserved nature of circulation around an arbitrary simply closed loop in a perfect barotropic flow. In Chapter 42 we explore the foundations of potential vorticity and then in Chapter 43 develop differential and integral potential vorticity budget equations. Our study of potential vorticity budgets exposes the remarkable impermeability property of the potential vorticity flux vector.

Chapter 38

Vorticity and circulation

Vorticity measures the angular motion contained in a fluid flow at each point within the fluid; i.e., it is a measure of spin. Vorticity generalizes to continuum mechanics the notion of angular momentum that central to the study of rigid body mechanics. We here relate the two, showing that flows with a nonzero strain lead to distinctions between vorticity and angular momentum. Circulation measures the fluid flow comptuted over a closed line integral (circuit) within the fluid. Helmholtz was an early proponent of vorticity whereas Kelvin introduced circulation to help understand vorticity. These two flow properties are connected through Stokes' theorem, with the study of vortex lines and vortex tubes clearly exposing the connections.

CHAPTER GUIDE

In this chapter, we introduce kinematic properties of vorticity and circulation. We make use of vector calculus using Cartesian coordinates as detailed in Chapter 2. The concepts and methods introduced in this chapter are fundamental to the remaining chapters in this part of the book.

38.1 Loose ends

- Redo Section 38.9 using the motion field from Chapter 18.

38.2 Vorticity

Vorticity is the curl of the velocity field

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v}. \tag{38.1}$$

Vorticity measures the rotation or spin of fluid flow at each point and, unlike angular momentum, it does so without reference to an origin. In this manner, vorticity is an intrinsic property of the flow. In addition to writing vorticity as the curl of the velocity, we may choose to use the equivalent expression

$$\boldsymbol{\omega} = [\nabla \cdot (\boldsymbol{v} \times \hat{\boldsymbol{x}})]\,\hat{\boldsymbol{x}} + [\nabla \cdot (\boldsymbol{v} \times \hat{\boldsymbol{y}})]\,\hat{\boldsymbol{y}} + [\nabla \cdot (\boldsymbol{v} \times \hat{\boldsymbol{z}})]\,\hat{\boldsymbol{z}}. \tag{38.2}$$

That is, a vorticity component in a particular coordinate direction is the divergence of the velocity field after being rotated by $-\pi/2$ around the coordinate axis direction. For example, the vector $\boldsymbol{v} \times \hat{\boldsymbol{z}}$ is the result of rotating the velocity by $-\pi/2$ radians around the $\hat{\boldsymbol{z}}$ axis, with the identity

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) = \nabla \cdot (\boldsymbol{v} \times \hat{\boldsymbol{z}}) = \partial_x v - \partial_y u \tag{38.3}$$

leading to the vertical component of the vorticity in equation (38.2).

Being the curl of a vector, the vorticity transforms as a vector under coordinate rotations. However, vorticity changes sign under mirror symmetry, thus making it a pseudo-vector (Section 1.4.2). A simple means to understand this property is to note that the spinning earth rotates counter-clockwise when viewed from above the north pole and clockwise when viewed from below the south pole (see Figure 10.1).

Figure 38.1 provides an example zonal flow with a meridional strain (shear). The vertical component to the vorticity is negative for this flow, as per the right hand rule

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) = \partial_x v - \partial_y u < 0. \tag{38.4}$$

Furthermore, an imaginary test "paddle wheel" placed anywhere within this flow spins clockwise about its axis. The nonzero spin of a test paddle wheel is a fundamental property of fluid flow

with nonzero vorticity.

FIGURE 38.1: An example zonal flow with a meridional shear, $\boldsymbol{v} = u(y)\,\hat{\boldsymbol{x}}$, and a corresponding vertical vorticity component that is negative: $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) = \partial v/\partial x - \partial u/\partial y = -\partial u/\partial y < 0$. The clockwise arrow surrounds a test "paddle wheel" that exhibits a clockwise spin about its axis when placed in this flow. Such test paddle wheels only spin when there is nonzero vorticity. The right hand rule determines the sign of the vorticity, which for this example is into the page (negative $\hat{\boldsymbol{z}}$).

38.2.1 Rotation of line elements

In Section 19.3 we considered the kinematics of a material line element, $\delta\boldsymbol{x}$, whose evolution is given by equation (19.38)

$$\frac{\mathrm{D}(\delta x_m)}{\mathrm{D}t} = \delta x_n \frac{\partial v_m}{\partial x_n} \Longrightarrow \frac{\mathrm{D}(\delta\boldsymbol{x})}{\mathrm{D}t} = (\delta\boldsymbol{x} \cdot \nabla)\,\boldsymbol{v}. \tag{38.5}$$

This equation says that the material line element evolves according to the velocity gradient tensor $\partial_n v_m$. The symmetric portion of this tensor is the strain rate tensor,

$$\mathbb{S}_{mn} = (\partial_n v_m + \partial_m v_n)/2, \tag{38.6}$$

whose action generates changes in the distance between the fluid particles (Section 19.4.4). The anti-symmetric portion to the velocity gradient tensor is known as the rotation tensor,

$$\mathbb{R}_{mn} = (\partial_n v_m - \partial_m v_n)/2. \tag{38.7}$$

The rotation tensor is related to vorticity via equation (19.55)

$$\mathbb{R}_{mn} = -\epsilon_{mnp}\,\omega_p/2 \Longleftrightarrow \mathbb{R} = \frac{1}{2}\begin{bmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{bmatrix}, \tag{38.8}$$

so that

$$2\,\mathbb{R}_{mn}\,\delta x_n = -\epsilon_{mnp}\,\omega_p\,\delta x_n \Longrightarrow 2\,\mathbb{R} \cdot \delta\boldsymbol{x} = \boldsymbol{\omega} \times \delta\boldsymbol{x}. \tag{38.9}$$

From our discussion of rotation in Section 11.2.3, this equation means that vorticity in a fluid generates a rigid rotation of a material line element around the instantaneous axis defined by the vorticity (Section 19.4.5). This result accords with Figure 38.1, whereby vorticity leads to the spin of a test paddle wheel; i.e., the rotation of line elements.

38.2.2 Rotating reference frame

For another means to understand the kinematics of vorticity, view the flow field from a reference frame that rotates with a constant angular velocity, $\boldsymbol{\Gamma}$, analogous to the case of observing geophysical flows from the non-inertial terrestrial reference frame. Following equation (13.42e), we

know that the velocity observed in the non-rotating or absolute reference frame, $\boldsymbol{v}_{\mathrm{a}}$, is related to the rotating reference frame velocity, $\boldsymbol{v}$, via

$$\boldsymbol{v}_a = \boldsymbol{v} + \boldsymbol{\Gamma} \times \boldsymbol{x}. \tag{38.10}$$

The vorticity measured in the absolute reference frame, $\boldsymbol{\omega}_{\mathrm{a}}$, is related to the relative vorticity measured in the rotating reference frame, $\boldsymbol{\omega}$, via

$$\boldsymbol{\omega}_{\mathrm{a}} = \nabla \times \boldsymbol{v}_{\mathrm{a}} = \nabla \times \boldsymbol{v} + \nabla \times (\boldsymbol{\Gamma} \times \boldsymbol{x}) = \boldsymbol{\omega} + 2\,\boldsymbol{\Gamma}. \tag{38.11}$$

If there is a point in the fluid whereby the rotating reference frame's angular velocity equals to one-half the absolute vorticity at that point, $\boldsymbol{\Gamma} = \boldsymbol{\omega}_{\mathrm{a}}/2$, then the rotating reference frame's vorticity (the relative vorticity) vanishes at that point

$$\boldsymbol{\Gamma} = \boldsymbol{\omega}_{\mathrm{a}}/2 \Longrightarrow \boldsymbol{\omega} = 0. \tag{38.12}$$

Hence, we may interpret $\boldsymbol{\omega}_{\mathrm{a}}/2$ as twice the local and instantaneous angular velocity of the fluid. Correspondingly, if the absolute vorticity, $\boldsymbol{\omega}_{\mathrm{a}}$, is spatially constant, then we can move to a rotating reference frame in which the relative vorticity vanishes everywhere, with such flow referred to as *irrotational*.

38.2.3 There are no vorticity sources

Vorticity has zero divergence

$$\nabla \cdot \boldsymbol{\omega} = \nabla \cdot (\nabla \times \boldsymbol{v}) = 0. \tag{38.13}$$

This property is akin to the non-divergent nature of the velocity vector in an incompressible flow (see Chapter 22). However, vorticity is non-divergent for both compressible and incompressible flow. Consequently, there are no interior sources or sinks of vorticity for any fluid. This very basic property plays an important role in developing some further kinematic properties of vorticity in Chapter 41.

38.2.4 Further study

This video from 3Blue1Brown provides some compelling graphics to help develop intuition for the divergence and curl of a vector, with particular emphasis on fluid flow. In so doing, one learns much about vorticity.

38.3 Irrotational flows

Most geophysical flows have nonzero vorticity. Indeed, even when at rest on the earth, a geophysical fluid carries the vorticity of the rotating planet. However, if we can ignore the planetary vorticity component, as when focused on motions too small to feel the Coriolis acceleration, we can find some geophysically relevant flows with vanishing vorticity. Linear gravity waves in the absence of planetary rotation provide a particularly relevant example (Section 53.3.3).

38.3.1 Characterizing irrotational flows

Irrotational fluid flow is characterized by a zero vorticity

$$\boldsymbol{\omega} = 0 = \text{irrotational flow}. \tag{38.14}$$

Since the curl of a gradient vanishes, irrotational flow has a velocity field equal to the gradient of a velocity potential

$$\nabla \times \boldsymbol{v} = 0 \Longrightarrow \boldsymbol{v} = \nabla \Psi. \tag{38.15}$$

Irrotational flow is therefore sometimes call *potential flow*. Figure 38.2 illustrates a two-dimensional flow field generated by taking the gradient of a scalar potential so that the flow has zero vorticity. In this case, the vertical component of the vorticity vanishes at each point since $\partial v/\partial x = \partial u/\partial y$.

If the flow is non-divergent (solenoidal), as in a Boussinesq ocean (Section 30.1), then the velocity potential is a harmonic function since it satisfies Laplace's equation

$$\nabla \cdot \boldsymbol{v} = 0 \Longrightarrow \nabla^2 \Psi = 0. \tag{38.16}$$

The study of harmonic functions is a very mature area of mathematical physics, thus providing a great deal of analytic power towards the study of potential / non-divergent flows.

FIGURE 38.2: An example horizontal flow based on a potential, $\Psi = \sin(x/5)\,\sin(y/5)$. The flow has zero vorticity, $\boldsymbol{\omega} \cdot \hat{\boldsymbol{z}} = \zeta = \partial v/\partial x - \partial u/\partial y = 0$, since the flow is based on a scalar potential: $\boldsymbol{\omega} = \nabla \times \boldsymbol{v} = \nabla \times \nabla \Psi = 0$. This example illustrates how irrotational flow may have nontrivial structure even though a test paddle wheel will not spin anywhere in the flow, since there is zero vorticity given that $\partial v/\partial x = \partial u/\partial y$.

38.3.2 Comments

This book does not discuss turbulence in any depth. Nevertheless, we here note that three dimensional turbulence fundamentally relies on vorticity. Hence, irrotational flows, though they may exhibit chaotic motions, are not turbulent since they do not allow for the nonlinear cascade of energy to small spatial scales, with this cascade a fundamental characteristic of three dimensional turbulence. As we see in Section 41.3, vorticity evolves from sources that tilt and stretch vortex tubes. Vortex stretching is the key source for the turbulent cascade in three dimensional turbulence. Section 3.3 of *Tennekes and Lumley* (1972) provides a pedagogical discussion of vorticity in the context of three-dimensional turbulence.

38.4 Circulation of the velocity field

The velocity circulation, or more briefly the *circulation*, is defined as the oriented closed loop line integral of velocity as projected onto the unit tangent of the path

$$\mathcal{C} \equiv \oint_{\partial \mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x}, \tag{38.17}$$

with Figure 38.3 offering a schematic. The line element, $\mathrm{d}\boldsymbol{x}$, is oriented in the counter-clockwise direction around the circuit $\partial\mathcal{S}$. More precisely, let $\boldsymbol{x}(\varphi)$ be an expression for the position of a point on the circuit, with $\varphi(x, y, z, t)$ a parameter that measures the distance along the closed circuit (see Section 2.4). The difference between two very close positions along the circuit defines the increment

$$\mathrm{d}\boldsymbol{x} = \boldsymbol{x}(\varphi + \delta\varphi) - \boldsymbol{x}(\varphi). \tag{38.18}$$

By construction, $\mathrm{d}\boldsymbol{x}$ is tangent to the circuit so that $\boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x}$ picks out the component of the velocity that is tangent to the path.

FIGURE 38.3: The velocity circulation around the boundary of a surface, $\partial\mathcal{S}$, is determined by the line integral of the velocity projected into the direction of the line integral, $\boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x}$. Stokes' theorem shows that the velocity circulation computed as a line integral is identical to the normal projection of the vorticity integrated over the area of the region, $\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}$.

Stokes' theorem (Section 2.6) renders the very important identity

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} (\nabla\times\boldsymbol{v})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{S}} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{38.19}$$

where $\hat{\boldsymbol{n}}$ is the outward unit normal vector orienting the area according to the right-hand rule applied to the bounding circuit. The area integral expression motivates interpreting velocity circulation as the "integrated flux of vorticity" that penetrates the surface. Stokes' theorem provides the means to connect the vorticity theories promoted by Helmholtz to the circulation theories of Kelvin.

38.5 The free vortex

Consider a two-dimensional rotating fluid in the x-y plane with angular velocity given by

$$\boldsymbol{\Omega} = \frac{\boldsymbol{x}\times\boldsymbol{v}}{r^2} = \frac{K\,\hat{\boldsymbol{z}}}{r^2}. \tag{38.20}$$

The constant K has dimensions $L^2\,T^{-1}$, and $r^2 = x^2 + y^2$ is the squared distance from the axis of rotation with $\hat{\boldsymbol{z}}$ the unit vector normal to the x-y plane. The angular velocity falls off as the squared distance from the center, whereas it is singular at the origin. As shown in this section, the fluid flow associated with this *free vortex* has zero vorticity and zero circulation for all points except the origin. Yet the same points with zero vorticity and zero circulation have a constant

angular momentum relative to the origin. As shown by Exercise 38.5, and pursued in more detail in Section 38.9, nonzero angular momentum can arise in a fluid with zero circulation so long as there is a nonzero strain within the fluid, such as the flow arising from the free vortex.

FIGURE 38.4: Irrotational counter-clockwise planar flow in the presence of a free vortex with velocity $\boldsymbol{v} = (K/r)\,\hat{\boldsymbol{\vartheta}}$. The tangential velocity decays as $1/r$ from the origin and the vorticity, $\nabla \times \boldsymbol{v}$, vanishes for all points except the origin. Test paddle wheels (colored line segments) do not spin when placed anywhere except at the origin. The free vortex has constant angular momentum per mass (computed relative to the origin), since the tangential velocity falls off as $1/r$ thus canceling the moment-arm distance r.

38.5.1 Velocity

Fluid flows in a circular orbit when in the free vortex flow field. Hence, the velocity of a fluid particle is perpendicular to its position vector, $\boldsymbol{x} = x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}$, with respect to the origin

$$\boldsymbol{v} \cdot \boldsymbol{x} = 0. \tag{38.21}$$

The velocity for pure rotational flow is given by (see Section 11.2.3)

$$\boldsymbol{v} = \boldsymbol{\Omega} \times \boldsymbol{x} = \frac{K\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}})}{r^2} = \frac{K\hat{\boldsymbol{\vartheta}}}{r}, \tag{38.22}$$

where $\hat{\boldsymbol{\vartheta}}$ is the polar angle unit vector oriented in the counter-clockwise direction (see Section 10.3). We illustrate the velocity field (38.22) in Figure 38.4, which reveals the $1/r$ behavior with a singularity at the origin.

38.5.2 Vorticity

Away from the origin the vorticity vector vanishes

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} = 0, \tag{38.23}$$

whereas it is singular at the origin. It is useful to expose a few details of this calculation by considering the vertical component to the vorticity, as computed using the polar coordinate curl (10.85c), in which

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) = r^{-1}\,\partial_r(r\,v^{\vartheta}) - r^{-1}\,\partial_{\vartheta} v^r. \tag{38.24}$$

Since $v^r = 0$ there is a contribution only from the first term. Yet for the velocity (38.22) we have $r\, v^\vartheta = K$, so that $\partial_r(r\, v^\vartheta) = 0$. It is further insightful to perform the product rule to render

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) = v^\vartheta / r + \partial_r v^\vartheta = K/r^2 - K/r^2 = 0, \tag{38.25}$$

which reveals that zero vorticity arises from an exact compensation between the curvature induced vorticity, v^ϑ/r, and the normal shear induced vorticity, $\partial_r v^\vartheta$

$$v^\vartheta / r = -\partial_r v^\vartheta = K/r^2. \tag{38.26}$$

We return to this result in Section 38.8, where we present a general means to decompose the vorticity into that arising from curvature in the flow plus that arising from normal shears (see Figure 38.10). The free vortex is a special case where these two contributions exactly counteract one another, thus leaving zero net vorticity.

In Figure 38.4 we exhibit a test paddle wheel in various positions around the free vortex. As the paddle wheel center moves counter-clockwise with the flow, the marked paddle wheel blades remain oriented at the same fixed angle. That is, the paddle wheel orbits around the vortex center but it does not spin since the vorticity vanishes in the region bounded away from the origin. The vorticity vanishes in this case since the curvature induced vorticity exactly counteracts the normal shear induced vorticity, as per equation (38.26).

38.5.3 Angular momentum

Although vorticity is zero everywhere, except at the origin, the angular momentum (computed relative to the origin) is nonzero, as expected since the fluid is rotating around the vortex center. The angular momentum arises just from the nonzero strain in the flow field (see Exercise 38.5), with the strain causing fluid particles to move relative to one another. The angular momentum per unit mass, relative to the center of the vortex, is constant and pointed vertically

$$\boldsymbol{x} \times \boldsymbol{v} = r\, \hat{\boldsymbol{r}} \times (K/r)\, \hat{\boldsymbol{\vartheta}} = K\, \hat{\boldsymbol{z}}. \tag{38.27}$$

This result follows since the velocity falls of as $1/r$ to cancel the moment-arm distance, r. Hence, the angular momentum per mass is the same for all fluid particles in the presence of a free vortex, no matter what radial distance the particles have from the vortex center.

38.5.4 Circulation

The circulation vanishes for any circuit bounded away from the origin since vorticity vanishes away from the origin. However, the circulation is nonzero for any circuit enclosing the origin

$$\mathcal{C} = \oint_{\partial \mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \int_0^{2\pi} \boldsymbol{v} \cdot \hat{\boldsymbol{\vartheta}}\, r\, \mathrm{d}\vartheta = 2\pi K. \tag{38.28}$$

To reach this result, we set the line element to

$$\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{\vartheta}}\, r\, \mathrm{d}\vartheta \tag{38.29}$$

and inserted the velocity (38.22) represented in cylindrical polar coordinates, $\boldsymbol{v} \cdot \hat{\boldsymbol{\vartheta}} = K/r$. Hence, the singular point vortex at $r = 0$ induces a nonzero circulation for all circuits that enclose the origin.

38.6 Translation and rigid-body rotation

Rigid-body fluid motion occurs when all fluid particles are rigidly locked into their relative positions. There are two kinds of rigid body motion: translation and rotation. The velocity field for this motion is given by

$$\boldsymbol{v} = \boldsymbol{U} + \boldsymbol{\Gamma} \times \boldsymbol{x}, \tag{38.30}$$

where $\boldsymbol{x}$ is the position vector relative to the origin, $\boldsymbol{U}$ is a translation velocity, and $\boldsymbol{\Gamma}$ is an angular velocity. For rigid body motion, both $\boldsymbol{U}$ and $\boldsymbol{\Gamma}$ are spatially uniform, but can in general be time dependent. The strain rate tensor vanishes for uniform translation or rigid-body motion (see Exercise 19.2)

$$S_{mn} = \frac{1}{2}(\partial_m v_n + \partial_n v_m) = 0. \tag{38.31}$$

A zero strain rate tensor is expected since strain measures the relative motion between fluid particles, and for a rigid-body motion there is no such motion. Even so, the vorticity for rigid-body flow is nonzero (see Exercise 38.2)

$$\boldsymbol{\omega} = \nabla \times (\boldsymbol{\Gamma} \times \boldsymbol{x}) = 2\,\boldsymbol{\Gamma}. \tag{38.32}$$

We encountered this vorticity in Section 38.2.2 when connecting vorticity and angular velocity. In the remainder of this section, we set the rotation rate to that of the planet, $\boldsymbol{\Gamma} = \boldsymbol{\Omega}$, and assume it to be constant in space and time.

38.6.1 Absolute vorticity

For planetary fluid dynamics, rotation of the planet imparts *planetary vorticity* to fluids. Hence, the total or *absolute* vorticity of a fluid is the vector sum of the *relative vorticity*, $\boldsymbol{\omega}$, plus the planetary vorticity

$$\boldsymbol{\omega}_{\text{absolute}} = \boldsymbol{\omega}_{\text{planet}} + \boldsymbol{\omega}. \tag{38.33}$$

In this equation,

$$\boldsymbol{\omega}_{\text{planet}} = 2\,\boldsymbol{\Omega}_{\text{planet}} \tag{38.34}$$

is the planetary vorticity associated with rigid-body motion of a fluid particle stationary with respect to the planet, and

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} \tag{38.35}$$

is the relative vorticity. The relative vorticity measures the vorticity of the fluid due to motion relative to the rotating sphere, with $\boldsymbol{v}$ the velocity relative to the rotating sphere.

38.6.2 Rigid-body rotation on a plane

Consider the circular rigid-body rotation on a plane shown in Figure 38.5, in which the velocity is purely tangential and linearly proportional to the distance from the center

$$\boldsymbol{v} = \boldsymbol{\Omega} \times \boldsymbol{x} = |\Omega|\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}) = |\Omega|\,r\,\hat{\boldsymbol{\vartheta}}. \tag{38.36}$$

Assuming the center of mass to be at the circle center, the angular momentum for the flow is the same as that for a rigid-body. Even though the motion of each fluid particle is rigidly fixed relative to all other particles, there is a nonzero vorticity in this flow as illustrated by the spin of colored test paddle wheels in Figure 38.5.

FIGURE 38.5: Rigid body fluid motion, whereby the fluid velocity is: (A) purely tangential and linearly proportional to the radial distance from the vortex center, $\boldsymbol{v} = |\Omega|\, r\, \hat{\boldsymbol{\vartheta}}$; (B) fluid particles maintain a fixed relative position; (C) and vorticity is constant and points perpendicular to the page, $\boldsymbol{\omega} = 2\,\boldsymbol{\Omega} = 2\,|\Omega|\,\hat{\boldsymbol{z}}$. Test paddle wheels rigidly move around the center, and they exhibit a spin about their axis that manifests the nonzero vorticity.

38.6.3 Circulation for rigid-body rotation

For rigid-body rotation, the velocity circulation around a circular path of radius R is given by

$$\mathcal{C} = \oint \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \oint (\boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x} = R^2\, |\Omega| \oint \mathrm{d}\vartheta = 2\pi R^2\, |\Omega| = 2A\, |\Omega|, \tag{38.37}$$

where $A = \pi R^2$ is the area of the circle. Hence, the circulation per area for rigid-body rotating fluid flow is twice the angular rotation rate, which is the magnitude of the vorticity

$$\mathcal{C}/A = |\boldsymbol{\omega}| = 2\,|\boldsymbol{\Omega}|. \tag{38.38}$$

38.6.4 Comments

As seen in Section 38.5, fluid flow in the presence of a free vortex has zero vorticity for all points except the origin of the vortex. However, the same points also have a constant angular momentum relative to the origin, and they experience a nonzero strain. In contrast, constant rigid-body rotating fluid flow has a nonzero vorticity, nonzero angular momentum, yet a zero strain. Section 38.9 details the connection between vorticity, strain, and angular momentum, where we see that angular momentum can be nonzero if either vorticity or strain are nonzero. These ideas are illustrated in this 3-minute video as well as in this 10 minute video from the Open University.

38.7 Kinematics of vortex lines and vortex tubes

We here develop the basics of vorticity kinematics, with this discussion closely following from the kinematics of material line elements discussed in Section 19.3.3.

38.7.1 Vortex lines and vortex tubes

A *vortex line* is a curve in the fluid that is instantaneously tangent to the vorticity at each point along the curve.[1] A vortex line is mathematically parameterized just like any other curve, whereby we write the spatial coordinates along the curve as a function of a suitable parameter φ (e.g., the arc-length)

$$\boldsymbol{x}(\varphi) = x(\varphi)\,\hat{\boldsymbol{x}} + y(\varphi)\,\hat{\boldsymbol{y}} + z(\varphi)\,\hat{\boldsymbol{z}}. \tag{38.39}$$

Correspondingly, the tangent vector for the curve is given by

$$\frac{\mathrm{d}\boldsymbol{x}(\varphi)}{\mathrm{d}\varphi} = \frac{\mathrm{d}x(\varphi)}{\mathrm{d}\varphi}\,\hat{\boldsymbol{x}} + \frac{\mathrm{d}y(\varphi)}{\mathrm{d}\varphi}\,\hat{\boldsymbol{y}} + \frac{\mathrm{d}z(\varphi)}{\mathrm{d}\varphi}\,\hat{\boldsymbol{z}}. \tag{38.40}$$

The three coordinates of the vortex line are constrained so that the tangent is parallel to vorticity at each point

$$\frac{\mathrm{d}\boldsymbol{x}(\varphi)}{\mathrm{d}\varphi} \times \boldsymbol{\omega} = 0, \tag{38.41}$$

which is satisfied by the following constraint

$$\frac{\mathrm{d}x/\mathrm{d}\varphi}{\omega_x} = \frac{\mathrm{d}y/\mathrm{d}\varphi}{\omega_y} = \frac{\mathrm{d}z/\mathrm{d}\varphi}{\omega_z}. \tag{38.42}$$

These equations are directly analogous to those satisfied by velocity streamlines as discussed in Section 18.11.2. Notably, the velocity is not constant along a velocity streamline, nor is vorticity constant along a vortex line. In a steady state, streamlines map the trajectory of a fluid particle (see Section 18.11). However, a vortex line does not offer an interpretation in terms of trajectories.

A *vortex tube* is a bundle of vortex lines that pass through a simple closed curve such as that illustrated in Figure 38.6. By definition, the sides of the vortex tube are parallel to the vorticity field, since the sides are constructed from vortex lines.[2]

38.7.2 Kinematic properties

Vorticity has zero divergence

$$\nabla \cdot \boldsymbol{\omega} = \nabla \cdot (\nabla \times \boldsymbol{v}) = 0, \tag{38.43}$$

which follows since the divergence of a curl vanishes. Integrating the non-divergence relation over an arbitrary closed volume within the fluid leads to

$$\int_{\mathcal{R}} \nabla \cdot \boldsymbol{\omega}\,\mathrm{d}V = \oint_{\partial\mathcal{R}} \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0, \tag{38.44}$$

where we made use of Gauss's divergence theorem to reach the surface integral expression, with $\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}$ the oriented area element on the boundary of the volume, $\partial\mathcal{R}$, and $\hat{\boldsymbol{n}}$ the outward normal on the boundary. This result means there is no net vorticity entering or leaving an arbitrary closed region. That is, there is a vanishing net integrated "flux" of vorticity across the surface bounding a closed region. Consequently, there are no sources or sinks of vorticity within the fluid, meaning there is no accumulation nor depletion of vorticity within any arbitrary closed region within the fluid.

Now specialize the surface integral in equation (38.44) to a volume along a chosen vortex tube

[1] As noted in Section 1.4 of *Saffman* (1992), a *vortex filament* is a vortex tube surrounded by irrotational fluid, which contrasts to the more general concept of a vortex line.

[2] We defined a similar notion, the streamtube, for a non-divergent velocity field in Figure 18.6.

FIGURE 38.6: A vortex line is a line in the fluid that is everywhere tangent to the vorticity vector. A vortex tube is the accumulation of vortex lines passing through a closed loop. A related, but distinct, concept arises when a vortex tube is surrounded by irrotational flow, with such tubes referred to as *vortex filaments* (see Section 1.4 of *Saffman* (1992)). We here depict a vortex tube within the fluid and illustrate the circulation around the tube $\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \int \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}$. Since vorticity has zero divergence, the circulation is the same for any loop embracing the vortex tube (Helmholtz's first theorem from Section 38.7.3). A uniform circulation along the tube means that the magnitude of the vorticity is larger in regions where the tube has a small area and conversely the circulation magnitude is smaller where the tube has a large area.

such as in Figure 38.6. The two ends of the tube generally have different cross-sectional areas. The integral over the sides of the vortex tube vanishes since the vorticity is parallel to the tube sides. Hence, the surface integral only picks up contributions from the two ends of the tube[3]

$$\int_{\mathrm{A}} \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}_A + \int_{\mathrm{B}} \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}_B = 0. \tag{38.45}$$

The outward normals point in the opposite direction so that the flux of vorticity is independent of position along the tube. Stoke's theorem transfers the vorticity constraint to a constraint on the circulation around the circumference of the tube

$$\oint_{\mathrm{A}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} + \oint_{\mathrm{B}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = 0. \tag{38.46}$$

Hence, the circulation around the vortex tube is the same no matter where it is computed. The circulation constraints (38.45) and (38.46) are kinematic, holding for any vorticity field. We now consider some consequences of this constraint.

38.7.3 Helmholtz's theorems

There are a few basic properties of vorticity that follow from its vanishing divergence. These properties are known as Helmholtz's theorems.

Helmholtz's first theorem

Since the cross-sectional slices used to derive the circulation constraint (38.46) are arbitrary, the constraint holds throughout the full extent of the vortex tube. Hence, as noted following equation (38.46), the circulation is the same for any position along the vortex tube; i.e., the strength of a vortex tube is the same value along its length (see Figure 38.6). This result is known as

[3] In Exercise 22.8, we developed a similar set of results for a streamtube in a non-divergent flow.

Helmholtz's first theorem.

FIGURE 38.7: A vortex tube idealization of a tornado. Since the circulation around the tube is uniform (Helmholtz's first theorem), the tangential velocity of a fluid particle has a larger magnitude in regions where the vortex area is smaller, such as near the ground. As the tornado reaches into the clouds, it generally has a larger cross-sectional area and thus a smaller magnitude for the tangential velocity.

As a corollary, we refer to the vorticity constraint (38.45) to note that any process that changes in the vortex tube cross-sectional area is compensated by changes in vorticity. For example, let the vortex tube shrink over some region. To maintain constant circulation along the tube, the vorticity magnitude must increase where the area decreases, which in turn means that the velocity circulating around the tube increases in magnitude as the area reduces. Think of a tornado as in Figure 38.7, which is a natural expression of a vortex tube. Near the ground, the cross-sectional area of the tornado is small, with the tangential velocity of a fluid particle within the tube relatively large. Near the tornado top, the cross-sectional area is large so the tangential velocity is relatively small.

Helmholtz's second theorem

The vorticity constraint (38.45) cannot be satisfied by a finite vorticity if the area of a vortex tube vanishes anywhere. Hence, a vortex tube cannot begin or end within the fluid. This result follows from the absence of vortex sources and sinks within the fluid. Hence, a vortex tube can only loop with itself (e.g., a smoke ring as in Figure 38.8), or intersect a boundary (as for a tornado in Figure 38.7, where the ground and clouds form the boundary).

Helmholtz's third theorem

Helmholtz's third theorem states that an unforced inviscid barotropic fluid that has zero vorticity remains irrotational forever. This theorem is a special case of Kelvin's circulation theorem that is studied in Section 41.2.

FIGURE 38.8: A vortex ring (torus) is a vortex tube that closes on itself. We here depict a vortex ring with vorticity pointing counter-clockwise around the ring. The tangential velocity is oriented as shown so that the vorticity points according to the right hand rule. That is, orient the fingers on the right hand according to the tangential velocity. The thumb of the right hand then points in the direction of the vorticity vector.

38.7.4 Further study

A particularly insightful and pedagogical discussion of the ideas in this section can be found in Chapter 5 of *Acheson* (1990). Additionally, the following videos offer laboratory demonstrations of vorticity in non-rotating and rotating flows.

- Helmholtz's theorems are vividly exhibited by this video from the *Physics Girl* of flow generated by a paddle in a swimming pool. She also discusses vortex rings in this video.
- Vorticity and Helmholtz's theorems are also described by this classic video from Prof. Shapiro.
- A rotating tank experiment shown near the 15 minute mark of this video from Prof. Fultz shows how vorticity is affected by vortex stretching.
- This video offers a classic tutorial on vorticity in non-rotating fluids from Prof. Shapiro.

38.8 Relative vorticity from curvature and shear

In this section we decompose the vorticity into two terms: one arising from curvature in the flow and another arising from shears in the direction normal to the flow. This decomposition is formulated for horizontal flows, but can be generalized to arbitrary flow. It offers yet another means to understand the kinematic properties of vorticity.

38.8.1 Circular flow

Before treating the general case, it is useful to consider a two-dimensional velocity that locally takes the form of an angular flow

$$\boldsymbol{u} = u^{\vartheta}(r, \vartheta)\, \hat{\boldsymbol{\vartheta}}, \tag{38.47}$$

where ϑ is the polar angle. Circulation around the circular wedge shown in Figure 38.9 has zero contributions from the two radial segments since these segments are perpendicular to the angular

flow. The circulation is thus given by

$$\mathcal{C} = \oint_{\text{wedge}} \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{x} \tag{38.48a}$$

$$= \int_{\vartheta}^{\vartheta+\delta\vartheta} u^{\vartheta}(r+\delta r, \vartheta')\,(r+\delta r)\,\mathrm{d}\vartheta' + \int_{\vartheta+\delta\vartheta}^{\vartheta} u^{\vartheta}(r, \vartheta')\,r\,\mathrm{d}\vartheta' \tag{38.48b}$$

$$= \int_{\vartheta}^{\vartheta+\delta\vartheta} \Big[u^{\vartheta}(r+\delta r, \vartheta')\,(r+\delta r) - r\,u^{\vartheta}(r, \vartheta')\Big]\,\mathrm{d}\vartheta' \tag{38.48c}$$

$$\approx \int_{\vartheta}^{\vartheta+\delta\vartheta} \left[u^{\vartheta}(r, \vartheta')\,\delta r + \frac{\partial u^{\vartheta}}{\partial r}\,r\,\delta r\right]\mathrm{d}\vartheta' \tag{38.48d}$$

$$= r\,\delta r \int_{\vartheta}^{\vartheta+\delta\vartheta} \left[\frac{u^{\vartheta}}{r} + \frac{\partial u^{\vartheta}}{\partial r}\right]\mathrm{d}\vartheta', \tag{38.48e}$$

where the approximation holds when $\delta r \to 0$. Taking the further limit $\delta\vartheta \to 0$ renders

$$\mathcal{C} \approx \zeta\,\delta A = \zeta\,r\,\delta r\,\delta\vartheta = \left[\frac{u^{\vartheta}}{r} + \frac{\partial u^{\vartheta}}{\partial r}\right] r\,\delta r\,\delta\vartheta \Longrightarrow \zeta = \frac{u^{\vartheta}}{r} + \frac{\partial u^{\vartheta}}{\partial r}. \tag{38.49}$$

The first term in the vorticity arises from the nonzero radius of curvature of the circular flow whereas the second term arises from radial shear.

FIGURE 38.9: Circulation around the circular wedge $[r, r+\delta r] \otimes [\vartheta, \vartheta+\delta\vartheta]$.

38.8.2 Generalization to natural coordinates

The decomposition (38.49) can be generalized to arbitrary horizontal flow by making use of the natural coordinates from Section 33.2. Here, we introduce the locally orthogonal coordinates, (s, n), with s the arc-length defined along the trajectory of a fluid element and n measuring the distance normal to the trajectory. We make the convention that the unit tangent direction, $\hat{\boldsymbol{s}}$, is aligned along the local flow direction whereas the unit normal direction, $\hat{\boldsymbol{n}}$, is to the left facing downstream. Furthermore, the radius of curvature at a point along a trajectory (see Section 7.2.3) is positive if the flow turns into the positive $\hat{\boldsymbol{n}}$ direction (left turn) and negative for oppositely curved flow (right turn) (see Figures 33.2 and 33.3). Finally, the radius of curvature is infinite for straight flow.

For the counter-clockwise circuit in Figure 38.9, a left turn occurs with $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{r}}$ so that

equation (38.49) takes on the general form

$$\zeta = \underbrace{\frac{|\boldsymbol{u}|}{R}}_{\text{curvature}} - \underbrace{\frac{\partial|\boldsymbol{u}|}{\partial n}}_{\text{shear}} = \zeta_{\text{curv}} + \zeta_{\text{shear}}. \tag{38.50}$$

Again, the first term arises from curvature in the flow, with R the radius of curvature. This *curvature vorticity* is sometimes also called the *orbital vorticity*. A trajectory turning to the left has $R > 0$ and this curved trajectory contributes to a positive vorticity; conversely for a trajectory turning to the right. The second term in equation (38.50) arises from shears computed normal to the flow direction. If the flow speed decreases in the normal direction (e.g., towards the center of the circle in Figure 38.9), then that too contributes to a positive vorticity. Furthermore, flow with $\zeta = 0$ arises if there is an exact compensation between the curvature-induced vorticity with the shear-induced vorticity

$$\zeta = 0 \Longrightarrow \frac{|\boldsymbol{u}|}{R} = \frac{\partial|\boldsymbol{u}|}{\partial n}. \tag{38.51}$$

38.8.3 Example vorticities

Rigid body vortex and free vortex

FIGURE 38.10: Decomposing the relative vorticity into its contributions from curvature and normal shear. Left panel: the free vortex from Figure 38.4 has $\zeta_{\text{curv}} = -\zeta_{\text{shear}} = K/r^2$ so that $\zeta = \zeta_{\text{curv}} + \zeta_{\text{shear}} = 0$. Right panel: the rigid-body vortex from Figure 38.5 has $\zeta_{\text{curv}} = \zeta_{\text{shear}} = \Omega$ so that $\zeta = 2\,\Omega$.

To help further understand the decomposition (38.50), consider the case of rigid-body rotation (Figure 38.5) where $\boldsymbol{v} = \Omega\, r\, \hat{\boldsymbol{\vartheta}}$ and $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{r}}$. For a circle the radius of curvature equals to the radius of the circle, so that

$$\zeta_{\text{curv}} = \frac{\Omega\, r}{r} = \Omega \quad \text{and} \quad \zeta_{\text{shear}} = -\partial_n|\boldsymbol{u}| = \partial_r(\Omega\, r) = \Omega, \tag{38.52}$$

in which case

$$\zeta = \zeta_{\text{curv}} + \zeta_{\text{shear}} = 2\,\Omega = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}), \tag{38.53}$$

as depicted in the right panel of Figure 38.10. Likewise, for the free vortex (Figure 38.4) we have $\boldsymbol{v} = (K/r)\,\hat{\boldsymbol{\vartheta}}$ so that

$$\zeta_{\text{curv}} = K/r^2 \quad \text{and} \quad \zeta_{\text{shear}} = \partial|\boldsymbol{u}|/\partial r = -K/r^2, \tag{38.54}$$

which yields zero relative vorticity

$$\zeta = \zeta_{\text{curv}} + \zeta_{\text{shear}} = 0, \tag{38.55}$$

as depicted in the left panel of Figure 38.10.

Gaussian jet moving along a line and around a circle

FIGURE 38.11: Top row: velocity and vorticity within a Gaussian jet that is moving along a straight line according to equations (38.56) and (38.57). We set the jet e-folding scale as $L = 50$ km, jet maximum at $x_{\max} = 150$ km, and velocity scale as $v_0 = 1$ m s^{-1}. Note the symmetry of the vorticity relative to the jet maximum, with the vorticity extrema corresponding to the inflection points of the Gaussian velocity field. Middle left: the same Gaussian velocity profile only now for a jet that is moving counter-clockwise around a circle so that $\boldsymbol{v} = v(r)\,\hat{\boldsymbol{\vartheta}}$ according to equation (38.58). To avoid a singularity of the curvature vorticity at $r = 0$ (infinite curvature) we assume the velocity field vanishes within a small distance from the origin. Middle right: vorticity for the Gaussian jet moving around the circle, with $\zeta = r^{-1}\,\partial_r(r\,v)$. Notice how the vorticity is not symmetric relative to the jet maximum. Rather, the zero vorticity occurs to the right of the jet maximum, and the vorticity on the inside of the jet maximum is larger in magnitude than the outer vorticity. Lower left: vorticity due to the curvature of the jet as it moves around the circle, $\zeta_{\text{curve}} = v(r)/r$. Lower right: vorticity due to the radial shear in the Gaussian jet, $\zeta_{\text{shear}} = -2\,(r - r_{\max})\,v(r)/L^2$.

Next consider a Gaussian jet moving along a straight line in the meridional direction with velocity field

$$\boldsymbol{v}(x) = v(x)\,\hat{\boldsymbol{y}} = v_0\,\exp[-(x - x_{\max})^2/L^2]\,\hat{\boldsymbol{y}}, \tag{38.56}$$

where v_0 is the velocity scale, L is the e-folding length scale for the jet, and $x_{\max}$ is the position of the jet maximum. The corresponding vorticity of the jet is given by

$$\zeta_{\text{line}} = \partial_x v = -2\,[(x - x_{\max})/L^2]\,v(x). \tag{38.57}$$

We depict the velocity (38.56) and vorticity (38.57) in the top row of Figure 38.11. Note the symmetry of the vorticity around the jet maximum at $x = x_{\max}$, with the vorticity extrema

corresponding to inflection points of the jet.[4]

Now assume the same jet is moving counter-clockwise around a circle so that the velocity field is given by

$$\boldsymbol{v}(r) = v(r)\,\hat{\boldsymbol{\vartheta}} = v_0\,\exp[-(r - r_{\max})^2/L^2]\,\hat{\boldsymbol{\vartheta}}, \tag{38.58}$$

where we made use of the polar coordinates from Section 10.3 with $r^2 = x^2 + y^2$ the squared radial distance from the center, and $\hat{\boldsymbol{\vartheta}}$ the unit vector pointing in the counter-clockwise direction from the $\hat{\boldsymbol{x}}$ axis. Making use of the curl operation in polar coordinates given by equation (10.85c) renders the vorticity

$$\zeta = r^{-1}\,\partial_r(r\,v) = \frac{v}{r} - \frac{2\,(r - r_{\max})\,v}{L^2} = \zeta_{\text{curve}} + \zeta_{\text{shear}}. \tag{38.59}$$

We depict these terms in the third row of Figure 38.11. Note how the vorticity, ζ, has the amplitude of its maximum increased, whereas the amplitude of its minimum is decreased. Correspondingly, the vorticity is not symmetric about the jet maximum, with its zero crossing to the outside of the jet maximum. Asymmetry of the vorticity arises from the curvature vorticity, $\zeta_{\text{curve}} = v/r$, which has its peak inside the jet maximum. So although the shear vorticity, ζ_{curve}, is symmetric around the jet axis, the curvature vorticity causes a movement of vorticity towards the center of the circle.

38.9 Relating angular momentum to vorticity and strain

As noted in Section 38.6.4, fluid flow in the presence of a free vortex (Section 38.5) has zero vorticity for all points except the origin of the vortex. However, the same points with zero vorticity also have a constant angular momentum relative to the origin, and they experience a nonzero strain. In contrast, rigid-body fluid flow (Section 38.6) has a nonzero vorticity, nonzero angular momentum, yet a zero strain rate. In this section we study the connection between vorticity, strain rate, and angular momentum for a fluid. We here show that angular momentum and vorticity are fundamentally distinct in a fluid that has straining motion between fluid elements. In contrast, angular momentum and vorticity are directly proportional (through the moment of inertia tensor) when the fluid exhibits rigid-body motion in which the strain rate tensor vanishes.

In this section we make use of the Lagrangian description from Section 18.6, whereby we write the trajectory of a fluid particle as in equation (18.7) using the motion field. Namely, by fixing the material coordinate, $\boldsymbol{a}$, the motion field provides the spatial position, $\boldsymbol{x}$, of the fluid particle as a function of the Lagrangian time, T

$$\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{a}, T). \tag{38.60}$$

38.9.1 Linear momentum

Consider the velocity and linear momentum of a simply connected material fluid region denoted by $\mathcal{R}(\boldsymbol{v})$, with each point of the region moving with the fluid velocity. Let an arbitrary fluid particle within this region be marked with the material label, $\boldsymbol{a}$, so that its position vector is $\boldsymbol{X}(\boldsymbol{a}, T)$ and its velocity is

$$\boldsymbol{v}^{\text{L}}(\boldsymbol{a}, T) = \partial_T \boldsymbol{X}(\boldsymbol{a}, T), \tag{38.61}$$

where the time derivative is computed holding the material label fixed. Since the fluid particle is within a finite material region, we can decompose its motion into the sum of the region's center

[4] Inflection points are where the curvature changes sign.

of mass motio plus motion of the particle relative to the center of mass

$$\boldsymbol{v}^{\mathrm{L}}(\boldsymbol{a},T) = \partial_T \boldsymbol{X}(\boldsymbol{a},T), \tag{38.62a}$$
$$= \partial_T[\overline{\boldsymbol{X}}(T) + \boldsymbol{X}'(\boldsymbol{a},T)] \tag{38.62b}$$
$$= \overline{\boldsymbol{v}^{\mathrm{L}}}(T) + \boldsymbol{v}^{\mathrm{L}'}(\boldsymbol{a},T). \tag{38.62c}$$

The velocity, $\boldsymbol{v}^{\mathrm{L}'}(\boldsymbol{a},T)$, is defined relative to the region's center of mass velocity, $\overline{\boldsymbol{v}^{\mathrm{L}}}(T)$. Furthermore, the center of mass velocity is given by

$$\overline{\boldsymbol{v}^{\mathrm{L}}} = \frac{\mathrm{d}\overline{\boldsymbol{X}}}{\mathrm{d}T} \tag{38.63a}$$
$$= \frac{\mathrm{d}}{\mathrm{d}T}\left[\frac{\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{x}\,\rho\,\mathrm{d}V}{\int_{\mathcal{R}(\boldsymbol{v})} \rho\,\mathrm{d}V}\right] \tag{38.63b}$$
$$= \frac{1}{M}\int_{\mathcal{R}(\boldsymbol{v})} \frac{\mathrm{D}\boldsymbol{x}}{\mathrm{D}t}\,\rho\,\mathrm{d}V \tag{38.63c}$$
$$= \frac{1}{M}\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{v}\,\rho\,\mathrm{d}V. \tag{38.63d}$$

The identity (38.63c) follows since the material region maintains a constant mass,

$$M = \int_{\mathcal{R}(\boldsymbol{v})} \rho\,\mathrm{d}V \Longrightarrow \frac{\mathrm{d}M}{\mathrm{d}t} = 0, \tag{38.64}$$

allowing the denominator to come outside the Lagrangian time derivative. Additionally, each of the fluid parcels in the region maintains constant mass. As per Reynold's transport theorem (Section 20.3.4), the time derivative moves across the integral to act materially on the position vector. The final equality, (38.63d), follows since the material time derivative of a particle trajectory, when evaluated at a point, $\boldsymbol{x}$, equals to the velocity field at that point

$$\boldsymbol{v}(\boldsymbol{x},t) = \frac{\mathrm{D}\boldsymbol{x}}{\mathrm{D}t}. \tag{38.65}$$

It follows that the linear momentum for the material fluid region is given by

$$\boldsymbol{P} = \int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{v}\,\rho\,\mathrm{d}V = M\,\overline{\boldsymbol{v}^{\mathrm{L}}}. \tag{38.66}$$

We conclude that the total linear momentum of an material fluid region equals to that of a point particle of mass, $M = \int_{\mathcal{R}(\boldsymbol{v})} \rho\,\mathrm{d}V$, moving with the center of mass velocity, $\overline{\boldsymbol{v}^{\mathrm{L}}}$. The analogous result was derived in Section 11.5 for a system of discrete point particles.

38.9.2 Angular momentum

We here consider angular momentum for a material fluid region, which is determined by the material integral of the angular momentum for each fluid parcel

$$\boldsymbol{L} = \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}\times\boldsymbol{v})\,\rho\,\mathrm{d}V. \tag{38.67}$$

Our goal is to expose how physically distinct aspects of the fluid motion contribute to the angular momentum. To proceed, decompose the position vector of a point within the region into the

center of mass position plus a deviation, $\boldsymbol{x} = \overline{\boldsymbol{x}} + \boldsymbol{x}'$, where $\overline{\boldsymbol{x}} = \overline{X}$ is the instantaneous position of the moving center of mass. The angular momentum thus takes the form

$$\boldsymbol{L} = \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x} \times \boldsymbol{v})\, \rho \, \mathrm{d}V \tag{38.68a}$$

$$= \int_{\mathcal{R}(\boldsymbol{v})} [(\overline{\boldsymbol{x}} + \boldsymbol{x}') \times \boldsymbol{v}]\, \rho \, \mathrm{d}V \tag{38.68b}$$

$$= \overline{\boldsymbol{X}} \times \left[\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{v}\, \rho \, \mathrm{d}V \right] + \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \times \boldsymbol{v})\, \rho \, \mathrm{d}V \tag{38.68c}$$

$$= (\overline{\boldsymbol{X}} \times \boldsymbol{P}) + \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \times \boldsymbol{v})\, \rho \, \mathrm{d}V. \tag{38.68d}$$

The final equality introduced the linear momentum for the fluid region, $\boldsymbol{P}$, in the form of equation (38.66). The first term in equation (38.68d) is the angular momentum of the region with respect to the position of the center of mass. The second term arises from deviations of fluid particle positions relative to the center of mass.

We now focus on how the deviation term, $\int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \times \boldsymbol{v})\, \rho \, \mathrm{d}V$, contributes to the angular momentum (38.67). As we will see, this analysis exposes how angular momentum of the extended material fluid region is affected by vorticity and strain rate in the fluid flow. To facilitate some of the manipulations, we make use of basic Cartesian tensor analysis from Chapter 1, including the summation convention whereby repeated indices are summed over their range.

38.9.3 Taylor expanding the velocity

We perform a Taylor expansion of the velocity $\boldsymbol{v}(\boldsymbol{x})$ around the instantaneous center of mass position, $\overline{\boldsymbol{x}} = \overline{X}$, and truncate the expansion to the leading order term[5]

$$\boldsymbol{v}(\boldsymbol{x}) = \boldsymbol{v}(\overline{\boldsymbol{x}} + \boldsymbol{x}') \approx \boldsymbol{v}(\overline{\boldsymbol{x}}) + (\boldsymbol{x}' \cdot \nabla)\, \boldsymbol{v}|_{\boldsymbol{x}=\overline{\boldsymbol{x}}}. \tag{38.69}$$

We are thus left with

$$\boldsymbol{L} = (\overline{\boldsymbol{X}} \times \boldsymbol{P}) + \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \times \boldsymbol{v})\, \rho \, \mathrm{d}V \tag{38.70a}$$

$$= (\overline{\boldsymbol{X}} \times \boldsymbol{P}) + \int_{\mathcal{R}(\boldsymbol{v})} [\boldsymbol{x}' \times \boldsymbol{v}(\overline{\boldsymbol{x}})]\, \rho \, \mathrm{d}V + \int_{\mathcal{R}(\boldsymbol{v})} [\boldsymbol{x}' \times (\boldsymbol{x}' \cdot \nabla)\, \boldsymbol{v}(\overline{\boldsymbol{x}})]\, \rho \, \mathrm{d}V. \tag{38.70b}$$

The velocity, $\boldsymbol{v}(\overline{\boldsymbol{x}})$, can be removed from the integration since it is evaluated at the center of mass point. Hence, the second term in equation (38.70b) vanishes

$$\int_{\mathcal{R}(\boldsymbol{v})} [\boldsymbol{x}' \times \boldsymbol{v}(\overline{\boldsymbol{x}})]\, \rho \, \mathrm{d}V = \left[\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{x}'\, \rho \, \mathrm{d}V \right] \times \boldsymbol{v}(\overline{\boldsymbol{x}}) = 0, \tag{38.71}$$

where $\int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{x}'\, \rho \, \mathrm{d}V = 0$ by definition of the center of mass. The angular momentum is thus given by the two terms

$$\boldsymbol{L} = (\overline{\boldsymbol{X}} \times \boldsymbol{P}) + \int_{\mathcal{R}(\boldsymbol{v})} [\boldsymbol{x}' \times (\boldsymbol{x}' \cdot \nabla)\, \boldsymbol{v}(\overline{\boldsymbol{x}})]\, \rho \, \mathrm{d}V. \tag{38.72}$$

[5] The velocity field evaluated at the center of mass position, $\boldsymbol{v}(\overline{\boldsymbol{x}})$, is not equal to the center of mass velocity: $\boldsymbol{v}(\overline{\boldsymbol{x}}) \neq \overline{\boldsymbol{v}^{\mathrm{L}}}$.

The $m'th$ component of the second right hand side term can be written

$$\int_{\mathcal{R}(\boldsymbol{v})} [\boldsymbol{x}' \times (\boldsymbol{x}' \cdot \nabla)\, \boldsymbol{v}(\overline{\boldsymbol{x}})]_m \, \rho \, \mathrm{d}V = \epsilon_{mnp} \int_{\mathcal{R}(\boldsymbol{v})} x'_n \, [(\boldsymbol{x}' \cdot \nabla)\, \boldsymbol{v}(\overline{\boldsymbol{x}})]_p \, \rho \, \mathrm{d}V \tag{38.73a}$$

$$= \epsilon_{mnp} \int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \partial_q v_p(\overline{\boldsymbol{x}}) \, \rho \, \mathrm{d}V \tag{38.73b}$$

$$= \epsilon_{mnp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \; \rho \, \mathrm{d}V \right] \partial_q v_p(\overline{\boldsymbol{x}}). \tag{38.73c}$$

We removed the velocity derivatives

$$\partial_q v_p(\overline{\boldsymbol{x}}) = \left[\frac{\partial v_p}{\partial x_q} \right]_{\boldsymbol{x}=\overline{\boldsymbol{x}}} \tag{38.74}$$

from the integral, since they are evaluated at the center of mass point and so do not participate in the integration.

38.9.4 Angular momentum, strain rate, and vorticity

Following from the discussion in Section 19.4, we know that the velocity derivatives, $\partial_q v_p$, appearing in equation (38.73c) form the components to a second order tensor known as the *velocity gradient tensor*, which can be decomposed into the strain rate tensor, $\mathbb{S}$, and the rotation tensor, $\mathbb{R}$. Introducing these two tensors brings the angular momentum for a continuum fluid region into the form

$$L_m = (\overline{\boldsymbol{X}} \times \boldsymbol{P})_m + \epsilon_{mnp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \rho \, \mathrm{d}V \right] \mathbb{S}_{qp} + \epsilon_{mnp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \rho \, \mathrm{d}V \right] \mathbb{R}_{qp} \tag{38.75a}$$

$$= (\overline{\boldsymbol{X}} \times \boldsymbol{P})_m + \epsilon_{mnp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \rho \, \mathrm{d}V \right] \mathbb{S}_{qp} + \frac{1}{2} \, \epsilon_{mnp} \, \epsilon_{sqp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \rho \, \mathrm{d}V \right] \omega_s \tag{38.75b}$$

$$= \underbrace{(\overline{\boldsymbol{X}} \times \boldsymbol{P})_m}_{\text{center of mass}} + \underbrace{\epsilon_{mnp} \left[\int_{\mathcal{R}(\boldsymbol{v})} x'_n \, x'_q \, \rho \, \mathrm{d}V \right] \mathbb{S}_{qp}}_{\text{strain rate contribution}} + \underbrace{\frac{1}{2} \left[\int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \cdot \boldsymbol{x}' \, \delta_{ms} - x'_m \, x'_s) \, \rho \, \mathrm{d}V \right] \omega_s}_{\text{vorticity contribution}} . \tag{38.75c}$$

Since each point in the fluid continuum can be considered the center of mass for an arbitrary material region, the decomposition (38.75c) holds in general.

- Center of mass angular momentum: The first term on the right hand side of equation (38.75c) arises from the angular momentum of the material region as measured with respect to the center of mass position. It has the form of that for a point particle (see equation (11.39)).

- Strains: The second contribution is proportional to fluid deformations studied in Section 19.4. At each point of the fluid, deformations are measured by the strain rate tensor, $\mathbb{S}_{qp}$. A rigid body moves by uniform translations and/or rigid-body rotations, with the strain rate tensor vanishing for rigid-body motions (see Section 38.6). The contribution from strain rates is weighted by an integral of fluid particle position relative to the center of mass position. A closed form expression for this integral is available only for special shapes.

- VORTICITY: The third contribution to angular momentum (38.75c) contains the vorticity as weighted by the moment of inertia tensor

$$I_{ms} \equiv \int_{\mathcal{R}(\boldsymbol{v})} (\boldsymbol{x}' \cdot \boldsymbol{x}' \, \delta_{ms} - x'_m \, x'_s) \, \rho \, \mathrm{d}V. \tag{38.76}$$

  Since the material region is evolving and is not rigid, the moment of inertia tensor is time dependent. Even so, the contribution

$$L_m^{\text{vorticity}} \equiv \frac{1}{2} \, I_{ms} \, \omega_s \tag{38.77}$$

  has the same form as angular momentum for a rigid body, with one-half the vorticity playing the role of angular velocity (see equation (11.41a) for the point particle expression). Evidently, vorticity in fluid flow contributes to angular momentum for a material region via its product with the moment of inertia tensor for the region.

38.9.5 Comments and further reading

Angular momentum is computed relative to a chosen origin, whereas vorticity is an intrinsic property measuring the spin of the fluid at a point. So although they both offer measures of the rotational properties of fluid motion, they are distinct when the fluid experiences a nonzero strain rate. It is only for the special case of a rigid-body motion that the strain rate vanishes, in which case the angular momentum of a fluid region is directly related to vorticity.

Further discussion of the material in this section can be found in *Chatwin* (1973), Section 2.3.1 of *Davidson* (2015), and the online notes "The Vorticity Equation and Conservation of Angular Momentum" from A.J. DeCaria. See also Section 1.2 of the vorticity monograph by *Saffman* (1992).

38.10 Exercises

EXERCISE 38.1: VORTICITY AT A STATIC NO-SLIP BOUNDARY
Show that $\boldsymbol{\omega} \cdot \hat{\boldsymbol{n}} = 0$ at a static no-slip boundary, such as a solid wall. Here, $\hat{\boldsymbol{n}} = 0$ is the outward normal at the boundary. Hint: make use of Stoke's theorem and the adherence condition, $\boldsymbol{v} = 0$, at a static no-slip boundary.

EXERCISE 38.2: VORTICITY FOR RIGID-BODY ROTATION
Show that a fluid in rigid-body rotation with angular velocity

$$\boldsymbol{v}_{\text{rigid-body}} = \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{38.78}$$

has a vorticity given by

$$\nabla \times \boldsymbol{v}_{\text{rigid-body}} = 2 \, \boldsymbol{\Omega}. \tag{38.79}$$

EXERCISE 38.3: PLANETARY ROTATION IS NON-DIVERGENT
Show that a fluid in rigid-body rotation with angular velocity

$$\boldsymbol{v}_{\text{rigid-body}} = \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{38.80}$$

has zero divergence

$$\nabla \cdot \boldsymbol{v}_{\text{rigid-body}} = 0. \tag{38.81}$$

Consequently, rotation of the planet imparts zero divergence to fluid motion. We make use of this result in part to justify our study of non-rotating fluid kinematics in Part III of this book.

EXERCISE 38.4: VELOCITY POTENTIAL FOR THE FREE VORTEX
What is the velocity potential (38.15) for the free vortex whose velocity field is given by (38.22)? Hint: The problem is two-dimensional and rotationally symmetric, so it is convenient to make use of polar coordinates $x = r\cos\vartheta$ and $y = r\sin\vartheta$ as in Section 10.3.

EXERCISE 38.5: STRAIN TENSOR FOR THE FREE VORTEX
Determine all components to the strain tensor

$$S_{pq} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \begin{bmatrix} \frac{\partial u}{\partial x} & \frac{1}{2}\left[\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right] \\ \frac{1}{2}\left[\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right] & \frac{\partial v}{\partial y} \end{bmatrix} \tag{38.82}$$

for the free vortex as specified by the velocity field (38.22). Present the answer in the form of a 2×2 matrix.

EXERCISE 38.6: VANISHING VISCOUS FRICTION FOR RIGID-BODY MOTION
As discussed in Section 26.8.6, viscous effects from molecular viscosity in a non-divergent flow appear in the momentum equation as a Laplacian weighted by a constant molecular viscosity

$$\text{viscous force per mass} = \nu\,\nabla^2 \boldsymbol{v}, \tag{38.83}$$

where $\nu > 0$ is the molecular kinematic viscosity, which is a constant that is a property of the fluid. Show that the viscous operator vanishes for a non-divergent flow in rigid-body rotation. That is, rigid-body motion engenders no frictional dissipation. This result reflects the lack of frictional interaction in a strain-free flow.

EXERCISE 38.7: VORTICITY FOR A C-GRID NUMERICAL MODEL
Vorticity is commonly diagnosed in numerical model simulations. In this exercise we consider how one might determine a discrete equation for the vertical vorticity when the horizontal velocity is arranged according to the Arakawa C-grid (*Arakawa and Lamb*, 1977) commonly used in ocean models, and as depicted in Figure 38.12. Derive an expression for the area averaged vorticity over the shaded grid cell region centered at the vorticity point, $q_{i,j}$. Make use of Stokes' theorem with the surrounding C-grid velocity components and the corresponding grid distances.

EXERCISE 38.8: MOMENT OF INERTIA FOR CYLINDER AND SPHERE
The moment of inertia for a continuous distribution of matter is defined by equation (38.76). In this exercise we compute the moment of inertia for two matter distributions with constant density but with different shapes. The results can be found through Google, so be sure to check your answer.

(a) Determine the moment of inertia for a right circular cylinder, where the moment is computed relative to the axis through the center of the cylinder. For simplicity, use cylindrical-polar coordinates and orient the vertical axis through the center of the cylinder.

(b) Determine the moment of inertia for a sphere computed around an axis through the center of the sphere.

FIGURE 38.12: Layout for velocity on a discrete Arakawa C-grid for use in Exercise 38.7. The central T-point is labeled $T_{i,j}$ and its corresponding vorticity point, $q_{i,j}$, is located to its northeast. This exercise aims to determine the area averaged vorticity for the shaded region. The zonal velocity, $u_{i,j}$, is arranged on the east face of the T-cell, whereas the meridional velocity, $v_{i,j}$, is on the north face. The zonal and meridional grid distances are indicated, thus measuring distances between adjacent tracer points and so measuring the sides of the shaded region.

Chapter 39

Non-divergent barotropic flow

A single layer of homogeneous shallow water fluid is among the simplest conceptual models available for the study of fluid motion. In the language of vorticity as described in Chapter 41, a shallow water layer is a barotropic fluid since it has zero baroclinicity (Section 41.4). Notably, the shallow water layer has constant density, and so the flow has zero three-dimensional divergence ($\nabla \cdot \boldsymbol{v} = 0$). Yet the layer thickness fluctuates as a result of a nonzero divergence to the horizontal flow ($\nabla_z \cdot \boldsymbol{u} \neq 0$), thus prompting some to refer to the shallow water model as a *divergent barotropic model*.

For some geophysical studies, we are primarily interested in the vortical (Rossby wave) motions (Chapters 53 and 52), with these motions having far lower frequency than the gravity wave motions associated with horizontal divergence (Section 53.5 and Chapter 54). The *non-divergent barotropic model* focuses on vortical motion by assuming the horizontal velocity has zero divergence, thus filtering out gravity waves. We here study the non-divergent barotropic model with a flat free surface (i.e., *rigid lid*). For this flow the vertical fluid columns have a fixed thickness, which contrasts to the extensible columns in the shallow water model. To retain a flat upper boundary requires the imposition of an externally imposed *lid pressure*. Indeed, it is the lid pressure that provides the force generating fluid motion. We study the nature of these pressure forces, and in so doing important garner insights into the pressure gradient force.

For many purposes, we do not need to compute the lid pressure since the relative vorticity is the primary dynamical field in the non-divergent barotropic model. Namely, knowledge of the vorticity is sufficient to determine the streamfunction, which then renders the velocity. Furthermore, the absolute vorticity is materially invariant in the absence of irreversible processes such as friction. Hence, meridional motion of a fluid column is associated with an exchange of vorticity between the fluid and the rotating reference frame (i.e., the rotating planet). This exchange constrains the flow, and we examine case studies to illustrate how this constraint affects motion. In particular, this constraint, in its linearized form, provides the physical mechanism for Rossby waves, which we study in Section 52.3.

CHAPTER GUIDE

We here develop some properties of the non-divergent barotropic model, and use this model to exemplify basic features of geophysical flows constrained by conservation of absolute vorticity. The model served as the basis for the pioneering numerical weather prediction model described by *Charney et al.* (1950), and it has become a valued theoretical model for large-scale dynamics. It is also useful for studies of coherent vortex structures, with Chapter 3 of *McWilliams* (2006) exploring analytical vortex solutions. We return to this model in Sections 52.2 and 52.3 when studying Rossby waves. Since all fields in this chapter are a spatial function only of the horizontal position, the vector gradient operator is itself two-dimensional; e.g., $\nabla\psi = \nabla_z\psi$. Furthermore, we retain the use of Cartesian coordinates as per the tangent plane approximation, with extensions to general coordinates following the tensor analysis methods from Chapter 9.

39.1 Basic equations and their properties

The non-divergent barotropic model arises from the following assumptions.

- The flow occurs in a single homogeneous fluid layer, as for the shallow water model from Chapter 36.
- The horizontal velocity is non-divergent: $\nabla \cdot \boldsymbol{u} = \partial_x u + \partial_y v = 0$, which means that the thickness of the layer is time independent.

The second property provides some rather strict constraints on the flow relative to flow in the horizontally divergent shallow water layer. In this section we exhibit the governing equations and derive some of their properties.

39.1.1 Equations for velocity

The velocity equation for the non-divergent barotropic model follows in a manner akin to the shallow water model from Chapter 36. Namely, the fluid is a homogeneous (uniform and constant density) layer so that the horizontal velocity satisfies

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\varphi \qquad \text{and} \qquad \nabla \cdot \boldsymbol{u} = 0, \tag{39.1}$$

where the pressure is normalized according to

$$\varphi = p/\rho \tag{39.2}$$

with ρ the constant layer density, and where material evolution occurs with the two-dimensional non-divergent flow

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla. \tag{39.3}$$

All fields are depth independent and there is no vertical motion ($w = 0$), so that the flow occurs in rigid fluid columns. Making use of the vector identity (2.38)

$$(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = \zeta\,\hat{\boldsymbol{z}} \times \boldsymbol{u} + \nabla(\boldsymbol{u}^2/2), \tag{39.4}$$

brings the velocity equation (39.1) into its vector-invariant form

$$\partial_t \boldsymbol{u} + (f + \zeta)\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla(\varphi + \boldsymbol{u} \cdot \boldsymbol{u}/2), \tag{39.5}$$

which is a useful starting point in Section 39.2 for deriving the equation for the vorticity

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \partial_x v - \partial_y u. \tag{39.6}$$

The horizontal non-divergent flow can be described by a streamfunction

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi \quad \Longrightarrow \quad u = -\partial_y \psi \quad \text{and} \quad v = \partial_x \psi. \tag{39.7}$$

Making use of the identities

$$\nabla\psi = -\hat{\boldsymbol{z}} \times \boldsymbol{u} \Longrightarrow \boldsymbol{u} \cdot \nabla\psi = 0 \tag{39.8}$$

brings the vector-invariant velocity equation (39.5) into the form

$$\partial_t \boldsymbol{u} - (f + \zeta)\,\nabla\psi = -\nabla(\varphi + \boldsymbol{u} \cdot \boldsymbol{u}/2). \tag{39.9}$$

39.1.2 Kinetic energy of the flow

Taking the scalar product of the velocity with the velocity equation (39.9) yields the kinetic energy equation

$$\partial_t \mathcal{K} = -\nabla \cdot [\boldsymbol{u}\,(\mathcal{K} + \varphi)] \Longrightarrow \frac{\mathrm{D}\mathcal{K}}{\mathrm{D}t} = -\nabla \cdot (\boldsymbol{u}\,\varphi), \tag{39.10}$$

where we introduced the kinetic energy per mass

$$\mathcal{K} = \boldsymbol{u} \cdot \boldsymbol{u}/2 = (u^2 + v^2)/2 = \nabla\psi \cdot \nabla\psi/2. \tag{39.11}$$

The gravitational potential energy is constant since the fluid density is a uniform constant and the vertical velocity vanishes. Hence, mechanical energy transformation only involves kinetic energy. Furthermore, the domain integrated kinetic energy is a constant, as shown in Exercise 39.5.

39.1.3 Kinematics of rigid fluid columns

Recall the thickness equation (36.20) for a shallow water layer

$$\frac{\mathrm{D}h}{\mathrm{D}t} = -h\,\nabla \cdot \boldsymbol{u}, \tag{39.12}$$

where $h = \eta - \eta_{\mathrm{b}}$ is the column thickness, $z = \eta(x, y, t)$ is the upper layer interface (the free surface), and $z = \eta_{\mathrm{b}}(x, y)$ is the lower interface (the bottom topography) (see Figure 36.1). With zero divergence in the horizontal velocity, the thickness of a fluid column is constant when moving with the horizontal flow

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\, h = \partial_t(\eta - \eta_{\mathrm{b}}) + \boldsymbol{u} \cdot \nabla(\eta - \eta_{\mathrm{b}}) = 0. \tag{39.13}$$

We *choose* to satisfy this equation by setting the upper surface to be static and flat

$$\eta = 0, \tag{39.14}$$

and furthermore by constraining the horizontal flow to follow the bottom topography

$$\boldsymbol{u} \cdot \nabla\eta_{\mathrm{b}} = (\nabla\psi \times \nabla\eta_{\mathrm{b}}) \cdot \hat{\boldsymbol{z}} = 0. \tag{39.15}$$

As formulated, we study horizontally non-divergent flow within a homogeneous fluid layer, for which a fluid column does not expand or contract, thus constraining the flow to move along lines of constant topography.

For the case of a flat bottom domain that is bounded on its side by a vertical wall, then the no-flow boundary condition takes the form

$$\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{z}} \times \nabla\psi) \cdot \hat{\boldsymbol{n}} = \hat{\boldsymbol{t}} \cdot \nabla\psi = 0, \tag{39.16}$$

where $\hat{\boldsymbol{n}}$ is the horizontal outward unit vector at the boundary, and $\hat{\boldsymbol{t}} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}$ is the unit tangent vector along the boundary. The kinematic condition (39.16) means that the streamfunction is a constant along the solid vertical sidewall boundary. We encountered this boundary condition in Section 22.4.2 when studying two-dimensional non-divergent flow. A zonally reentrant channel is an example considered in Section 52.3 when introducing Rossby waves, whereby ψ is a constant along the northern and southern walls.

39.1.4 Vertical velocity

Vanishing vertical velocity

Without horizontal divergence and with a flat free surface ($\eta = 0$), there is identically zero vertical motion within the layer

$$w = 0. \tag{39.17}$$

Another manner to deduce this property is by noting that the surface kinematic boundary condition for a static and flat free surface leads to

$$w(\eta) = \partial_t \eta + \boldsymbol{u} \cdot \nabla \eta = 0 + 0, \tag{39.18}$$

so that the vertical velocity at $z = \eta = 0$ vanishes. With $w(0) = 0$, and with $\nabla \cdot \boldsymbol{u} = 0$ for the horizontal velocity, then $w = 0$ throughout the layer. Correspondingly, this constraint means that the no-normal flow bottom kinematic condition (Section 20.4.1) renders a horizontal velocity that is aligned with the topography, $\boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} = 0$, which is a property we already encountered in Section 39.1.3. Since the vertical velocity is zero, the gravitational potential energy is a uniform constant, so that the mechanical energy budget involves only the kinetic energy.

What about a non-vanishing vertical velocity?

In Section 39.1.3 we chose to satisfy the thickness equation kinematics by setting $\partial_t \eta = 0$ and $\nabla \eta = 0$, in which case the vertical velocity vanishes so long as the horizontal flow follows the bottom topography. However, a static and flat upper boundary is a sufficient condition but it is not necessary.

Another approach to satisfying the thickness equation (39.13) is to consider a static yet non-flat free surface ($\eta \neq 0$) with horizontal flow constrained so that

$$\boldsymbol{u} \cdot \nabla(\eta - \eta_{\mathrm{b}}) = 0. \tag{39.19}$$

The surface and bottom kinematic boundary conditions then result in a vertical velocity at the surface and bottom

$$w(\eta) = -\boldsymbol{u} \cdot \nabla \eta \quad \text{and} \quad w(\eta_{\mathrm{b}}) = -\boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}}. \tag{39.20}$$

Now these two boundary velocities are equal, thus satisfying $\partial_z w = 0$. If the bottom topography is flat, $\nabla \eta_{\mathrm{b}} = 0$, then $w(\eta_{\mathrm{b}}) = w(\eta) = 0$, in which case $\nabla \eta = 0$, so that the upper surface is flat. If the bottom is not flat, then the kinematic constraints lead to

$$\nabla \eta = \nabla \eta_{\mathrm{b}}, \tag{39.21}$$

so that the upper surface slope equals to the slope of the bottom topography. In the ocean, it is generally the case that the upper ocean surface undulates far less than the bottom topography. Hence, $\nabla \eta = \nabla \eta_{\mathrm{b}}$ is not generally a realistic behavior, though one may study this case particularly with weakly sloping bottom topography.

For the remainder of this chapter we follow the conventional approach whereby $w = 0$. Hence, the upper boundary is static and flat, and we set $\eta = 0$. In the presence of a non-flat bottom, then the horizontal flow follows lines of constant bottom topography, $\boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} = 0$.

39.1.5 Velocity self-advection and the kinetic stress tensor

The velocity self-advection appearing in the velocity equation (39.1) can be written as the divergence of a 2×2 symmetric tensor

$$-(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} = \nabla \cdot \mathbb{E} \Longleftrightarrow -u_m \partial_m u_n = -\partial_m (u_m\, u_n) = \partial_m \mathbb{E}_{mn}, \tag{39.22}$$

where

$$\mathbb{E}_{mn} = -u_m\, u_n \longleftrightarrow \mathbb{E} = -\boldsymbol{u} \otimes \boldsymbol{u} = \begin{bmatrix} -u^2 & -u\, v \\ -u\, v & -v^2 \end{bmatrix}, \tag{39.23}$$

thus bringing the momentum equation (39.1) to the Eulerian form

$$\partial_t \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla \varphi + \nabla \cdot \mathbb{E}. \tag{39.24}$$

We refer to

$$\rho\, \mathbb{E} = -\rho\, \boldsymbol{u} \otimes \boldsymbol{u} \tag{39.25}$$

as the *kinetic stress tensor*, with its three-dimensional form introduced in Section 26.6.

In anticipation of our study of vorticity in Section 39.2, we find it useful to decompose the kinetic stress tensor into its horizontally isotropic and horizontally anisotropic components[1]

$$\mathbb{E} = \begin{bmatrix} -u^2 & -u\, v \\ -u\, v & -v^2 \end{bmatrix} = -\mathcal{K} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} -(u^2 - v^2)/2 & -u\, v \\ -u\, v & (u^2 - v^2)/2 \end{bmatrix} \equiv -\mathcal{K}\, \mathbb{I} + \mathbb{F}, \tag{39.26}$$

where we introduced the kinetic energy per mass according to equation (39.11), as well as the trace-free anisotropic portion of the kinetic stress tensor

$$\mathbb{F} = \mathcal{K}\, \mathbb{I} + \mathbb{E} = \begin{bmatrix} -(u^2 - v^2)/2 & -u\, v \\ -u\, v & (u^2 - v^2)/2 \end{bmatrix} \Longleftrightarrow \mathbb{F}_{mn} = \mathcal{K}\, \delta_{mn} - u_m\, u_n. \tag{39.27}$$

Making use of the decomposition (39.26) brings the velocity equation (39.28) to the form

$$\partial_t \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = \nabla \cdot [\mathbb{F} - \mathbb{I}(\mathcal{K} + \varphi)]. \tag{39.28}$$

Comparing to the vector-invariant velocity equation (39.5) allows us to infer the identity

$$\nabla \cdot \mathbb{F} = -\zeta\, (\hat{\boldsymbol{z}} \times \boldsymbol{u}). \tag{39.29}$$

We provide an alternative derivation of this identity in Exercise (39.1).

39.1.6 Further reading

As discussed by *Hoskins et al.* (1983), *Waterman and Hoskins* (2013) and *Waterman and Lilly* (2015), the decomposition (39.26) is useful for developing a geometric interpretation of eddying flow features.

39.2 Vorticity

For the two-dimensional non-divergent flow with a vanishing vertical velocity, the vertical component of the relative vorticity is the only nonzero vorticity component, and it is given by the

[1] Recall our discussion of isotropy in Section 1.8.

Laplacian of the streamfunction

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \partial_x v - \partial_y u = \nabla^2 \psi. \tag{39.30}$$

We here derive basic features of the vorticity for this fluid on the β-plane whereby the Coriolis parameter is (Section 25.5)

$$f = f_0 + \beta\,(y - y_0). \tag{39.31}$$

39.2.1 Vorticity equation

To form the dynamical equation for the vorticity, take the zonal derivative of the meridional momentum equation (see equation (39.1)) and meridional derivative of the zonal momentum equation

$$\frac{\partial}{\partial t}\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right) + \frac{\partial}{\partial x}\left[\nabla \cdot (\boldsymbol{u}\, v)\right] - \frac{\partial}{\partial y}\left[\nabla \cdot (\boldsymbol{u}\, u)\right] + f \nabla \cdot \boldsymbol{u} + \beta\, v = 0. \tag{39.32}$$

Notice how the pressure gradient dropped out since there is zero baroclinicity for a barotropic flow (see Section 41.4 for a discussion of baroclinicity). We now make use of the identity

$$\frac{\partial}{\partial x}\left[\nabla \cdot (\boldsymbol{u}\, v)\right] - \frac{\partial}{\partial y}\left[\nabla \cdot (\boldsymbol{u}\, u)\right] = \frac{\partial \boldsymbol{u}}{\partial x} \cdot \nabla v - \frac{\partial \boldsymbol{u}}{\partial y} \cdot \nabla u + \boldsymbol{u} \cdot \nabla \zeta = \boldsymbol{u} \cdot \nabla \zeta, \tag{39.33}$$

where we used the non-divergence condition, $\partial_x u + \partial_y v = 0$, thus rendering

$$\frac{\partial \boldsymbol{u}}{\partial x} \cdot \nabla v - \frac{\partial \boldsymbol{u}}{\partial y} \cdot \nabla u = \frac{\partial u}{\partial x}\frac{\partial v}{\partial x} + \frac{\partial v}{\partial x}\frac{\partial v}{\partial y} - \frac{\partial u}{\partial y}\frac{\partial u}{\partial x} - \frac{\partial v}{\partial y}\frac{\partial u}{\partial y} \tag{39.34a}$$

$$= -\frac{\partial v}{\partial y}\frac{\partial v}{\partial x} + \frac{\partial v}{\partial x}\frac{\partial v}{\partial y} + \frac{\partial u}{\partial y}\frac{\partial v}{\partial y} - \frac{\partial v}{\partial y}\frac{\partial u}{\partial y} \tag{39.34b}$$

$$= 0. \tag{39.34c}$$

We are thus led to the vorticity equation

$$\frac{\partial \zeta}{\partial t} + \nabla \cdot (\boldsymbol{u}\, \zeta) = -\beta\, v \quad \text{and} \quad \frac{\mathrm{D}\zeta}{\mathrm{D}t} = -\beta\, v. \tag{39.35}$$

Hence, the material evolution of relative vorticity in the non-divergent barotropic fluid is only affected by meridional advection of planetary vorticity. Since $\beta > 0$ over the globe, northward flow ($v > 0$) produces a negative source (clockwise tendency) for relative vorticity following a fluid parcel. This source term is the *beta effect* that we study in Section 41.6.

39.2.2 Absolute vorticity is the potential vorticity

Since f is time independent, we can write the vorticity equation (39.35) in the form

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\zeta_{\mathrm{a}} = 0, \tag{39.36}$$

where

$$\zeta_{\mathrm{a}} = \zeta + f \tag{39.37}$$

is the vertical component of the absolute vorticity. This is the simplest of the variety of vorticity equations we encounter in this book. It is simple because there are no sources on the right hand side, with such sources studied in Chapter 41. In particular, there is no stretching or tilting of fluid columns in the non-divergent barotropic fluid, which means that such processes do not

provide a source to the vorticity in this fluid.[2] Anticipating our discussion of potential vorticity in Chapter 42, we note that the material conservation of ζ_{a} allows us to identify the potential vorticity with the absolute vorticity for the non-divergent barotropic fluid

$$q = \zeta_{\mathrm{a}} = \zeta + f \Longrightarrow (\partial t + \boldsymbol{u}\cdot)\nabla q = 0 \Longrightarrow \mathrm{D}q/\mathrm{D}t = 0. \tag{39.38}$$

We return to this connection in equation (42.24), showing that the absolute vorticity is indeed the Ertel potential vorticity for a two-dimensional non-divergent barotropic fluid with $w = 0$.

To maintain a materially constant absolute vorticity requires the relative vorticity to change oppositely to that of the planetary vorticity. For example, in the northern hemisphere, the relative vorticity must decrease ($\zeta \downarrow$) for fluid particles moving northward. This change in the relative vorticity is needed to counteract the increasing planetary vorticity ($f \uparrow$) when moving northward. This result accords with the $-\beta\, v$ source found in the relative vorticity equation (39.35). Furthermore, it is a reflection of the beta effect studied in Section 41.6.2.

The presence of topography adds further richness to the flow. According to the kinematic boundary condition (39.15), horizontal flow is aligned with isobaths (lines of constant bathymetry or topography). Flow moving along constant isobaths generally crosses latitude lines, and in so doing the relative vorticity must change precisely to maintain $f + \zeta$ materially constant.

39.2.3 Jacobian forms of vorticity advection

In some contexts it is convenient to write the advection operator acting on relative vorticity as

$$\begin{aligned}
\boldsymbol{u}\cdot\nabla\zeta &= u\,\partial_x\zeta + v\,\partial_y\zeta && (39.39\mathrm{a})\\
&= -\partial_y\psi\,\partial_x\zeta + \partial_x\psi\,\partial_y\zeta && (39.39\mathrm{b})\\
&= \hat{\boldsymbol{z}}\cdot(\nabla\psi\times\nabla\zeta) && (39.39\mathrm{c})\\
&\equiv J(\psi,\zeta), && (39.39\mathrm{d})
\end{aligned}$$

where J is the Jacobian operator

$$J(A,B) = \hat{\boldsymbol{z}}\cdot(\nabla A\times\nabla B) = \frac{\partial A}{\partial x}\frac{\partial B}{\partial y} - \frac{\partial A}{\partial y}\frac{\partial B}{\partial x}. \tag{39.40}$$

We can also make use of the Jacobian for the advection of absolute vorticity[3]

$$\boldsymbol{u}\cdot\nabla\zeta_{\mathrm{a}} = \hat{\boldsymbol{z}}\cdot(\nabla\psi\times\nabla\zeta_{\mathrm{a}}) \equiv J(\psi,\zeta+f). \tag{39.41}$$

39.2.4 Taylor-Bretherton identity

An equivalent means to write the vorticity equation is to start from the velocity equation in the form (39.28). Taking the curl and projecting onto the vertical direction then leads to

$$\partial_t\zeta = -\beta\, v + \hat{\boldsymbol{z}}\cdot[\nabla\times\nabla\cdot\mathbb{F}]. \tag{39.42}$$

[2] In Section 41.5, we see how stretching and tilting of fluid columns provides a sources of vorticity for more general fluid flow.

[3] The Jacobian operator corresponds to the Poisson bracket used in Hamiltonian mechanics.

The nonlinear forcing from the anisotropic kinetic stress can be written

$$\hat{\boldsymbol{z}} \cdot [\nabla \times \nabla \cdot \mathbb{F}] = \hat{\boldsymbol{z}}_n \, \epsilon_{npq} \, \partial_p (\partial_m \mathbb{F}_{mq}) \tag{39.43a}$$
$$= \partial_m \partial_p (\epsilon_{npq} \, \hat{\boldsymbol{z}}_n \, \mathbb{F}_{mq}) \tag{39.43b}$$
$$= -\partial_m \partial_p (\epsilon_{pnq} \, \hat{\boldsymbol{z}}_n \, \mathbb{F}_{qm}) \tag{39.43c}$$
$$= -\partial_m \partial_p (\hat{\boldsymbol{z}} \times \mathbb{F})_{pm} \tag{39.43d}$$
$$= -\nabla \cdot [\nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})], \tag{39.43e}$$

where we used symmetry of the anisotropic kinetic tensor, $\mathbb{F}_{mq} = \mathbb{F}_{qm}$.

Taylor-Bretherton identity for relative vorticity

Comparing to the vorticity equation in the form (39.35) reveals the identity

$$\nabla \cdot (\boldsymbol{u} \, \zeta) = \nabla \cdot [\nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})] \Longrightarrow \boldsymbol{u} \, \zeta = \nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F}). \tag{39.44}$$

This equation says that the advective vorticity flux equals to the divergence of the counter-clockwise rotated anisotropic kinetic stress tensor. Equation (39.44) is a special form of the *Taylor-Bretherton identity* that provides a connection between the vorticity flux and the momentum flux. We encounter the shallow water form of this identity Chapter 63 when studying the decomposition of eddy and mean flows.

Verifying the Taylor-Bretherton identity

The divergence expression on the left hand side of equation (39.44) can be satisfied by $\hat{\boldsymbol{z}} \times \nabla \Upsilon + \nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})$, with Υ an arbitrary gauge function. However, $\Upsilon = 0$ is zero for the anisotropic kinetic tensor (39.27), as seen by

$$[\nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})]_1 = \partial_m (\epsilon_{mnp} \, \hat{\boldsymbol{z}}_n \, \mathbb{F}_{p1}) \tag{39.45a}$$
$$= \epsilon_{m3p} \, \partial_m \mathbb{F}_{p1} \tag{39.45b}$$
$$= -\epsilon_{3mp} \, \partial_m \mathbb{F}_{p1} \tag{39.45c}$$
$$= -\epsilon_{312} \, \partial_1 \mathbb{F}_{21} - \epsilon_{321} \, \partial_2 \mathbb{F}_{11} \tag{39.45d}$$
$$= -\partial_x \mathbb{F}_{21} + \partial_y \mathbb{F}_{11} \tag{39.45e}$$
$$= \partial_x (u \, v) + \partial_y (-u^2 + v^2)/2 \tag{39.45f}$$
$$= v \, \partial_x u + u \, \partial_x v - u \, \partial_y u + v \, \partial_y v \tag{39.45g}$$
$$= u \, \zeta, \tag{39.45h}$$

and likewise

$$[\nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})]_2 = \partial_y \mathbb{F}_{12} - \partial_x \mathbb{F}_{22} = v \, \zeta. \tag{39.46}$$

Taylor-Bretherton identity for potential vorticity

Building from the development for relative vorticity, we can readily connect the potential vorticity flux, $\boldsymbol{u} \, q$, to the anisotropic kinetic stress. We do so by considering the two equivalent forms for the potential vorticity equation

$$\partial - tq = -\nabla \cdot (\boldsymbol{u} \, q) \quad \text{and} \quad \partial_t q = -\nabla \cdot [\boldsymbol{u} \, f + \nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F})]. \tag{39.47}$$

Hence, the Taylor-Bretherton identity for potential vorticity in the two dimensional non-divergent flow is given by

$$\boldsymbol{u}\, q = \boldsymbol{u}\, f + \nabla \cdot (\hat{\boldsymbol{z}} \times \mathbb{F}). \tag{39.48}$$

39.2.5 Poisson equation for the streamfunction

Given boundary conditions, the barotropic vorticity equation (39.36) allows us to determine the evolution of vorticity. We can in turn invert the Poisson equation[4]

$$\nabla^2 \psi = \zeta \tag{39.49}$$

to determine the streamfunction and then the velocity field, $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$. This inversion requires information about the boundary conditions for the streamfunction, as discussed in Section 39.1.3. By this method, time integration of the absolute vorticity equation is sufficient to fully specify time evolution of the horizontal velocity. Notably, we do not need to explicitly determine pressure to determine the flow.

39.2.6 Zonal flow as an exact geostrophic solution

An arbitrary zonal velocity with a meridional shear, $\boldsymbol{u} = U(y)\,\hat{\boldsymbol{x}}$, is an exact solution of the perfect fluid non-divergent barotropic model. We see this property by plugging into the velocity equation (39.1) and noting that $\mathrm{D}\boldsymbol{u}/\mathrm{D}t = 0$. Hence, this flow is an exact geostrophic solution whose pressure field is itself also just a function of latitude and whose meridional gradient is determined by

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\varphi \Longrightarrow \partial_y \varphi = -f(y)\,U(y). \tag{39.50}$$

Furthermore, each term in the vorticity equation (39.35) identically vanishes, so that the vorticity

$$\zeta = -\partial_y U \tag{39.51}$$

remains constant in time at each point in space. These properties make $\boldsymbol{u} = U(y)\,\hat{\boldsymbol{x}}$ a common choice for when studying fluctuations such as Rossby waves in the presence of a nonzero background flow (Section 52.3).

39.2.7 A point vortex and the free space Green's function

Consider an axially symmetric vortex centered at the origin, $\boldsymbol{x} = 0$, and in an infinite free space so there are no boundaries. Making use of polar coordinates from Section 10.3, we know that the relative vorticity for this vortex is related to the velocity via

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = r^{-1}\,\partial_r(r\,u^\vartheta), \tag{39.52}$$

which holds since all of the flow fields have axial symmetry, meaning that all fields are a function only of the radial distance from the origin. Now further assume the vorticity is given by

$$\zeta^{\text{point}} = -\alpha\,\delta(r), \tag{39.53}$$

where α is a constant and $\delta(r)$ is the Dirac delta whose value is formally infinite at $r = 0$ and vanishes for $r > 0$. That is, we assume the vortex has zero extent yet infinite strength.[5] We can

[4] See Section 3.4 for a study of the Poisson equation.
[5] See Section 5.3 for properties of the Dirac delta.

connect the constant, α, to the circulation by considering an arbitrary circuit that encloses the origin

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{r} = \int_{\mathcal{S}} \zeta^{\text{point}} \, \mathrm{d}\mathcal{S} = -\alpha, \tag{39.54}$$

so that

$$\zeta^{\text{point}} = \mathcal{C}\, \delta(r). \tag{39.55}$$

Referring to the Green's function discussion in Section 5.4, we see that the streamfunction for the point vortex (again, in the absence of boundaries) is the free space Green's functions for the Laplace operator. Equation (5.40b) provides an expression for this Green's function in the two-dimensional space of the barotropic model, which then leads to the point vortex streamfunction

$$\nabla^2 \psi^{\text{point}} = \mathcal{C}\, \delta(r) \Longleftrightarrow \psi^{\text{point}} = (\mathcal{C}/2\pi) \ln(r/r_0). \tag{39.56}$$

We introduced the arbitrary constant, r_0, to ensure the argument to the natural log is dimensionless. But r_0 merely adds a constant to the streamfunction, and so its precise value is physically irrelevant and so it is ignored in the following. The flow associated with the point vortex is given by

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla \psi^{\text{point}} = \frac{\mathcal{C}\, \hat{\boldsymbol{\vartheta}}}{2\,\pi\, r}. \tag{39.57}$$

Evidently, the flow is a purely angular swirling motion around the point vortex that falls off as the inverse distance from the vortex.

Though highly idealized, the flow field arising from the point vortex is aligned with that in the far field for realistic localized vorticies, thus making the point vortex a physically relevant theoretical idealization. The discussion here briefly touched upon the theoretical richness of point vorticies in fluid mechanics, with chapter 3 of *McWilliams* (2006) offering a more thorough study, also in the context of two dimensional non-divergent flow.

39.2.8 Green's function solution for the streamfunction

Since the Poisson equation for the streamfunction is a linear partial differential equation, we can use the principle of superposition to have the point vortex solution (39.56) build up the streamfunction arising from an arbitrary vorticity. This approach makes use of the Green's function method from Chapter 5. For brevity, we only consider the case without boundaries, with the more general case including boundaries detailed in Sections 5.6 and 5.7.

So we seek a streamfunction that satisfies the Poisson equation

$$\nabla^2 \psi = \zeta, \tag{39.58}$$

with ζ a given vorticity that is localized in space. Making use of the Green's function solution (5.114), and assuming all boundary terms vanish,[6] leads to

$$\psi(\boldsymbol{x}) = \frac{1}{2\pi} \int \zeta(\boldsymbol{y}) \ln(|\boldsymbol{x} - \boldsymbol{y}|) \, \mathrm{d}A(\boldsymbol{y}) \tag{39.59}$$

where $\mathrm{d}A(\boldsymbol{y})$ is the area element for the horizontal integral over $\boldsymbol{y}$. This streamfunction is built by convolving the vorticity source with the free space Green's function. The corresponding velocity

[6] This assumption means that all boundary terms decay sufficiently rapidly when moving away from the vorticity source region.

is given by

$$\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi = \frac{1}{2\pi} \int \zeta(\boldsymbol{y}) \frac{\hat{\boldsymbol{z}} \times (\boldsymbol{x} - \boldsymbol{y})}{|\boldsymbol{x} - \boldsymbol{y}|^2} \, \mathrm{d}\boldsymbol{y}. \tag{39.60}$$

As a check, we see that if the vorticity source is chosen to be a point vortex at the origin, $\zeta(\boldsymbol{y}) = \mathcal{C}\,\delta(\boldsymbol{y})$, then $\boldsymbol{u}$ correctly reduces to the point vortex velocity (39.57).

39.3 Connection to equivalent barotropic flow

In many cases, flows respecting the quasi-geostrophic assumptions (Section 44.5) possess a vertical profile that can be separated from the horizontal. In this case we write the horizontal velocity as

$$\boldsymbol{u}(x, y, z, t) = \Gamma(z)\, \boldsymbol{u}^{\mathrm{eb}}(x, y, t), \tag{39.61}$$

where $\Gamma > 0$ is a single-signed non-dimensional structure function that has a unit vertical average, $\langle \Gamma \rangle = 1$, when computed over the fluid layer thickness, and where $\boldsymbol{u}^{\mathrm{eb}}(x, y, t)$ carries the horizontal spatial dependence of the flow. With $\Gamma > 0$, the horizontal flow remains in the same direction throughout the fluid column; i.e., eastward flow at the top of the column remains eastward at the bottom. This orientation of the flow is generally referred to as *equivalent barotropic*.

39.3.1 Vorticity equation for the depth averaged flow

To connect the very particular form (39.61) for the flow with the non-divergent barotropic model, we anticipate a discussion in Section 46.2.2 in which the quasi-geostrophic vorticity equation is shown to be

$$\frac{\partial \zeta_{\mathrm{g}}}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla \zeta_{\mathrm{g}} = -\beta\, \zeta_{\mathrm{g}} + f_0 \frac{\partial w}{\partial z}, \tag{39.62}$$

where $\boldsymbol{u}_{\mathrm{g}}$ is the horizontally non-divergent geostrophic velocity, and $\zeta_{\mathrm{g}} = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}_{\mathrm{g}})$ is the geostrophic relative vorticity. We see that the quasi-geostrophic vorticity is affected by both the beta-effect and by vertical stretching of fluid columns (the $\partial w/\partial z$ term), whereas vertical stretching is absent from the non-divergent barotropic vorticity equation (39.35). There are occasions in which it is sensible to assume the vertical velocity for a quasi-geostrophic flow vanishes at the top and bottom of the fluid domain, such as when considering flow in the absence of topography. In this case, performing the decomposition (39.61) for the horizontal flow and then taking a vertical average of the quasi-geostrophic vorticity equation (39.62) leads to

$$\frac{\partial \zeta_{\mathrm{g}}^{\mathrm{eb}}}{\partial t} + \langle \Gamma^2 \rangle\, \boldsymbol{u}_{\mathrm{g}}^{\mathrm{eb}} \cdot \nabla \zeta_{\mathrm{g}}^{\mathrm{eb}} = -\beta\, v_{\mathrm{g}}^{\mathrm{eb}}. \tag{39.63}$$

This equation motivates us to define

$$\boldsymbol{u}^* = \langle \Gamma^2 \rangle\, \boldsymbol{u}_{\mathrm{g}}^{\mathrm{eb}} \quad \text{and} \quad \zeta^* = \langle \Gamma^2 \rangle\, \zeta_{\mathrm{g}}^{\mathrm{eb}}, \tag{39.64}$$

which are the original geostrophic fields, $\boldsymbol{u}_{\mathrm{g}}(x, y, z, t)$ and $\zeta_{\mathrm{g}}(x, y, z, t)$, when evaluated at a depth where $\Gamma(z^*) = \langle \Gamma^2 \rangle$. The depth, z^*, is known as the *equivalent barotropic depth*. Introduction of the starred fields then brings the vorticity equation (39.63) into the form of the non-divergent barotropic vorticity equation

$$\frac{\partial \zeta^*}{\partial t} + \boldsymbol{u}^* \cdot \nabla \zeta^* = -\beta\, v^*. \tag{39.65}$$

39.3.2 Comments

Charney et al. (1950) justified their study of the non-divergent barotropic vorticity model by noting its connection to the commonly observed equivalent barotropic stucture of the large-scale middle latitude atmosphere. The equivalent barotropic model has been a very useful analysis and prediction tool for meteorologists, and it formed the basis of many numerical weather prediction models into the 1980s. Section 7.1 of *Haltiner and Williams* (1980) offers further details on such numerical models.

One hypothesis for why quasi-geostrophic flows tend towards an equivalent barotropic profile relates to movement of energy in rotationally dominant turbulent flows, whereby energy cascades to the larger scales. As discussed in *Smith and Vallis* (2001) and *Venaille et al.* (2012), among others, this *inverse* energy cascade pumps mechanical energy into a vertically uniform or "barotropic" stucture. In a realistic flow, including topography, stratification, and variable forcing, this cascade is never realized completely, thus rendering a flow that approaches the equivalent barotropic structure.

The case of $f = 0$ with flat bottom is referred to as *two-dimensional turbulence* (*Kraichnan and Montgomery*, 1980). This model has a history of key theoretical results that presaged their analog in quasi-geostrophic turbulence. See chapters 11 and 12 of *Vallis* (2017) for further discussion of this model and its relevance to geostrophic turbulence of the ocean and atmosphere.

39.4 The externally applied lid pressure

As noted in Section 39.2.5, we do not need to determine the lid pressure to determine the evolution of the non-divergent barotropic flow. Instead, we can determine the flow by time stepping vorticity and then inverting the elliptic problem to get the streamfunction. Furthermore, the free surface is absolutely flat even in the presence of topography. Hence, there is no pressure generated by undulations of the free surface. So how is there flow in this model?

As we see in this section, the non-divergent barotropic model maintains a flat *rigid lid* upper surface due to an externally imposed *lid pressure*. In turn, it is the lid pressure that provides the force that drives flow in this model. We here expose details to understand the fundamental, yet somewhat hidden, role for the lid pressure.

To further motivate the analysis, we again emphasize the strong constraints placed on the velocity field, which must satisfy the following conditions at each space and time point

$$\nabla \cdot \boldsymbol{u} = 0 \quad \text{and} \quad \boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} = 0 \quad \text{and} \quad w = 0. \tag{39.66}$$

Kinematics of the constrained flow induce a depth-independent pressure that enforces these constraints. Examining the resulting pressure field furthers our understanding of the forces acting in the fluid. This role for pressure as an enforcer of non-divergence is shared by the three-dimensional non-divergent flow found in a Boussinesq ocean (see Section 30.3). It is simpler to visualize fields in the two dimensional non-divergent barotropic model, thus facilitating understanding and insights that are also useful for the three dimensional case.

39.4.1 Poisson equation for pressure

We derive the pressure equation by using the two-dimensional non-divergence property of the horizontal flow and then developing a diagnostic relation. We can eliminate the time derivative from equation (39.1) by taking $\partial/\partial x$ on the zonal equation and $\partial/\partial y$ on the meridional equation,

then adding. The result is a diagnostic relation for the Laplacian of the pressure[7]

$$-\nabla^2\varphi = \partial_x[\nabla\cdot(\boldsymbol{u}\,u)] + \partial_y[\nabla\cdot(\boldsymbol{u}\,v)] - f\,\zeta + \beta\,u, \tag{39.67}$$

where we set

$$\nabla\cdot\partial_t\boldsymbol{u} = \partial_t\nabla\cdot\boldsymbol{u} = 0 \Longrightarrow \partial_x(\partial_t u) = -\partial_y(\partial_t v). \tag{39.68}$$

Making use of the boundary conditions discussed in Section 39.1.3, the elliptic partial differential equation (39.67) can be inverted to find the pressure field (Section 3.4). As for the three-dimensional Boussinesq ocean, or for a three-dimensional incompressible fluid, pressure is the force that instantaneously constrains the velocity to remain non-divergent.

Numerically inverting an elliptic operator in equation (39.67) is straightforward on simple domains, such as flat bottom rectangular regions or a smooth sphere. However, when the bottom is not flat, or when there are islands (i.e., the domain is not simply connected), then the elliptic inversion can be numerically difficult to perform. This algorithmic complexity is one reason numerical barotropic models are less commonly used for realistic numerical experimentation than the more general shallow water models. Even so, as pursued in the remainder of this section, we can make use of idealized configurations to garner insight into how pressure maintains the flow constraints.

39.4.2 Gradient wind balance

For two-dimensional non-divergent flow we can write the self-advection in terms of the streamfunction, or equivalently as the Jacobian of the velocity field, through the following manipulations

$$\begin{aligned}
\partial_x[\nabla\cdot(\boldsymbol{u}\,u)] + \partial_y[\nabla\cdot(\boldsymbol{u}\,v)] &= \nabla\cdot(\partial_x\boldsymbol{u}\,u) + \nabla\cdot(\boldsymbol{u}\,\partial_x u) + \nabla\cdot(\partial_y\boldsymbol{u}\,v) + \nabla\cdot(\boldsymbol{u}\,\partial_y v) && \text{(39.69a)}\\
&= \partial_x\boldsymbol{u}\cdot\nabla u + \partial_y\boldsymbol{u}\cdot\nabla v && \text{(39.69b)}\\
&= (\partial_x u)^2 + (\partial_y v)^2 + 2\,\partial_x v\,\partial_y u && \text{(39.69c)}\\
&= 2\,[(\partial_x u)^2 + \partial_x v\,\partial_y u] && \text{(39.69d)}\\
&= 2\,[(\partial_{xy}\psi)^2 - \partial_{xx}\psi\,\partial_{yy}\psi] && \text{(39.69e)}\\
&= 2\,\hat{\boldsymbol{z}}\cdot(\partial_x\nabla\psi\times\partial_y\nabla\psi) && \text{(39.69f)}\\
&= -2\,J(\partial_x\psi,\partial_y\psi), && \text{(39.69g)}\\
&= 2\,J(v,u), && \text{(39.69h)}
\end{aligned}$$

where we introduced the Jacobian operator from equation (39.35). The pressure equation (39.67) thus takes on the form

$$-\nabla^2\varphi = 2\,J(u,v) - \nabla\cdot(f\,\nabla\psi), \tag{39.70}$$

where we also wrote

$$-\nabla\cdot(f\,\nabla\psi) = -f\,\nabla^2\psi - \beta\,\partial_y\psi = -f\,\zeta + \beta\,u. \tag{39.71}$$

We refer to this equation as a *gradient wind balance* in analog to the gradient wind balance discussed in Section 33.6. Here, the Jacobian term accounts for the centrifugal acceleration of the curved fluid motion, and the $\nabla\cdot(f\,\nabla\psi)$ term accounts for the Coriolis acceleration, both for the f-plane and β-plane. Equation (39.70) thus offers a more accurate diagnostic relation for the

[7] We maintain the minus sign on the left hand side of equation (39.67) so that a positive source on the right hand side leads to a positive φ. We can readily understand the sign by taking a Fourier transform, whereby the Laplacian operator picks up a minus sign when converted to Fourier space. We follow the same sign convention when studying the Green's function for the Poisson equation in Chapter 5.

pressure field than provided by assuming a geostrophically balanced flow.

39.4.3 Pressure source from self-advection

We here introduce yet another way to examine the self-advection source appearing in the pressure equation (39.67) by writing it as

$$\partial_x[\nabla\cdot(\boldsymbol{u}\,u)] + \partial_y[\nabla\cdot(\boldsymbol{u}\,v)] = \mathbb{S}_{mn}\,\mathbb{S}_{mn} - \mathbb{R}_{mn}\,\mathbb{R}_{mn}, \tag{39.72}$$

where the strain rate tensor, $\mathbb{S}$, and rotation tensor, $\mathbb{R}$, have components given by equations (19.43a) and (19.43b)

$$\mathbb{S}_{mn} = (\partial_n v_m + \partial_m v_n)/2 = \mathbb{S}_{nm} \qquad \text{strain rate tensor} \tag{39.73}$$

$$\mathbb{R}_{mn} = (\partial_n v_m - \partial_m v_n)/2 = -\mathbb{R}_{nm} \qquad \text{rotation tensor.} \tag{39.74}$$

For two-dimensional flow the rotation tensor is related to the relative vorticity via

$$\mathbb{R}_{mn} = -\epsilon_{mn}\,\zeta/2 = -\epsilon_{mn}\,\nabla^2\psi/2, \tag{39.75}$$

where ϵ_{mn} is the anti-symmetric Levi-Civita permutation symbol (see Section 1.4.1)

$$\epsilon_{mn} = \begin{bmatrix} \epsilon_{11} & \epsilon_{12} \\ \epsilon_{21} & \epsilon_{22} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \tag{39.76}$$

which leads to

$$\mathbb{R}_{mn}\,\mathbb{R}_{mn} = \zeta^2/2. \tag{39.77}$$

The identity (39.72) indicates that the squared strain rate (sometimes referred to as the *splat*) provides a positive source to the Poisson equation (39.67) whereas squared vorticity provides a negative source. Bringing these results together leads us to write the pressure equation as

$$-\nabla^2\varphi = \mathbb{S}_{mn}\,\mathbb{S}_{mn} - \zeta^2/2 - \nabla\cdot(f\,\nabla\psi) = 2\,[(\partial_{xy}\psi)^2 - \partial_{xx}\psi\,\partial_{yy}\psi] - \nabla\cdot(f\,\nabla\psi), \tag{39.78}$$

where the second equality made use of equation (39.69e) to write the pressure source fully in terms of the streamfunction.

In the following sections, we present two examples to help support understanding of how pressure gradients arise in a 2d-barotropic flow to maintain, at each time instance, a non-divergent two-dimensional velocity field. We start by assuming a non-rotating reference frame, so that it is sufficient to examine how pressure responds to the nonlinear source term $\mathbb{S}_{mn}\,\mathbb{S}_{mn} - \zeta^2/2$. Thereafter we include sources from the rotating reference frame.

39.4.4 Pressure source from circular rigid-body motion

Consider a velocity field in a flat domain that is initialized in circular rigid-body motion (Figure 39.1)

$$\boldsymbol{u} = \boldsymbol{\Omega}\times\boldsymbol{x} = \Omega\,(-y\,\hat{\boldsymbol{x}} + x\,\hat{\boldsymbol{y}}), \tag{39.79}$$

where $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}$ is a constant angular velocity. This flow has zero strain (as do all rigid-body flows) yet constant vorticity

$$\hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{u}) = \zeta = 2\,\Omega \Longrightarrow -\mathbb{R}_{mn}\,\mathbb{R}_{mn} = -2\,\Omega^2. \tag{39.80}$$

FIGURE 39.1: Left panel: example flow field from rigid-body rotation, $\boldsymbol{u} = \boldsymbol{\Omega} \times \boldsymbol{x} = \Omega\,(-y, x)$, which has vorticity $\nabla \times \boldsymbol{u} = 2\,\boldsymbol{\Omega}$ and zero strain. Right panel: corresponding acceleration from self-advection, $-(\boldsymbol{u} \cdot \nabla)\,\boldsymbol{u} = \Omega^2\,\boldsymbol{x}$. The acceleration from self-advection is exactly compensated by the pressure gradient force: $-(\boldsymbol{u} \cdot \nabla)\,\boldsymbol{u} - \nabla\varphi = 0$, thus allowing for the rigid-body motion to be an exact solution to two-dimensional non-divergent flow. The units are arbitrary.

The velocity time tendency from the self-advection acceleration is

$$-(\boldsymbol{u} \cdot \nabla)\,\boldsymbol{u} = \Omega^2\,\boldsymbol{x}, \tag{39.81}$$

which is the outward directed centrifugal acceleration associated with the circular rigid-body motion.[8]

Pressure gradient acceleration exactly balances centrifugal acceleration

If acting alone, the centrifugal acceleration would create a velocity field that diverges from the origin. However, the velocity is constrained to remain non-divergent at each instance, so the centrifugal acceleration cannot be the full story. Indeed, to maintain a non-divergent flow we find a pressure gradient that exactly balances the centrifugal acceleration. This pressure gradient is established instantaneously as per the solution to the elliptic pressure equation. We thus infer that there is a low pressure at the origin so that the pressure gradient force points inward, thus balancing the centrifugal acceleration.

We can extrapolate from this example to conclude that vorticity provides a source of low pressure in a non-divergent flow. Furthermore, since the centrifugal acceleration from the velocity self-advection is exactly balanced by the pressure gradient acceleration, the rigid-body flow is an exact steady solution for the non-divergent and non-rotating (zero Coriolis) barotropic system. This result holds even in the presence of viscosity, since the rigid-body flow has no strain and hence it does not support viscous stresses (see Section 26.8).

Rotationally symmetric pressure field

We can support the above general statements by deriving an explicit expression for the pressure field, and we do so by solving the pressure Poisson equation (39.67). Since we have assumed zero planetary rotation ($f = 0$), equation (39.67) reduces to

$$-\nabla^2\varphi = -2\,\Omega^2. \tag{39.82}$$

[8] We considered the more general case in Section 33.2.2 when decomposing the material acceleration for two-dimensional flow into natural coordinates.

FIGURE 39.2: Left panel: example purely strained flow field with zero vorticity, $\boldsymbol{u} = \Omega\,(-x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}})$. Right panel: corresponding converging acceleration from self-advection, $-(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} = -\Omega^2\,\boldsymbol{x}$. The units are arbitrary.

Furthermore, the solid-body flow is assumed to be rotationally symmetric so that all fields have only radial dependence. In this case, pressure satisfies the ordinary differential equation

$$r^{-1}\,\partial_r(r\,\partial_r\varphi) = 2\,\Omega^2, \tag{39.83}$$

where r is the radial distance from the origin and we used the polar coordinate version of the Laplacian given by equation (10.83b). The solution to the pressure equation (39.83) is given by

$$\varphi = (\Omega\,r)^2/2 \quad \text{and} \quad -\nabla\varphi = -\Omega^2\,\boldsymbol{x} = (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}, \tag{39.84}$$

where we set $\varphi(r=0) = 0$. Evidently, the pressure grows parabolically moving radially away from the center.

The pressure field in relation to rigid-body rotating shallow water

To help understand the physics of the pressure field (39.84), recall the analysis in Section 28.4 of a rigid-body rotating homogeneous shallow water fluid layer in a cylindrical tank. In contrast to the barotropic system, the horizontal velocity in a homogeneous fluid layer, such as in a shallow water fluid, is divergent so that the layer thickness is not constrained to remain flat. Hence, the centrifugal acceleration causes the velocity to diverge from the center so that the layer thickness increases radially outward, with the layer bounded by the tank wall. At steady state, the homogeneous fluid layer has a parabolic free surface with a minimum at the center (see equation (28.95)). The parabolic free surface creates a pressure field that precisely corresponds to the pressure field (39.84) in the non-divergent barotropic system. Note that the dynamical adjustment of a homogeneous shallow water fluid layer contain linear fluctuations in the form of gravity waves such as discussed in Chapter 37. In contrast, the adjustment required to reach a steady state occurs instantaneously in the non-divergent barotropic fluid.

39.4.5 Pressure source from irrotational flow

Now consider the following pure strain flow (Figure 39.2)

$$\boldsymbol{u} = \Omega\,(-x\,\hat{\boldsymbol{x}} + y\,\hat{\boldsymbol{y}}), \tag{39.85}$$

whose vorticity vanishes and whose self-advection acceleration is given by

$$-(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} = -\Omega^2\,\boldsymbol{x} \Longrightarrow \mathbb{S}_{mn}\,\mathbb{S}_{mn} = 2\,\Omega^2. \tag{39.86}$$

This acceleration is exactly the opposite of that produced by the rigid-body motion studied in the previous example. Hence, to maintain the non-divergent nature of the barotropic flow, a pressure (again, assuming $f = 0$) is established with a high pressure at the center that exactly counteracts the converging self-advection acceleration arising in the strained flow

$$\varphi = -(\Omega\, r)^2/2 \quad \text{and} \quad -\nabla\varphi = \Omega^2\, \boldsymbol{x} = (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}. \tag{39.87}$$

This example illustrates how strain provides a source for high pressure in a non-divergent flow. Furthermore, we see that this flow, in the absence of viscosity, is an exact steady solution for non-divergent barotropic flow in a non-rotating reference frame. However, in contrast to the rigid-body flow in Section 39.4.4, the purely strained flow (39.85) supports viscous friction, so that this flow does not remain steady in the presence of viscosity.

39.4.6 Pressure source from Coriolis acceleration

In addition to the self-advection source, pressure is affected by a source from the Coriolis acceleration

$$-\nabla^2\varphi_{\text{geostrophy}} \equiv \nabla\cdot(f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}) = -\nabla\cdot(f\,\nabla\psi) = \beta\, u - \zeta\, f. \tag{39.88}$$

As such, we can write the pressure gradient as[9]

$$-\nabla\varphi_{\text{geostrophy}} = f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}. \tag{39.89}$$

Consider cyclonic flow around an arbitrary point. What is the pressure field induced by this flow? As in our discussion in Section 39.4.4 of the rigid-body rotating flow, a cyclonic flow has an associated centrifugal acceleration that points outward. To counteract the centrifugal acceleration, and thus to maintain a non-divergent flow, requires an inward pointing pressure force; i.e., a low pressure center. Hence, cyclonic circulation induces, through the Coriolis acceleration, a negative pressure source whereas anti-cyclonic circulation induces a positive pressure source. This is indeed an interesting perspective on geostrophic balance!

39.4.7 Pressure source from friction

Consider flow with friction, in which case the velocity equation (39.1) takes the form

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\nabla\varphi + \boldsymbol{F}, \tag{39.90}$$

with $\boldsymbol{F}$ a frictional acceleration. In this case we have yet another source for pressure given by

$$-\nabla^2\varphi_{\text{friction}} \equiv -\nabla\cdot\boldsymbol{F}. \tag{39.91}$$

As discussed in Section 26.8, viscous friction is generally associated with a nonzero strain rate. We see that the frictional acceleration induces a high pressure source in regions where frictional accelerations converge, $-\nabla\cdot\boldsymbol{F} > 0$, with this source acting to maintain non-divergent flow in the presence of converging frictional acceleration.

[9] Formally, we can add an arbitrary gauge function to the right hand side of equation (39.89), with this term of the form $\hat{\boldsymbol{z}}\times\nabla\chi$. However, since we derived the pressure Poisson equation from the velocity equation, then we know there is no gauge function arising in equation (39.89).

39.4.8 Comments and further study

- The pressure equation (39.67) is elliptic, and elliptic equations need boundary conditions. In the presence of topography the boundary conditions are modified relative to the flat bottom case. Hence, pressure knows about topography through its boundary conditions. The resulting pressure force keeps the flow non-divergent and the flow aligned with topography as per the kinematic conditions in Section 39.1.3.

- The discussion of pressure induced by self-advection in Sections 39.4.4 and 39.4.5 is based on a similar presentation in Appendix B of *Jeevanjee and Romps* (2015a).

- *Bryan* (1969) provided the first working numerical algorithm to simulate the ocean general circulation. Bryan's method made use of the rigid lid approximation of Section 39.4 so that the depth integrated velocity is non-divergent. However, the vorticity in Bryan's ocean model is affected by more than just the beta-effect. The reason is that the depth integrated velocity equation includes contributions from baroclinic processes, and such processes affect the barotropic vorticity in a baroclinic fluid. We detail such effects in Sections 45.6 and 45.7.

  The rigid lid method was used for large-scale ocean circulation modeling until the late 1990s. Free surface methods, allowing divergence in the depth integrated flow, have largely displaced the rigid lid as a practical method for time stepping ocean models (e.g., see chapter 12 of *Griffies* (2004)).

39.5 Constraints from absolute vorticity invariance

We here examine constraints on the flow imposed by material invariance of absolute vorticity, which holds for two-dimensional non-divergent flow when there is no dissipation

$$\frac{\mathrm{D}(\zeta + f)}{\mathrm{D}t} = 0. \tag{39.92}$$

These constraints offer insights into the flow behavior and allow us to predict responses to perturbations. Notably, these predictions arise even without direct information about the forces giving rise to the responses. Rather, we deduce the responses based on vorticity constraints alone.

We frame the discussion in terms of the decomposition (38.50) of relative vorticity into a curvature (or orbital) term and normal shear term

$$\zeta = \frac{|\boldsymbol{u}|}{R} - \frac{\partial |\boldsymbol{u}|}{\partial n} \equiv \zeta_{\text{curv}} + \zeta_{\text{shear}}, \tag{39.93}$$

so that

$$\frac{\mathrm{D}(\zeta_{\text{curv}} + \zeta_{\text{shear}} + f)}{\mathrm{D}t} = 0. \tag{39.94}$$

When the flow turns, the curvature term contributes with R the radius of curvature.[10] If the flow develops shears in the direction normal to the flow, then the shear term contributes. In the presence of $\beta = \partial_y f$, meridional motion through the planetary vorticity field requires a compensating response from relative vorticity. In general each of the three terms contribute to the relative vorticity, yet for pedagogical purposes we consider cases where one term is subdominant.

[10] As discussed in Section 33.2, we take the convention whereby the normal direction is to the left of flow when facing downstream. Flow turning into the normal direction (to the left) has a positive radius of curvature, $R > 0$, and flow turning opposite to the normal direction (to the right) has $R < 0$.

39.5.1 Relative vorticity from curvature and planetary beta

According to the decomposition (39.93), fluid that curves to the left (facing downstream) picks up a positive relative vorticity from flow curvature, $R > 0 \Rightarrow \zeta > 0$, as depicted in Figure 39.3. The oppositely curved flow has a negative radius of curvature so flow curving to the right picks up a negative relative vorticity, $R < 0 \Rightarrow \zeta < 0$. We focus here on the case where the normal shear induced relative vorticity can be neglected so that we are only concerned with curvature induced vorticity plus planetary vorticity (beta effect).

Consider a flow that is initially zonal with zero relative vorticity. If the flow turns meridionally then it experiences a change in relative vorticity both through the curvature term plus a change in planetary vorticity since f changes. To maintain constant absolute vorticity, a fluid column that moves meridionally requires the relative vorticity induced by the curved flow path to counteract the change in planetary vorticity. As we now discuss, the constraint of fixed absolute vorticity, in the absence of induced normal shears, means that eastward flow (westerly winds) cannot turn meridionally while maintaining fixed absolute vorticity, whereas westward flow (easterly winds) can turn (see Figure 39.3).

FIGURE 39.3: Illustrating the constraints on a two dimensional non-divergent flow imposed by material invariance of absolute vorticity: $\zeta + f =$ constant. We assume flow is over a flat region and assume there is only curvature induced relative vorticity (no shear-induced relative vorticity; $\partial|\boldsymbol{u}|/\partial n = 0$) as per the decomposition in equation (39.93). In each of the four cases depicted, the entering flow has zero relative vorticity, which means that absolute vorticity must remain constant at the initial Coriolis parameter, $\zeta + f = f_{\text{initial}}$. The red eastward flow (westerly winds) that turns meridionally picks up a curvature vorticity that supports the change in planetary vorticity, thus precluding material invariance of absolute vorticity. Hence, the meridional turning of eastward flow is not allowed so that flow must remain zonal for absolute vorticity to remain invariant. In contrast, the oppositely directed westward flow (easterly winds) can deviate either to the north or south and still retain a constant absolute vorticity. We illustrate flows for both the northern and southern hemispheres. Note that the allowed westward flow is consistent with the westward phase propagation of Rossby waves as detailed in Section 52.3. This figure is adapted from Figure 4.8 of *Holton* (1992).

Consider westward flow in the northern hemisphere ($f > 0$). If the flow turns to the north (to the right facing downstream) then this flow picks up a curvature-induced negative relative vorticity, $\zeta < 0$, and an increase in the planetary vorticity (f increases). Likewise, a westward flowing fluid column that turns equatorward (to the left) has a positive curvature-induced relative vorticity ($\zeta > 0$) and a reduction in planetary vorticity (f decreases). Hence, westward flow in the northern hemisphere can turn either poleward (to the north) or equatorward (to the south) and still maintain constant absolute vorticity, so long as the curved motion induces the proper relative vorticity to counteract the changes to f. The same arguments also hold in the southern

hemisphere, so that the general scenarios are depicted in Figure 39.3.

The situation is different for eastward flow. Consider again flow in the northern hemisphere. A poleward (to the left) turning fluid column is associated with a positive curvature-induced relative vorticity, $\zeta > 0$, as well as an increase in the planetary vorticity. Hence, this motion changes the absolute vorticity and as such it is not allowed if the absolute vorticity is constrained to remain constant. Likewise, an equatorward (to the right) turning eastward fluid column induces a negative curvature-induced relative vorticity, $\zeta < 0$, and a decrease in planetary vorticity, again leading to a change in absolute vorticity. Hence, eastward flow (westerly winds) in either hemisphere must remain zonal to maintain a constant absolute vorticity.

As an application of these results, consider the situation depicted in Figure 39.4, whereby inviscid flow in the interior of an ocean domain moves westward into a frictional western boundary layer. The constraints imposed by absolute vorticity invariance allow for this flow to occur, whereas the opposite is disallowed whereby eastward inviscid flow cannot enter an eastern boundary. We return to this example in Section 40.7 when discussing western intensification of ocean gyres.

FIGURE 39.4: Illustrating the constraints on a homogeneous and constant thickness fluid layer imposed by material invariance of absolute vorticity: $\zeta + f =$ constant. As per the results from Figure 39.3, inviscid flow with initially zero relative vorticity can enter a western boundary layer as depicted here, whereas it cannot enter an eastern boundary layer. This conclusion assumes that there is no shear-induced relative vorticity ($\partial|\boldsymbol{u}|/\partial n = 0$) that can overcome changes in the vorticity induced by changes to f and by curvature-induced relative vorticity (see Section 38.8.2). This figure is adapted from Figure 19.12 of *Vallis* (2017).

39.5.2 Relative vorticity from curvature and normal shears

Now consider the case in which the meridional displacements are small so that the beta effect can be neglected. In this case there is an exchange between relative vorticity arising from curvature and relative vorticity from normal shears, thus leaving their sum materially invariant

$$\frac{D(\zeta_{\text{curv}} + \zeta_{\text{shear}})}{Dt} = 0. \tag{39.95}$$

We depict an example in Figure 39.5 whereby a vortex undergoes a left turn facing downstream. While on the curve, the relative vorticity of the vortex is in part due to the positive curvature vorticity, $\zeta_{\text{curv}} > 0$. If the relative vorticity is positive on the straight portion of the trajectory,

FIGURE 39.5: Material invariance of relative vorticity, $\mathrm{D}\zeta/\mathrm{D}t = \mathrm{D}(\zeta_{\text{curv}} + \zeta_{\text{shear}})/\mathrm{D}t = 0$, means that as a vortex moves around a curve its shear vorticity is modified to keep the total relative vorticity invariant. On the straight portion of these trajectories, the relative vorticity is due only to shear vorticity, $\zeta = \zeta_{\text{shear}}$ since $\zeta_{\text{curve}} = 0$. However, when the vortex enters the curve, maintaining a constant relative vorticity requires an exchange of shear vorticity with the curvature vorticity. In this example we illustrate a steady flow that turns to the left so that the vortex picks up a positive curvature vorticity when on the curve, $\zeta_{\text{curve}} > 0$. Left panel: a vortex that enters the left turn with a positive relative vorticity must give some of its shear vorticity to the curvature vorticity in order to maintain ζ constant along the trajectory. Right panel: a vortex that enters the curve with a negative relative vorticity sees its shear vorticity increase in magnitude to compensate for the positive curvature vorticity.

then when on the curve the shear vorticity must lose some of its strength in order to compensate for the curvature vorticity. Conversely, if the relative vorticity is negative on the straight portion of the trajectory, then when on the curve the shear vorticity gains in strength to allow for the positive curvature vorticity.

39.5.3 Curvature, shear, and planetary contributions

We now consider all three terms appearing in the vorticity equation (39.94). Let us consider again the eastward flow that turns to the north in the northern hemisphere. Such flow is not allowed if the only source for relative vorticity is curvature. However, if the eastward flow, as it turns, picks up a shear that induces a nonzero negative relative vorticity, then such flow can turn so long as the shear-induced negative relative vorticity balances the positive absolute vorticity from increases in f and the curvature-induced vorticity. Writing this condition for the shear-induced relative vorticity yields

$$\zeta_{\text{shear}} = -\Delta f - \zeta_{\text{curv}} = -(f_{\text{final}} - f_{\text{init}}) - \zeta_{\text{curv}} < 0, \tag{39.96}$$

where f_{init} and f_{final} are the initial and final Coriolis parameters. Conversely, if the flow deviates towards the equator then it can do so only if there is a positive shear-induced relative vorticity

$$\zeta_{\text{shear}} = -(f_{\text{final}} - f_{\text{init}}) - \zeta_{\text{curv}} > 0. \tag{39.97}$$

39.5.4 Beta drift

In Exercise 25.5 we introduced the *Rossby effect* (*Rossby*, 1948), in which a circular cyclonic vortex experiences an area integrated Coriolis acceleration that is directed poleward, and with the integrated acceleration vanishing on the f-plane. Hence, this poleward drift arises from the beta effect. Following *Rossby* (1948), we did not consider the pressure field associated with the vortex, so it is unclear whether such a vortex would actually drift due northward. Indeed,

FIGURE 39.6: Schematic cyclonic and circularly symmetric northern hemisphere ($f > 0$) monopole flow in a two-dimensional non-divergent barotropic fluid. The monopole has positive circulation and thus positive relative vorticity. On the β-plane, parcels moving around the monopole pick up anomalous relative vorticity according to the beta effect: $\mathrm{D}\zeta/\mathrm{D}t = -\beta\, v$. On the western side, parcels move southward and thus pick up a positive relative vorticity anomaly ($-\beta\, v > 0$), whereas on the eastern side the northward flow picks up a negative relative vorticity anomaly. The beta effect thus induces a westward drift of the monopole maximum, towards where the relative vorticity is increasing. Additionally, the positive anomaly on the western side of the monopole induces a secondary circulation known as a *beta gyre*, with this gyre rotating counter-clockwise, whereas there is an oppositely oriented beta gyre on the eastern side. The secondary circulation from the counter-rotating beta gyres induces a northward drift to the monopole. The combined effect of the westward beta induced drift and the northward drift from the beta gyres leads to a net northwestward *beta drift* for the monopole.

subsequent studies showed that motion of an initially circular vortex sets up a secondary flow that renders a poleward+westward *beta drift*; i.e., northwestward in the northern hemisphere and southwestward in the southern hemisphere. As for the other motions considered in this section, we describe the mechanism for beta drift by invoking conservation of absolute vorticity respected by an inviscid non-divergent barotropic flow. This discussion reflects similar ideas encountered when studying Rossby waves in Section 52.3.

Consider a circularly symmetric northern hemisphere cyclonic monopole as shown in Figure 39.6. The monopole flow has positive circulation and thus positive relative vorticity. On an f-plane this circulation is stationary, whereas parcels moving around the monopole on the β-plane pick up anomalous relative vorticity according to the beta effect: $\mathrm{D}\zeta/\mathrm{D}t = -\beta\, v$. On the west side of the monopole, fluid elements are moving southward and thus pick up a positive anomalous relative vorticity ($-\beta\, v > 0$), whereas on the east side the northward flow picks up a negative relative vorticity anomaly. We note that the material evolution of relative vorticity is also reflected in the local time changes, since for an initially circular monopole, the only contribution to the local evolution is given by the beta effect. We see this property by writing the vorticity equation using polar coordinates (see Section 10.3)

$$\partial_t \zeta = -\beta\, v - \boldsymbol{u} \cdot \nabla \zeta = -\beta\, v - (\dot{r}\, \partial_r + \dot{\vartheta}\, \partial_\vartheta)\, \zeta, \tag{39.98}$$

where r is the radial coordinate and ϑ is the angular coordinate measured counter-clockwise from the x-axis. By assumption, the flow is initially moving only in the angular direction, so that $\dot{r} = 0$. Additionally, the monopole is symmetric in the angular direction, so that $\partial_\vartheta \zeta = 0$. As a result, $\partial_t \zeta = -\beta\, v$.

From the above analysis, we see that throughout the western side of the monopole, beta induces

a positive anomalous vorticity, whereas beta induces a negative vorticity anomaly throughout the eastern side. When combined with the vorticity from the monopole, we see that the beta induced anomalous vorticity leads to a westward drift of the location for the maximum vorticity; i.e., the monopole maximum drifts to the west. Yet that is not the full story. Additionally, the positive vorticity anomaly on the western side induces a positive gyre-like circulation referred to as a *beta gyre*, whereas the negative vorticity on the eastern side induces a negative beta gyre. The beta gyre circulations are referred to as *secondary circulations* since they arise in response to the anomalies induced by motion through the primary monopole circulation. Furthermore, the counter-rotating beta gyres induce a northward drift of the monopole. The combined westward drift induced by beta acting on the primary monopole circulation, plus the northward drift from the secondary beta gyre circulations, leads to an overall northwestward drift of the monopole. More generally, a cyclonic monopole experiences a poleward and westward beta drift, whereas for anti-cyclonic monopoles the beta drift is equatorward and westward.

The extent to which beta drift is respected by more realistic monopoles depends on many factors, such as the strength and radius of the monopole, strength of the background planetary vorticity gradient, and stability of the monopole. The literature on these topics makes use of numerical models to probe the nonlinearities associated with these relatively strong, and sometimes unstable, flow regimes. Some of the papers are motivated by motion of coherent ocean eddies (e.g., *McWilliams and Flierl*, 1979; *Carnevale et al.*, 1991), and others are motivated by motion of atmospheric tropical cyclones (e.g., *Holland*, 1983; *Smith*, 1993). For tropical cyclones born off the coast of Africa in the tropical Atlantic, beta drift gives the cyclones a general tendency to move northwestward toward North America (absent environmental flows that can counteract the beta drift). More recently, *Gavriel and Kaspi* (2021) employed these concepts to help understand vortices found in the polar regions of the Jovian atmosphere.

39.5.5 Understanding and prediction

The examples in this section illustrate the power of vorticity constraints for the purpose of predicting flow responses. The power largely rests on our ability to determine flow responses without directly determining forces causing the response. Even so, without determining the forces acting in the fluid, our understanding of the dynamics remains incomplete even if our ability to predict is complete. So when one can determine the forces (it is not always as simple as the examples in Section 39.4), then doing so offers further physical insights into the nature of the flow.

39.6 Exercises

EXERCISE 39.1: VORTICITY IDENTITY IN TWO-DIMENSIONAL BAROTROPIC MODEL
Directly prove the identity (39.29) holding for the two-dimensional non-divergent barotropic model.

EXERCISE 39.2: ALTERNATIVE FORM OF THE VORTICITY FLUX
Show that the vorticity flux can be written

$$\boldsymbol{u}\,\zeta = u\,\nabla v - v\,\nabla u + \hat{\boldsymbol{z}} \times \nabla \mathcal{K}, \tag{39.99}$$

so that the vorticity equation (39.35) can be written in the alternative form

$$\frac{\partial \zeta}{\partial t} + \nabla \cdot (u\,\nabla v - v\,\nabla u) = -\beta\, v. \tag{39.100}$$

As a corollary, we see that steady f-plane flow satisfies the constraint

$$\nabla \cdot (u\,\nabla v - v\,\nabla u) = u\,\nabla^2 v - v\,\nabla^2 u = 0. \tag{39.101}$$

EXERCISE 39.3: EXAMPLE TWO-DIMENSIONAL NON-DIVERGENT FLOW

Consider a perfect two-dimensional non-divergent flow in a non-rotating reference frame

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = -\nabla\varphi \quad \text{and} \quad \nabla \cdot \boldsymbol{u} = 0. \tag{39.102}$$

Let the velocity be given by the steady flow

$$\boldsymbol{u} = U\,[\hat{\boldsymbol{x}}\sin(k\,y) + \hat{\boldsymbol{y}}\sin(k\,x)], \tag{39.103}$$

where U is a constant with dimensions L T^{-1} and k is a wavenumber with dimensions L^{-1}. We provide a sketch of this flow in Figure 39.7.

(a) Compute the streamfunction, ψ, so that $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$.

(b) Compute the self-advection, $(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}$ and show that $\nabla \times [(\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u}] = \boldsymbol{0}$.

(c) Compute the vorticity, $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u})$.

(d) Compute the pressure, to within an arbitrary constant.

FIGURE 39.7: A sketch of the steady two-dimensional non-divergent sinusoidal flow (39.103), as given by $\boldsymbol{u} = U\,[\hat{\boldsymbol{x}}\sin(k\,y) + \hat{\boldsymbol{y}}\sin(k\,x)]$. The units are arbitrary. This flow is considered in Exercise 39.3.

EXERCISE 39.4: VELOCITY ARISING FROM A GIVEN VORTICITY

Following the discusson in Section 39.2.7, consider an axially symmetric two-dimensional non-divergent flow with a single vortex of the form

$$\zeta(r) = \left[\begin{array}{ll} \zeta_0 & \text{for } r < r_0 \\ 0 & \text{for } r > r_0. \end{array}\right. \tag{39.104}$$

(a) What is the velocity field corresponding to this vorticity?

(b) What is the circulation around a circular circuit with radius $r < r_0$? Assume the velocity is non-singular at the origin.

(c) What is the circulation around a circular circuit with radius $r > r_0$?

(d) For both the circular circuits with $r < r_0$ and $r > r_0$, write the circulation in terms of the velocity.

EXERCISE 39.5: INTEGRAL PROPERTIES OF THE INVISCID 2D NON-DIVERGENT FLOW
In this exercise, we establish some global conservation properties for inviscid two-dimensional non-divergent flow on a β-plane. Assume the geometry is a flat plane defined over a region, $\mathcal{S}$, with static material boundary, $\partial\mathcal{S}$. Many of the properties derived here are discussed in Section 3.1 of *McWilliams* (2006).

(a) Show that the domain integrated kinetic energy per mass remains constant in time

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}} \mathcal{K}\,\mathrm{d}\mathcal{S} = \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}} \boldsymbol{u}\cdot\boldsymbol{u}\,\mathrm{d}\mathcal{S} = 0, \tag{39.105}$$

where the horizontal integral extends over the full fluid domain $\mathcal{S}$.

(b) Why is the mechanical energy budget only associated with kinetic energy? What about the gravitational potential energy?

(c) Show that the domain integrated relative vorticity (equal also to the relative circulation) is constant in time

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}} \zeta\,\mathrm{d}\mathcal{S} = 0. \tag{39.106}$$

(d) Show that the domain integrated enstrophy is constant in time for f-plane motion ($\beta = 0$)

$$\frac{\mathrm{d}\mathrm{Z}^{(\zeta)}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}} \zeta^2\,\mathrm{d}\mathcal{S} = 0. \tag{39.107}$$

(e) Show that the domain integrated potential enstrophy is constant in time even with $\beta \neq 0$

$$\frac{\mathrm{d}\mathrm{Z}^{(q)}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}} q^2\,\mathrm{d}\mathcal{S} = 0. \tag{39.108}$$

EXERCISE 39.6: ALTERNATIVE EXPRESSION FOR THE GLOBALLY INTEGRATED KINETIC ENERGY
For a simply connected region, $\mathcal{S}$, with static material boundary, $\partial\mathcal{S}$, show that the globally integrated kinetic energy per mass can be written

$$\int_{\mathcal{S}} \mathcal{K}\,\mathrm{d}\mathcal{S} = \frac{1}{2}\int_{\mathcal{S}} \boldsymbol{u}\cdot\boldsymbol{u}\,\mathrm{d}\mathcal{S} = \frac{1}{2}\int_{\mathcal{S}} \zeta\,(\psi_{\mathrm{b}} - \psi)\,\mathrm{d}\mathcal{S} = \frac{1}{2}\big[\psi_{\mathrm{b}}\,\mathcal{C} - \int_{\mathcal{S}} \psi\,\zeta\,\mathrm{d}\mathcal{S}\big], \tag{39.109}$$

where $\boldsymbol{u} = \hat{\boldsymbol{z}}\times\nabla\psi$ is the horizontally non-divergent velocity, ψ is the streamfunction, ψ_{b} is the streamfunction on the boundary, and $\zeta = \nabla^2\psi$ is the vorticity. Hint: recall from Section 22.4.2 that the streamfunction for two-dimensional non-divergent flow is a constant on material boundaries.

EXERCISE 39.7: CIRCULATION IN A 2D BAROTROPIC FLOW
Consider a non-divergent barotropic flow on a β-plane in the presence of a biharmonic friction operator, where the governing vorticity equation is

$$\frac{\partial \zeta}{\partial t} + J(\psi, \zeta + \beta y) = -\nu \nabla^4 \zeta, \tag{39.110}$$

with $\nu > 0$ a constant biharmonic viscosity with dimensions of $\mathrm{L}^4\ \mathrm{T}^{-1}$. Show that the circulation around a fixed material area, $\mathcal{S}$, in the fluid evolves according to

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = -\oint_{\partial \mathcal{S}} \left[\psi \frac{\partial q}{\partial s} + \nu \frac{\partial (\nabla^2 \zeta)}{\partial n} \right] \mathrm{d}s, \tag{39.111}$$

where s is the arc-length along the boundary of the region and n is a coordinate normal to the boundary.

EXERCISE 39.8: KINEMATICS OF VORTICITY GRADIENTS
For many purposes it is of interest to develop equations describing the evolution of scalar gradients. We developed a general expression in Exercise 18.3. Here, we derive a similar equation for the gradient of relative vorticity in a non-divergent barotropic flow. For this purpose, consider the inviscid barotropic vorticity equation on an f-plane

$$\frac{\partial \zeta}{\partial t} + J(\psi, \zeta) = 0. \tag{39.112}$$

(a) Show that the material evolution of the vorticity gradient is given by

$$\frac{\mathrm{D}(\nabla \zeta)}{\mathrm{D}t} = -J(\nabla \psi, \zeta). \tag{39.113}$$

(b) Show that the material evolution of the squared vorticity gradient is given by

$$\frac{\mathrm{D}|\nabla \zeta|^2}{\mathrm{D}t} = 2\, J(\zeta, \nabla \psi) \cdot \nabla \zeta. \tag{39.114}$$

EXERCISE 39.9: ANGULAR MOMENTUM FOR BAROTROPIC FLOW IN A BASIN
The exercise derives some equations presented in *Holloway and Rhines* (1991), who offer a specialized example of the shallow water angular momentum discussed in Section 37.8.

As in Section 37.8.1, the relative angular momentum for a region of fluid is given by

$$\boldsymbol{L} = \int \mathrm{d}\mathcal{S} \int (\boldsymbol{x} \times \boldsymbol{v})\, \rho\, \mathrm{d}z, \tag{39.115}$$

where $\boldsymbol{x}$ is the position vector and the relative angular momentum is that due to the motion of the fluid with respect to the rigid-body. For a barotropic fluid of constant density and constant thickness, and correspondingly a zero vertical velocity, the relative angular momentum reduces to

$$\boldsymbol{L} = \rho\, H \int_{\mathcal{S}} (\boldsymbol{x} \times \boldsymbol{u})\, \mathrm{d}\mathcal{S}, \tag{39.116}$$

with $\boldsymbol{u}$ the horizontal velocity and $\mathcal{S}$ the horizontal region. For barotropic motion on a tangent plane we are interested in the vertical component of the relative angular momentum

$$L^z = \rho\, H \int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot (\boldsymbol{x} \times \boldsymbol{u})\, \mathrm{d}\mathcal{S}. \tag{39.117}$$

Show for a simply connected and bounded region, L^z can be written

$$L^z = 2\,\rho\,H \int_{\mathcal{S}} (\psi_b - \psi)\,\mathrm{d}\mathcal{S} \tag{39.118}$$

where ψ is the streamfunction satisfying $\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\psi$, and ψ_b is the value of the streamfunction evaluated on the region boundary. Hint: note that $\nabla \cdot \boldsymbol{x} = 2$ for a horizontal position vector. Also recall from Section 22.4.2 that the streamfunction equals to a spatial constant when evaluated along the domain boundary.

EXERCISE 39.10: STEADY AXIALLY SYMMETRIC FLOW
Consider a two-dimensional non-divergent velocity

$$\boldsymbol{v} = \hat{\boldsymbol{z}} \times \nabla\psi. \tag{39.119}$$

Assume the streamfunction is static and depends only on the radial distance from an arbitrary origin,

$$\psi = \psi(r), \tag{39.120}$$

where $r = \sqrt{x^2 + y^2}$, and assume the velocity is a solution to the steady inviscid non-divergent barotropic dynamics on an f-plane.

(a) Show that the velocity only has an angular component

$$\boldsymbol{v} = v^{\varphi}\,\hat{\boldsymbol{\varphi}}, \tag{39.121}$$

where $\hat{\boldsymbol{\varphi}}$ is the angular unit vector oriented counter-clockwise from the $\hat{\boldsymbol{x}}$ axis.[11] Express v^{φ} in terms of the streamfunction ψ. Hint: see Figure 10.2 and Section 10.3 for a reminder of polar coordinates.

(b) Write the relative vorticity in terms of the streamfunction using polar coordinates.

(c) Consider the circulation

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{r}, \tag{39.122}$$

where $\mathcal{S}$ is a circular region in the x-y plane centered at $r = 0$. Express the circulation in terms of v^{φ} and the radius of the circle.

(d) Write the pressure gradient acceleration in terms of v^{φ}, f, and r. Hint: remember that $\hat{\boldsymbol{\varphi}}$ is a function of the polar angle φ.

(e) Interpret the steady balance of accelerations in terms of the balanced dynamics in Chapter 33.

(f) Why is this axial symmetric solution only valid for an f-plane? Hint: show that if $\beta \neq 0$ that there is an inconsistency in the velocity equation.

EXERCISE 39.11: GALILEAN TRANSFORMATION OF PV ADVECTION AND THE APV METHOD
In Section 18.9 we established the invariance of the material time derivative operator under a Galilean transformation

$$\overline{\boldsymbol{x}} = \boldsymbol{x} + \boldsymbol{U}\,t \quad \text{and} \quad \overline{\boldsymbol{u}} = \boldsymbol{u} + \boldsymbol{U}, \tag{39.123}$$

[11] The azimuthal angular coordinate, φ, that appears in $\boldsymbol{v} = v^{\varphi}\,\hat{\boldsymbol{\varphi}}$, is not the same as the density normalized pressure, $\varphi = p/\rho$, defined by equation (39.2) and used throughout this chapter.

where $\boldsymbol{U}$ is a constant. Here we study the Galilean transformation properties of the non-divergent barotropic model on a β-plane.

(a) Determine the Galilean transformation properties of the potential vorticity equation (39.38)

$$\frac{\partial q}{\partial t} + \boldsymbol{u} \cdot \nabla q = \frac{\partial q}{\partial t} + J(\psi, q) = 0, \tag{39.124}$$

where $q = \zeta + f$, $\hat{\boldsymbol{z}} \times \psi = \boldsymbol{u}$, and J is the Jacobian operator.

(b) Determine the Galilean transformation properties of the relative vorticity equation (39.35)

$$\frac{\partial \zeta}{\partial t} + \boldsymbol{u} \cdot \nabla \cdot \zeta = -\beta\, v. \tag{39.125}$$

Discuss why there is Galilean invariance *only* for zonal Galilean boosts, $\boldsymbol{U} = \hat{\boldsymbol{x}}\, U$.

(c) An Euler forward time stepping scheme for the PV equation leads to

$$q^{n+1} = q^n - \Delta t\, \boldsymbol{u}^n \cdot \nabla q^n, \tag{39.126}$$

where Δt is the discrete time step and the integer n represents the discrete time label. Inspired by this time discrete expression, *Sadourny and Basdevant* (1985) proposed the *anticipated potential vorticity* (APV) method for parameterizing subgrid scale processes. The simplest form of APV is given by

$$\frac{\partial q}{\partial t} = -\boldsymbol{u} \cdot \nabla[q - \tau\, \boldsymbol{u} \cdot \nabla q] = -J[\psi, q - \tau\, J(\psi, q)], \tag{39.127}$$

with τ a constant time scale. From the time discrete expression (39.126), we see that the APV method makes use of an estimate for the future value of PV in computing the advection operator, thus motivating the term "anticipated" in the method's name.

Show that $\tau \neq 0$ breaks Galilean invariance for the equation (39.127). Provide a discussion of why invariance is broken. Hint: *Vallis and Hua* (1988) offer a technical reason for why Galilean invariance is broken, making use of the streamfunction and Jacobian form. You do not necessarily need to follow their approach. Rather, it is sufficient to merely note how velocity appears in the APV operator.

EXERCISE 39.12: ELEMENTS OF THE FOFONOFF GYRE

A Fofonoff gyre is an unforced inviscid solution in a flat bottom bounded domain with a rigid lid. For a single layer of homogeneous fluid with constant thickness, the absolute vorticity is materially invariant, $\mathrm{D}(\zeta + f)/\mathrm{D}t = 0$. An explicit solution is derived in Section 19.5.3 of *Vallis* (2017) for quasi-geostrophic flow using the method of matched asymptotics. We depict elements of a double Fofonoff gyre in Figure 39.8. Provide a narrative for this flow based on material conservation of absolute vorticity. In particular, discuss how the flow enters and leaves the side boundaries and conversely how it leaves and enters the interior region. We are not concerned with how this flow is established. Instead, assume the flow exists and discuss how its existence is consistent with $\mathrm{D}(\zeta + f)/\mathrm{D}t = 0$. Hint: recall our discussion of Figure 39.3.

EXERCISE 39.13: PRESSURE EQUATION WITH $w \neq 0$

Equation (39.67) or equation (39.70) provide equivalent expressons for the pressure Poisson equation with $\nabla\eta = 0$ and, correspondingly, with $w = 0$. However, in Section 39.1.4 we considered the possibility of $\nabla\eta = \nabla\eta_{\mathrm{b}}$, thus providing a solution with $w \neq 0$. In this case, derive the Poisson equation for pressure as decomposed according to $\varphi = g\,\eta + \varphi'$.

FIGURE 39.8: A Fofonoff gyre is an unforced inviscid flow in a bounded domain where $\mathrm{D}(\zeta + f)/\mathrm{D}t = 0$. We here depict elements of this double-gyre flow in the northern hemisphere as part of Exercise 39.12.

Chapter 40

Shallow water vorticity and potential vorticity

In this chapter we study vorticity and potential vorticity within the shallow water system. We start by deriving the evolution equation for vorticity by taking the curl of the velocity equation. Combining vorticity evolution with mass continuity then renders the evolution equation for potential vorticity. Potential vorticity is a material invariant for inviscid shallow water motion, thus providing a mechanical constraint on the fluid flow. After developing the basic concepts and equations, we consider a variety of flow regimes and case studies, mostly with an ocean focus. These case studies illustrate where the study of vorticity, potential vorticity, and circulation enhances our understanding of geophysical fluid mechanics.

CHAPTER GUIDE

The shallow water fluid offers a fruitful conceptual model to introduce the dynamics of vorticity and potential vorticity while requiring a relatively modest level of mathematical sophistication. Even so, we require vector calculus identities for Cartesian coordinates as detailed in Chapter 2. We also require an understanding of shallow water mechanics from Chapters 36 and 37, as well as the vorticity kinematics introduced in Chapter 38. The concepts and methods developed in this chapter are fundamental to the remaining chapters in this part of the book.

40.1 Shallow water vorticity equation

In this section we formulate the vorticity equation for the shallow water fluid, starting with a single layer and then extending to multiple layers. We sometimes make use of the vertical component to the absolute vorticity from equation (36.107)

$$\boldsymbol{\omega}^* = (\zeta + f)\,\hat{\boldsymbol{z}} = \zeta_{\mathrm{a}}\,\hat{\boldsymbol{z}}, \tag{40.1}$$

which is the sum of the relative vorticity of the horizontal flow, $\boldsymbol{\omega}^* = \zeta\,\hat{\boldsymbol{z}}$, plus the rigid-body vorticity, $f\,\hat{\boldsymbol{z}}$, due to motion of the rotating reference frame (recall Section 38.6.1). The absolute vorticity appears in the vector-invariant velocity equation (36.112), which is valid for each of the layers in a shallow water fluid

$$\partial_t \boldsymbol{u} + \boldsymbol{\omega}^*_{\mathrm{a}} \times \boldsymbol{u} = -\nabla(p/\rho_{\mathrm{ref}} + \boldsymbol{u}\cdot\boldsymbol{u}/2). \tag{40.2}$$

This equation forms the starting point for deriving the shallow water vorticity equation.

40.1.1 Vorticity equation for a single layer

We make use of the vector identity from Section 2.3.4 to express the curl of the Magnus acceleration plus Coriolis acceleration in the form

$$\nabla \times (\boldsymbol{\omega}_{\rm a}^* \times \boldsymbol{u}) = \boldsymbol{\omega}_{\rm a}^* (\nabla \cdot \boldsymbol{u}) + (\boldsymbol{u} \cdot \nabla) \boldsymbol{\omega}_{\rm a}^* - \boldsymbol{u} (\nabla \cdot \boldsymbol{\omega}_{\rm a}^*) - (\boldsymbol{\omega}_{\rm a}^* \cdot \nabla) \boldsymbol{u} \tag{40.3a}$$

$$= \boldsymbol{\omega}_{\rm a}^* (\nabla \cdot \boldsymbol{u}) + (\boldsymbol{u} \cdot \nabla) \boldsymbol{\omega}_{\rm a}^*, \tag{40.3b}$$

so that

$$\hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\omega}_{\rm a}^* \times \boldsymbol{u})] = \nabla \cdot (\boldsymbol{u}\, \zeta_{\rm a}) \tag{40.4}$$

Equation (40.3b) required setting

$$\nabla \cdot \boldsymbol{\omega}_{\rm a}^* = \nabla \cdot \boldsymbol{\omega}^* + \nabla \cdot (f\, \hat{\boldsymbol{z}}) = 0, \tag{40.5}$$

which follows since this expression involves the divergence of a curl (first right hand side term) and since f has no z dependence. We furthermore set

$$(\boldsymbol{\omega}_{\rm a}^* \cdot \nabla) \boldsymbol{u} = \zeta_{\rm a}\, \partial_z \boldsymbol{u} = 0, \tag{40.6}$$

which follows since the horizontal velocity in a shallow water fluid is depth independent within a layer (see Section 36.2).

Applying the operator $\hat{\boldsymbol{z}} \cdot (\nabla \times)$ onto the vector-invariant velocity equation (40.2) annihilates the gradient of pressure and kinetic energy, with the identity (40.4) leading to the flux-form evolution equation for absolute vorticity

$$\partial_t \zeta_{\rm a} + \nabla \cdot (\boldsymbol{u}\, \zeta_{\rm a}) = 0. \tag{40.7}$$

This equation says that the vertical component to the absolute vorticity, $\zeta_{\rm a}$, at a point in the inviscid shallow water fluid changes according to the horizontal convergence of vorticity advected to that point

$$\partial_t \zeta_{\rm a} = -\nabla \cdot (\boldsymbol{u}\, \zeta_{\rm a}). \tag{40.8}$$

We can write the vorticity equation (40.7) in the material form

$$\frac{{\rm D}\zeta_{\rm a}}{{\rm D}t} = -\zeta_{\rm a}\, \nabla \cdot \boldsymbol{u}, \tag{40.9}$$

where the material time derivative for the shallow water fluid includes advection just by the horizontal flow

$$\frac{{\rm D}}{{\rm D}t} = \frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla = \frac{\partial}{\partial t} + u\, \partial_x + v\, \partial_y. \tag{40.10}$$

The material evolution equation (40.9) means that the absolute vorticity of a shallow water fluid column, moving with the horizontal flow, changes according to the horizontal convergence of the fluid flow as multiplied by the absolute vorticity.

40.1.2 Vorticity equation for N-layers

The previous results for a single layer are readily extended to N-layers, simply because the velocity for layer-k evolves according to equation (40.2), now with a subscript k to denote the layer

$$\partial_t \boldsymbol{u}_{\rm k} + (f + \zeta_{\rm k})\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm k} = -\nabla (p_{\rm k}/\rho_{\rm ref} + \boldsymbol{u}_{\rm k} \cdot \boldsymbol{u}_{\rm k}/2), \tag{40.11}$$

where $\zeta_{\mathrm{k}} = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}_{\mathrm{k}})$ is the vertical component to the layer-k relative vorticity. Taking the curl and making use of the mathematical identities used for single layer in Section 40.1.1 renders the vorticity equation for layer-k

$$\partial_t \zeta_{\mathrm{ak}} + \nabla \cdot (\boldsymbol{u}_{\mathrm{k}}\, \zeta_{\mathrm{ak}}) = 0 \Longleftrightarrow \frac{\mathrm{D_k}\zeta_{\mathrm{ak}}}{\mathrm{D}t} = -\zeta_{\mathrm{ak}}\, \nabla \cdot \boldsymbol{u}_{\mathrm{k}} \tag{40.12}$$

where

$$\zeta_{\mathrm{ak}} = f + \zeta_{\mathrm{k}} \tag{40.13}$$

is the vertical component to the absolute vorticity of layer-k. Hence, the vorticity equation for an arbitrary layer in a stacked shallow water model is the same as that for a single shallow water layer.

40.1.3 Vorticity flux divergence and curl of nonlinear advection

We revisit the manipulations from Section 40.1.1 to explicitly identify a connection between the nonlinear terms in the vorticity equation. Start by writing the velocity equation in the advective form and the vector invariant form

$$\partial_t \boldsymbol{u} + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\, \nabla \eta \tag{40.14a}$$

$$\partial_t \boldsymbol{u} + (f + \zeta)\, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\, (g\, \eta + \boldsymbol{u} \cdot \boldsymbol{u}/2)\,. \tag{40.14b}$$

Taking their curl yields two expressions of the vorticity equation

$$\partial_t \boldsymbol{\omega}^* + \nabla \times [(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u}] + \nabla \times [f\, \hat{\boldsymbol{z}} \times \boldsymbol{u}] = 0 \tag{40.15a}$$

$$\frac{\partial \boldsymbol{\omega}^*}{\partial t} + \nabla \times [(f + \zeta)\, \hat{\boldsymbol{z}} \times \boldsymbol{u}] = 0, \tag{40.15b}$$

whose equality leads to

$$\nabla \times [(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} - \zeta\, \hat{\boldsymbol{z}} \times \boldsymbol{u}] = 0. \tag{40.16}$$

Making use of the identity

$$\hat{\boldsymbol{z}} \cdot [\nabla \times (\zeta\, \hat{\boldsymbol{z}} \times \boldsymbol{u})] = \nabla \cdot (\boldsymbol{u}\, \zeta) \tag{40.17}$$

renders the relation

$$\hat{\boldsymbol{z}} \cdot \nabla \times [(\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u}] = \nabla \cdot (\boldsymbol{u}\, \zeta). \tag{40.18}$$

We thus see that the divergence of the advective vorticity flux (right hand side) equals to the curl of the nonlinear advection (left hand side). This identity holds for each layer in an N-layer shallow water model.

40.2 Potential vorticity for a rotating cylinder

To introduce the concept of shallow water potential vorticity, consider a fluid cylinder of constant mass M, constant density ρ, variable radius R, and variable height h, and assume the cylinder rotates about its central axis. Furthermore, assume the fluid particles within the cylinder rotate as a rigid-body, meaning there are no strains in the fluid, and yet allow the cylinder radius and height to change. This analysis offers a useful (albeit incomplete) conceptual picture for a coherently rotating column of a shallow water layer, in which time derivatives in the following are interpreted as material derivatives.

40.2.1 Mass conservation

With a constant density, mass conservation for the material cylinder means that its volume is fixed. Hence, mass conservation constrains the relative changes to the radius and height of the cylinder. A materially constant cylinder mass

$$M = \pi R^2 h \rho \tag{40.19}$$

implies

$$\frac{2}{R}\frac{\mathrm{D}R}{\mathrm{D}t} = -\frac{1}{h}\frac{\mathrm{D}h}{\mathrm{D}t}. \tag{40.20}$$

That is, mass conservation means that the relative height decreases as twice the relative radius increases. So if the cylinder is squashed (h decreases) then it thickens (R increases). Conversely, the cylinder thins (R decreases) as it extends (h increases).

40.2.2 Angular momentum conservation

A second constraint arises from angular momentum conservation. Choose the center of mass coordinate axes through the center of the cylinder, with the z-axis along the central line of the cylinder and with $z = 0$ at the cylinder mid-point. The angular rotation vector is thus given by

$$\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{z}}. \tag{40.21}$$

With this axis orientation, rotation occurs about the center of mass so that the angular momentum of the center of mass vanishes. The moment of inertia tensor for a cylinder with this axis orientation is given by[1]

$$I_{mn} = \delta_{mn}\frac{MR^2}{2}. \tag{40.22}$$

The moment of inertia is a measure of the rotational inertia of a moving continuous body. For the cylinder it is directly related to the cylinder mass (assumed fixed here) and the radius (which can change). Notably, the moment of inertia about the central vertical axis is not a function of the cylinder height. The reason is that the moment measures the inertia relative to the rotational axis, which is here along the central vertical axis. The angular momentum for the cylinder is thus given by

$$\boldsymbol{L} = \frac{MR^2}{2}\,\Omega\,\hat{\boldsymbol{z}}. \tag{40.23}$$

The familiar *ice skater* example occurs when the cylinder radius changes and thus changes the moment of inertia (e.g., the ice skater's arms are brought in toward the central axis of the body or out away from the body). Maintaining constant angular momentum and constant mass means that the angular velocity, Ω, increases in magnitude (rotates faster) when the cylinder radius decreases, and vice versa. Explicitly for the cylinder we have $\mathrm{d}\boldsymbol{L}/\mathrm{d}t = 0$ and $\mathrm{d}M/\mathrm{d}t = 0$ thus rendering

$$\frac{2}{R}\frac{\mathrm{D}R}{\mathrm{D}t} = -\frac{1}{\Omega}\frac{\mathrm{D}\Omega}{\mathrm{D}t}. \tag{40.24}$$

We see that reducing the moment of inertia for a constant mass body by bringing its mass distribution towards the central axis (converging mass) leads, through angular momentum conservation, to an increase in rotation speed. The opposite occurs when mass diverges from a region, thus reducing the rotation speed.

[1] See *Marion and Thornton* (1988) or other classical mechanics texts for a discussion of the moment of inertia for a variety of bodies.

FIGURE 40.1: Illustrating the conservation of angular momentum for a spinning cylinder of constant mass rotating around its central axis. Furthermore, fluid particles within the cylinder rotate as a rigid-body, meaning there are no strains in the fluid, and yet the cylinder radius and height are allowed to change. The moment of inertia (relative to the central axis) for the left cylinder is larger since more of its mass is distributed away from the central axis than in the right configuration. If the initial spin for the left cylinder is counterclockwise, then for the two configurations to have identical angular momentum means that the right cylinder spins more rapidly since its moment of inertia is smaller. This example exemplifies the familiar ice skater experience, whereby the skater's spin rate increases when bringing arms (mass) inward towards the central axis of the body (depicted by the inward arrows on the right panel), and the skater slows when extending the arms outward (depicted by the outward arrows on the left panel).

Although the angular momentum constraint means that the spin rate changes when changing the moment of inertia, it does not impose a preferred direction. For example, no matter what direction a skater is rotating, decreasing the moment of inertia increases the spin rate in that particular direction. Yet when placing the spinning column on a rotating planet, the planetary rotation breaks the symmetry and thus prescribes the direction for the spin changes. The reason is that planetary rotation contributes to the spin of the column, even if the column has no spin relative to the rotating planetary reference frame. We encounter this additional part of the story in Section 40.3.

40.2.3 Material invariance of potential vorticity

Combining angular momentum conservation (40.24) with mass conservation (40.20) leads to the material conservation law

$$\frac{\mathrm{D}(\Omega/h)}{\mathrm{D}t} = 0. \tag{40.25}$$

Equation (40.25) means that the potential vorticity is constant for a material fluid column, with potential vorticity for the cylinder given by

$$Q \equiv \Omega/h. \tag{40.26}$$

For example, if the column thickens then the rotational velocity increases in order to maintain $Q = \Omega/h$ constant. Equivalently, if the column cross-sectional area decreases, the column thickness increases according to volume conservation, which in turn results in an increase in the spin according to angular momentum conservation.

40.2.4 Connecting angular momentum and vorticity

When allowing the shallow water fluid to exhibit motion that is more general than a rigid-body cylinder rotation (i.e., when allowing for strains in the fluid), then the angular rotation rate appearing in the potential vorticity (40.26) is generalized to the absolute vorticity, and we consider this generalization in Section 40.3. Furthermore, as shown in Section 38.6, the vorticity equals to

twice the rotation rate, $2\,\mathbf{\Omega}$. Hence, the numerator for the potential vorticity of the rigid-body rotating cylinder equals to one-half the vorticity.

40.2.5 Comments and further study

The discussion in this section is motivated by Section 2.4 of *Salmon* (1998). The rotating cylinder succintly identifies the two mechanical properties contributing to the potential vorticity conservation law (40.25): a kinematic property (mass conservation) and a dynamic property (angular momentum conservation). For the rotating cylinder, the implications of potential vorticity conservation are well gleaned from the separate mass and angular momentum conservation principles. Hence, potential vorticity conservation lends little novel insight for the cylinder. However, the material invariance of potential vorticity is of fundamental use for studies of rotating and stratified fluids where the flow generally has strains that make vorticity distinct from angular momentum (Section 38.9).

Another important element missing from this discussion is the *beta effect*, which accounts for the changes in planetary vorticity when moving on a rotating spherical planet. We encounter this effect in the following sections.

40.3 Shallow water potential vorticity

We now consider the potential vorticity for a single layer of shallow water fluid. The derivation here makes use of fluid mechanical equations rather than those from rigid-body mechanics, thus allowing for the added feature of strains in the fluid that distinguish vorticity from angular momentum. We present two derivations: one based on manipulations of the mass and momentum equations, and one based on the small aspect ratio limit of Kelvin's circulation theorem, with Kelvin's theorem more thoroughly studied in Chapter 41.

Figure 40.2 summarizes key elements leading to potential vorticity conservation for a shallow water fluid layer. Namely, as shown in this section, shallow water potential vorticity conservation arises from combining the kinematic constraint of mass conservation (material invariance of $h\,A$) with either the vorticity equation or Kelvin's circulation theorem for a small aspect ratio fluid.

We comment on the terminology. In the absence of non-conservative processes, we show that shallow water potential vorticity for a material column of fluid remains constant. We often refer to this conservation property as *material invariance*, since the property remains invariant (constant) when following material fluid columns. This terminology was introduced in Section 18.8.6.

FIGURE 40.2: Illustrating the material invariance of potential vorticity for a layer of shallow water fluid column. Material invariance results from merging mass conservation (material invariance of the column volume, $h\,A$), to either the vorticity equation or Kelvin's circulation theorem for a small aspect ratio fluid (material invariance of $\zeta\,A$).

40.3.1 Mass conservation plus the vorticity equation

To derive the potential vorticity equation, we here make use of the vorticity equation (40.9) and combine it with mass conservation.

Shallow water vorticity and vortex stretching

Mass conservation in the form of the material thickness equation (36.20) leads to the following expression for the divergence of the horizontal velocity

$$\nabla \cdot \boldsymbol{u} = -\frac{1}{h}\frac{\mathrm{D}h}{\mathrm{D}t}. \tag{40.27}$$

Making use of this result in the vorticity equation (40.9) allows us to eliminate the horizontal convergence

$$\frac{\mathrm{D}\zeta_{\mathrm{a}}}{\mathrm{D}t} = -\zeta_{\mathrm{a}}\nabla \cdot \boldsymbol{u} = \frac{\zeta_{\mathrm{a}}}{h}\frac{\mathrm{D}h}{\mathrm{D}t}. \tag{40.28}$$

This equation says that material changes in shallow water absolute vorticity arise only from material changes in the layer thickness; i.e., absolute vorticity increases in magnitude if the column stretches and decreases if the column compresses. We refer to this process as *vortex stretching*.

We see in Section 41.5.3 that vorticity in continuously stratified fluids is affected by vortex stretching and *vortex tilting*, as well as torques from baroclinicity. In contrast, equation (40.28) says that the material evolution of absolute vorticity for a shallow water fluid is affected only through vortex stretching. This behavior is a result of the depth independence of the horizontal velocity within a shallow water layer and the associated vertical columnar motion of fluid within the layer. On a related note, we see in Section 40.3.3 that vortex tubes in a shallow water layer are nearly vertical, so that we are only concerned with the vertical component of shallow water vorticity. Correspondingly, shallow water vortex tubes never close.

Material invariance of shallow water potential vorticity

Equation (40.28) can be written as an expression of the material invariance of the shallow water potential vorticity

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = 0, \tag{40.29}$$

where

$$Q = \frac{\zeta_{\mathrm{a}}}{h} = \frac{\zeta + f}{h} \tag{40.30}$$

is the shallow water potential vorticity. As defined, shallow water potential vorticity is the ratio of absolute vorticity to the thickness of the fluid layer. The material conservation law (40.29) says that this ratio remains constant for the shallow water layer in the absence of non-conservative processes such as friction.

40.3.2 Motivating the name

Material invariance of the shallow water potential vorticity in equation (40.30) is most practically a statement about how the relative vorticity, ζ, changes when changing column thickness or latitude. That is, by maintaining Q fixed, ζ must change when either the column thickness, h, changes or when the column moves meridionally to thus alter the Coriolis parameter, f. By focusing on relative vorticity we are offered insights into how the fluid motion is constrained and thus a means to predict changes in that motion. In turn, these changes in ζ motivate the name "potential vorticity" as we now see.

Potential vorticity measures the ability for a shallow water fluid column to either spin up or spin down (change its relative vorticity) relative a standard configuration. For example, let the standard configuration be defined by an arbitrary standard thickness, h_{s}, at the equator (where $f = 0$). Now move an off-equatorial shallow water fluid column with zero relative vorticity to the equator and stretch/compress the column to the standard thickness. Material invariance of the column's potential vorticity allows us to deduce the column's relative vorticity at the equator, given information about the initial column thickness and initial Coriolis parameter (see Figure 40.3). Hence, potential vorticity, as an invariant material property, provides the "potential" for a fluid column to manifest a particular value of the relative vorticity when moved and stretched into a standard configuration. In this manner, the use of "potential" in "potential vorticity" is directly analogous to the use of "potential" in "potential temperature" as described in Section 24.3, or gravitational potential energy as discussed in Section 27.2.

FIGURE 40.3: Left panel: an arbitrary shallow water column with zero relative vorticity and potential vorticity $Q = f/h$, with $f > 0$ assumed for this figure (northern hemisphere). Right panel: the same fluid column moved to the equator (where $f = 0$) and stretched to have the standard thickness, $h_{\mathrm{s}} > h$. The relative vorticity of the column at the equator is given by $\zeta = f\,(h_{\mathrm{s}}/h)$, where f is the Coriolis parameter at the original latitude where $f > 0$. Potential vorticity thus provides a means to deduce the relative vorticity that can be realized by moving any particular configuration to a standard location and with a standard thickness. This property motivates the "potential" used in the name.

40.3.3 Mass conservation + Kelvin's circulation theorem

Although we have yet to discuss Kelvin's theorem (Section 41.2), we here invoke it to illustrate another way to derive the material invariance of shallow water potential vorticity. As we will see, this derivation lends itself to direct analog of the rotating cylinder discussed in Section 40.2.

When applied to an infinitesimal circuit in an inviscid and constant density fluid, Kelvin's theorem says that

$$\frac{\mathrm{D}\left(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\,\delta\mathcal{S}\right)}{\mathrm{D}t} = 0, \tag{40.31}$$

where $\boldsymbol{\omega}_{\mathrm{a}}$ is the absolute vorticity

$$\boldsymbol{\omega}_{\mathrm{a}} = \boldsymbol{\omega} + f\,\hat{\boldsymbol{z}}, \tag{40.32}$$

$\hat{\boldsymbol{n}}\,\delta\mathcal{S}$ is the infinitesimal surface area enclosed by the closed circuit, with $\hat{\boldsymbol{n}}$ the unit outward normal to the surface. Hence, equation (40.31) says that the projection of the absolute vorticity onto the local normal of an area element, multiplied by that area element, remains materially constant. This identity offers a very strong constraint on the flow.

To make use of equation (40.31) for the shallow water layer, decompose absolute vorticity into

$$\boldsymbol{\omega}_{\mathrm{a}} = \hat{\boldsymbol{z}}\,(\zeta + f) + \boldsymbol{\omega}_{\mathrm{h}}, \tag{40.33}$$

where (see equation (36.105d))

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{v}) \tag{40.34}$$

is the vertical component to the relative vorticity, and

$$\boldsymbol{\omega}_{\mathrm{h}} = -\hat{\boldsymbol{z}} \times \nabla w = \hat{\boldsymbol{x}}\,\partial_y w - \hat{\boldsymbol{y}}\,\partial_x w \tag{40.35}$$

is the horizontal component to the shallow water relative vorticity from equation (36.105d) (recall the expression for $\boldsymbol{\omega}_{\mathrm{h}}$ follows since the horizontal velocity components have no vertical dependence within a shallow water layer: $\partial u/\partial z = \partial v/\partial z = 0$). Inserting the absolute vorticity (40.33) into Kelvin's theorem (40.31) leads to

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[(\zeta + f)\,\delta A + \boldsymbol{\omega}_{\mathrm{h}} \cdot \hat{\boldsymbol{n}}\,\delta\mathcal{S}\right] = 0, \tag{40.36}$$

where the horizontal area element, δA, is the projection of the surface area element onto the vertical direction

$$\delta A = \hat{\boldsymbol{z}} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{40.37}$$

Shallow water fluid mechanics arises from considering a constant density fluid layer under the small aspect ratio limit ($H/L \ll 1$, with H the vertical length scale and L the horizontal length scale). Under this limit, the second term in equation (40.36) is much smaller than the first. It is further reduced in size since $\hat{\boldsymbol{n}}$ is nearly vertical, so that $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{z}} \approx 0$, in which case we are led to the scaling

$$\frac{|\boldsymbol{\omega}_{\mathrm{h}} \cdot \hat{\boldsymbol{n}}\,\delta\mathcal{S}|}{|(\zeta + f)\,\delta A|} \ll 1. \tag{40.38}$$

This result is consistent with our earlier comment in Section 40.3.1 that shallow water vortex tubes never close. Rather, they are nearly vertical, running from the bottom of a shallow water layer to the top. With the scaling (40.38), we find

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\left(\frac{\zeta + f}{h}\right) h\,\delta A\right] = 0, \tag{40.39}$$

where h is the layer thickness and $h\,\delta A$ is the volume of a fluid column extending through the shallow water layer. Given the incompressible nature of the fluid in a shallow water layer, the column volume is materially constant

$$\frac{\mathrm{D}\,(h\,\delta A)}{\mathrm{D}t} = 0, \tag{40.40}$$

so that equation (40.39) yields material invariance of shallow water potential vorticity

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\zeta + f}{h}\right] = \frac{\mathrm{D}Q}{\mathrm{D}t} = 0, \tag{40.41}$$

where $Q = (\zeta + f)/h$ is the same shallow water potential vorticity derived above in Section 40.3.1.

40.3.4 A fluid column with constant $f \neq 0$

Some of the essential features of shallow water potential vorticity material conservation are depicted in Figure 40.4 for the case of a fluid column with constant $f \neq 0$. In the left panel, the column thickness increases (column is stretched). Volume conservation for the column means that the column radius decreases. As the material in the column moves radially inward toward the center, it experiences a Coriolis deflection to the right in the northern hemisphere and to the left in the southern. Both of these deflections renders a cyclonic tendency to the relative vorticity, creating a positive relative vorticity tendency in the north and negative relative vorticity tendency in the south.

An equivalent way to understand the cyclonic tendency is to consider the angular momentum of the fluid column, assuming the column moves coherently as a rigid-body as in Section 40.2.[2] As the radius of the column decreases so too does its moment of inertia. Angular momentum conservation means that the column picks up a tendency that causes its spin to increase. The direction of this spin increase accords with the background f of the environment. Returning to the skater analog in Figure 40.1, we consider f to be the initial spin of the skater so that when the moment of inertia decreases the column picks up a spin in the same direction as f; i.e., a cyclonic tendency.[3]

In both hemispheres, the Coriolis deflection, or equivalently angular momentum conservation, creates a cyclonic relative vorticity tendency when the column stretches, thus maintaining $Q = (f + \zeta)/h$ fixed. Again, the cyclonic relative vorticity adds to the magnitude of the planetary vorticity to ensure that the absolute vorticity magnitude increases in accord with the column thickness increase, thus keeping $Q = \zeta_{\mathrm{a}}/h$ constant. The converse holds when the column is flattened/squashed, whereby the relative vorticity picks up an anti-cyclonic tendency (negative relative vorticity tendency in the northern hemisphere and positive relative vorticity tendency in the southern). Doing so reduces the magnitude of the absolute vorticity in accord with the reduced column thickness.

40.3.5 Material invariance of an arbitrary function of PV

The material invariance of shallow water potential vorticity, equation (40.29), means that any function, $F(Q)$ is also materially constant. We see this property through the chain rule

$$\frac{\mathrm{D}F}{\mathrm{D}t} = \frac{\mathrm{d}F}{\mathrm{d}Q}\frac{\mathrm{D}Q}{\mathrm{D}t} = 0. \tag{40.42}$$

Since F is arbitrary, there are an infinite number of material invariants corresponding to distinct functions F. This result holds for all materially invariant scalar properties of the fluid.

40.3.6 N-layer potential vorticity

The thickness equation (36.78a) and the vorticity equation (40.12) for an N-layer shallow water model are given by

$$\frac{\mathrm{D}_{\mathrm{k}}h_{\mathrm{k}}}{\mathrm{D}t} = -h_{\mathrm{k}}\,\nabla\cdot\boldsymbol{u}_{\mathrm{k}} \quad \text{and} \quad \frac{\mathrm{D}_{\mathrm{k}}\zeta_{\mathrm{ak}}}{\mathrm{D}t} = -\zeta_{\mathrm{ak}}\,\nabla\cdot\boldsymbol{u}_{\mathrm{k}}, \tag{40.43}$$

[2]Recall that in Section 40.2, the column rotates as a rigid-body, meaning there is no strain in the fluid, and yet the radius and thickness are allowed to change.

[3]The connection between the Coriolis acceleration and angular momentum conservation was discussed for particle mechanics in Section 14.7.

FIGURE 40.4: Material invariance for shallow water potential vorticity results from combining material invariance of the volume of a coherent fluid column with the material invariance of the area weighted absolute vorticity. As the cross-sectional area of the column decreases, as in a converging flow, the thickness of the fluid must increase in order to maintain constant volume. Furthermore, potential vorticity material invariance can be maintained by changing the fluid spin, as measured by the relative vorticity, or by changing the latitude and thus changing its planetary vorticity (the β-effect discussed in Section 41.6). We here depict the case with $f > 0$ constant (so that $\beta = 0$). Flow converging toward the center of the column picks up a Coriolis acceleration that creates a cyclonic tendency in the relative vorticity, just like the spinning cylinder in Figure 40.1. Equivalently, as the radius of the column decreases so too does its moment of inertia so that the column must pick up a cyclonic tendency to conserve angular momentum. Conversely, as the cross-sectional area increases, the diverging flow creates an anti-cyclonic tendency in the relative vorticity.

where there is no implied summation over the layer index k. These forms are isomorphic to the single layer equations so that the potential vorticity of layer-k is given by

$$Q_{\mathrm{k}} = \frac{f + \zeta_{\mathrm{k}}}{h_{\mathrm{k}}}, \tag{40.44}$$

and for a perfect shallow water fluid this layer potential vorticity is materially constant

$$\frac{\mathrm{D}_{\mathrm{k}} Q_{\mathrm{k}}}{\mathrm{D}t} = \frac{\partial Q_{\mathrm{k}}}{\partial t} + \boldsymbol{u}_{\mathrm{k}} \cdot \nabla Q_{\mathrm{k}} = 0, \tag{40.45}$$

where, again, there is no implied summation over k.

40.3.7 Further study

The shallow water potential vorticity (40.30) was introduced by *Rossby* (1940) and as such it is sometimes referred to as the *Rossby potential vorticity*. Non-rotating shallow water potential vorticity, ζ/h, is illustratated in this video from Prof. Shapiro at around the 11 minute mark. Note that he does not use the term "potential vorticity", instead invoking mass conservation and angular momentum conservation to describe the motion.

40.4 Potential vorticity with non-conservative processes

In this section we consider the role of a non-conservative force per mass, $\boldsymbol{F}$, with this term arising from friction and boundary stresses (Section 36.6.5). Additionally, we allow for the presence of a boundary volume source, $w^{(\dot{\eta})}$ (as in precipitation minus evaporation), thus changing the volume in the layer. We introduced such processes in Section 36.6, in which case the shallow water

equations take on the form

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\,\nabla\eta + \boldsymbol{F} \qquad \text{and} \qquad \frac{\mathrm{D}h}{\mathrm{D}t} + h\,\nabla\cdot\boldsymbol{u} = w^{(\dot{\eta})}. \tag{40.46}$$

40.4.1 Material time evolution of potential vorticity

In the presence of friction, the absolute vorticity equation (40.7) becomes

$$\frac{\partial\zeta_{\mathrm{a}}}{\partial t} + \nabla\cdot(\boldsymbol{u}\,\zeta_{\mathrm{a}}) = \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}) \Longrightarrow \frac{\mathrm{D}\zeta_{\mathrm{a}}}{\mathrm{D}t} + \zeta_{\mathrm{a}}\,\nabla\cdot\boldsymbol{u} = \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}), \tag{40.47}$$

so that vorticity is now affected by the curl of friction. As before, we make use of the thickness equation to replace the horizontal divergence according to

$$\nabla\cdot\boldsymbol{u} = \frac{1}{h}\left[-\frac{\mathrm{D}h}{\mathrm{D}t} + w^{(\dot{\eta})}\right]. \tag{40.48}$$

The presence of $w^{(\dot{\eta})}$ modifies the divergence of the horizontal velocity beyond that for a conservative fluid. We are thus led to the potential vorticity equation

$$h\,\frac{\mathrm{D}Q}{\mathrm{D}t} = -Q\,w^{(\dot{\eta})} + \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}). \tag{40.49}$$

Hence, with $w^{(\dot{\eta})} \neq 0$ and/or $\hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}) \neq 0$, shallow water potential vorticity is no longer materially invariant.

40.4.2 The potential vorticity flux

Deriving the flux-form equation

We can convert the potential vorticity equation (40.49) into a flux-form conservation equation by making use of the thickness equation

$$h\,\frac{\mathrm{D}Q}{\mathrm{D}t} = h\left[\frac{\partial Q}{\partial t} + \boldsymbol{u}\cdot\nabla Q\right] + Q\left[\frac{\partial h}{\mathrm{D}t} + \nabla\cdot(h\,\boldsymbol{u}) - w^{(\dot{\eta})}\right] = \frac{\partial(h\,Q)}{\partial t} + \nabla\cdot(\boldsymbol{u}\,h\,Q) - Q\,w^{(\dot{\eta})}, \tag{40.50}$$

thus rendering

$$\frac{\partial(h\,Q)}{\partial t} + \nabla\cdot(h\,\boldsymbol{u}\,Q) = \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}). \tag{40.51}$$

As a final step, make use of the identity

$$\hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{F}) = -\nabla\cdot(\hat{\boldsymbol{z}}\times\boldsymbol{F}), \tag{40.52}$$

so that the thickness weighted potential vorticity equation (40.51) can be written

$$\frac{\partial(h\,Q)}{\partial t} = -\nabla\cdot(h\,Q\,\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}). \tag{40.53}$$

Note how the volume source term, $w^{(\dot{\eta})}$, does not explicitly appear in the flux-form equation (40.53) since the effects from $w^{(\dot{\eta})}$ are captured by the divergence, $\nabla\cdot\boldsymbol{u}$, as per equation (40.48).

For the shallow water fluid, the thickness weighted potential vorticity equals to the absolute vorticity

$$h\,Q = \zeta_{\mathrm{a}}. \tag{40.54}$$

Consequently, the flux-form conservation form of the potential vorticity equation (40.53) is identical to equation (40.47) for the absolute vorticity

$$\frac{\partial(h\,Q)}{\partial t} = -\nabla\cdot(h\,Q\,\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}) \Longleftrightarrow \frac{\partial\zeta_{\mathrm{a}}}{\partial t} = -\nabla\cdot(\zeta_{\mathrm{a}}\,\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}). \tag{40.55}$$

Potential vorticity flux vector

It is remarkable that even with non-conservative forcing, the thickness weighted potential vorticity (equivalently, the absolute vorticity) has its Eulerian evolution determined by the convergence of a flux,

$$\boldsymbol{J}_{\mathrm{Q}} = h\,Q\,\boldsymbol{u} + \hat{\boldsymbol{z}}\times\boldsymbol{F}. \tag{40.56}$$

Observe that this potential vorticity flux is oriented in the horizontal direction. As detailed in Chapters 43 and 62, the potential vorticity flux never crosses the interface between two shallow water layers, even in the presence of non-conservatiive processes such as mixing and friction. This result is a special case of the more general *impermeability theorem* that holds for continuously stratified fluids (Section 43.2).

The flux convergence evolution for the potential vorticity equation (40.55) is a kinematic result of the definition of potential vorticity. Namely,

$$h\,Q - f = \zeta = \nabla\cdot(\boldsymbol{u}\times\hat{\boldsymbol{z}}) \tag{40.57}$$

so that

$$\partial_t(h\,Q) = \nabla\cdot(\partial_t\boldsymbol{u}\times\hat{\boldsymbol{z}}) \equiv -\nabla\cdot\boldsymbol{J}^{\mathrm{kin}}, \tag{40.58}$$

where we defined the kinematic potential vorticity flux vector

$$\boldsymbol{J}^{\mathrm{kin}} \equiv -\partial_t\boldsymbol{u}\times\hat{\boldsymbol{z}} = \boldsymbol{J} - \nabla\times(g\,\eta + \boldsymbol{u}\cdot\boldsymbol{u}/2). \tag{40.59}$$

Since the two potential vorticity fluxes differ by a curl; i.e., a rotational term, their divergences are identical

$$\nabla\cdot\boldsymbol{J}^{\mathrm{kin}} = \nabla\cdot\boldsymbol{J}, \tag{40.60}$$

so that their convergence leads to the same evolution of $h\,Q$. Stated more formally, $\boldsymbol{J}^{\mathrm{kin}}$ and $\boldsymbol{J}$ differ by a gauge, with the gauge function given by $g\,\eta + \boldsymbol{u}\cdot\boldsymbol{u}/2$.

40.5 Example implications of material PV invariance

The material invariance of shallow water potential vorticity provides nontrivial constraints on the shallow water motion by stating that f, h, ζ cannot change independently of the other. Rather, the combination $Q = (f+\zeta)/h$ must remain materially invariant (in the absence of friction and mixing). There are a variety of situations that induce changes in one or two of the terms, with the third term constrained to ensure Q remains unchanged. We here consider some thought experiments to garner experience with shallow water PV-thinking.

40.5.1 Topographic beta effect

Changes in the topography affect the potential vorticity by changing the thickness of a fluid column via (see Figure 36.1)

$$h = H + \Delta\eta - \Delta\eta_{\mathrm{b}}, \tag{40.61}$$

with $H = \overline{h}$ the area mean layer thickness, $\Delta\eta = \eta - \overline{\eta}$ the deviation of the free surface from its area mean, and $\Delta\eta_{\rm b} = \eta_{\rm b} - \overline{\eta_{\rm b}}$ the deviation of the bottom from its area mean. For relative vorticity, we note that spatial changes in the topography act to drive a vertical velocity at the layer bottom as per equation (36.28),

$$w = \frac{\mathrm{D}\eta_{\rm b}}{\mathrm{D}t} \quad \text{at } z = \eta_{\rm b}, \tag{40.62}$$

which then leads to vortex stretching and hence to a change in relative vorticity. In this subsection we highlight the analog between topographic slopes and planetary beta to thus motivate the term *topographic beta effect*.

To mathematically exhibit the topographic beta effect, consider a fluid column whose vorticity is dominated by planetary vorticity and with bottom topography having a small and linear slope in the meridional direction

$$\Delta\eta_{\rm b} = \delta\, y, \tag{40.63}$$

where $|\delta| \ll 1$ is the topographic slope. Assuming the free surface undulations are small relative to the resting layer thickness, $\Delta\eta \ll H$, we can expand the potential vorticity according to

$$Q = \frac{f + \zeta}{h} \tag{40.64a}$$

$$= \frac{f_0 + \beta\, y + \zeta}{H + \Delta\eta - \delta\, y} \tag{40.64b}$$

$$\approx \frac{f_0 + \beta\, y + \zeta}{H} \left[1 - H^{-1}\left(\Delta\eta - \delta\, y\right)\right] \tag{40.64c}$$

$$\approx \frac{f_0 + \beta\, y + \zeta}{H} - \frac{f_0}{H^2}\left(\Delta\eta - \delta\, y\right). \tag{40.64d}$$

Setting $\mathrm{D}Q/\mathrm{D}t = 0$ and rearranging leads to the material evolution of relative vorticity

$$\frac{\mathrm{D}\zeta}{\mathrm{D}t} = -v\left(\beta + f_0\delta/H\right) + \frac{f_0\, w(\eta)}{H}. \tag{40.65}$$

The second term on the right hand side is the vortex stretching associated with vertical motion at the top of the layer, where

$$w(\eta) = \mathrm{D}\Delta\eta/\mathrm{D}t = \mathrm{D}\eta/\mathrm{D}t \tag{40.66}$$

according to the surface kinematic boundary condition (36.36). The first term on the right hand side is vortex stretching arising from both planetary beta and topographic slopes. It is written in a form revealing the parallels between these two contributions, and it is readily generalized to the following for arbitrary topography

$$\beta_{\rm eff} = (H - \eta_{\rm b})\,\nabla[f/(H - \eta_{\rm b})] \approx \beta\,\hat{\boldsymbol{y}} + (f_0/H)\nabla\eta_{\rm b}. \tag{40.67}$$

One of the more prominant roles for topographic beta is in supporting topographic Rossby waves, which are analogous to the Rossby waves supported by planetary beta (see Section 52.3). We also encounter the topographic beta effect in Section 44.6.1 in our study of the quasi-geostrophic shallow water model.

40.5.2 Planetary geostrophic potential vorticity and f/H contours

As introduced in Section 32.5, planetary geostrophy (PG) is used to study the large-scale laminar ocean circulation where relative vorticity is ignored. Furthermore, as shown in Section 44.4, the

inviscid and adiabatic PG system materially preserves the PG potential vorticity, $Q = f/h$, so that

$$\frac{\mathrm{D}(f/h)}{\mathrm{D}t} = 0. \tag{40.68}$$

Consequently, fluid particles respecting the inviscid planetary geostrophic equations follow contours of constant f/h. These contours are referred to as *geostrophic contours* since the flow is under geostrophic balance.

Example f/H contours

If we assume the free surface undulations are negligible compared to the bottom topography (a useful assumption for planetary geostrophic flow), then shallow water columns follow contours of constant f/H, where $z = -H(x, y) = \eta_{\mathrm{b}}(x, y)$ is the vertical position of the bottom topography. In Figure 40.5 we illustrate f/H contours for a topographic seamount (bump), a topographic depression (bowl), and a shelf/slope along the western boundary. We see that f/H contours are diverted equatorward when depth decreases, whereas they are diverted poleward when encountering deeper water. Furthermore, those contours near to either a bump or bowl are closed, so that fluid columns following these contours are trapped around the topographic feature.

For the shelf/slope region in Figure 40.5, the f/H contours are horizontal where the topography is flat, which for this example is on the shelf and in the open ocean, whereas they are steered toward the equator as they pass from the shelf toward the coast. In this example, the difference between the shelf and deep ocean is only around 200 m, so that this example corresponds to upper ocean columns interacting with the continental slope. Part of the reason for choosing this geometry is that thicker fluid columns from the open ocean are unable to reach the continental shelf. The reason is that thick columns, as they reach the slope, have their f/H contours reach the equator along the slope before they reach the shelf. That is, the f/H contours for thick open ocean columns are almost entirely southward when reaching the continental slope, so that they cannot climb to shallower depths on the shelf.

FIGURE 40.5: When a shallow water fluid is governed by the inviscid and adiabatic planetary geostrophic equations and there is no external forcing, then shallow water fluid columns maintain fixed planetary geostrophic potential vorticity, $\mathrm{D}(f/h)/\mathrm{D}t = 0$. Ignoring free surface undulations relative to changes in the bottom depth means that f/H remains fixed following the inviscid geostrophic flow, where $z = -H(x, y) = \eta_{\mathrm{b}}(x, y)$ is the bottom topography. We illustrate these *geostrophic contours* for three topographic features: a Gaussian seamount or bump and a Gaussian bowl, both in the southern hemisphere; and a western boundary continental slope and shelf in the northern hemisphere. Contours of f/H follow lines of constant latitude when H is constant, f/H contours are steered equatorward when moving into a region of shoaling water (H decreases), and steered poleward when moving into deeper water (H increases). Futhermore, note that contours near the seamount and bowl can close, in which case the associated geostrophic contours are trapped next to the topographic features.

How planetary β affects f/H contours

The shelf example in Figure 40.5 reveals that for a given change in depth, the latitudinal diversion of an f/H contour is larger in magnitude for poleward contours relative to equatorward contours. We here show that this property of the f/H contours arises from planetary β.

For this purpose, consider a particular f/H contour, on which the latitude and depth change so as to keep f/H fixed so that

$$\delta(f/H) = 0, \tag{40.69}$$

where δ is a differential operator following the f/H contour. With $f = 2\,\Omega \sin\phi$, the constraint (40.69) relates deviations in latitude, $\delta\phi$, to deviations in depth, δH, along an f/H contour

$$\delta\phi = (\delta H/H)\tan\phi = \frac{f/H}{2\,\Omega\cos\phi} = \frac{f}{H}\,\frac{\delta H}{R_{\mathrm{e}}\,\beta} \Longrightarrow \frac{\delta\phi}{\delta H} = \frac{f}{H}\,\frac{1}{R_{\mathrm{e}}\,\beta}, \tag{40.70}$$

where we introduced planetary β according to

$$\beta = \partial_y f = (2\,\Omega/R_{\mathrm{e}})\cos\phi. \tag{40.71}$$

For a particular f/H contour, we see that $\delta\phi/\delta H$ is proportional to β^{-1}. Consequently, the magnitude of $\delta\phi/\delta H$ increases moving poleward, as β decreases toward zero.

40.5.3 Spin up of converging flow

Consider the flow shown in Figure 40.6, whereby mass in the shallow water layer converges into a region. Just as described in the potential vorticity derivation Figure 40.4, increasing the column thickness, without substantially altering the planetary vorticity (e.g., f-plane), requires $\partial\zeta/\partial t > 0$ in order to maintain $Q = (\zeta + f)/h$ materially constant. Following our discussion of the rotating column in Section 40.2, note that convergence of mass reduces the moment of inertia relative to the center of the region. Angular momentum conservation requires the fluid to rotate faster thus picking up a positive relative vorticity. This dynamical process is embedded in the material invariance of potential vorticity. Finally, note that the opposite occurs in a region of diverging fluid, whereby potential vorticity material invariance implies that the relative vorticity has a negative tendency ($\partial\zeta/\partial t < 0$) (see also Figure 40.4).

40.5.4 Further study

Section 4.3 of *Holton* (1992) discusses the case of flow over topography where the full shallow water potential vorticity is materially invariant, $\mathrm{D}(f+\zeta)/\mathrm{D}t = 0$. In that case there is a dramatic difference between easterly and westerly flows. In the northern hemisphere, westerly winds (eastward flow) deflects over the topography and downstream it undulates as topographic leewaves. A rotating tank offers a useful controlled setting to observe leewaves, such as shown near the 20 minute mark in this video from Prof. Fultz. Easterly winds (westward flow) do not exhibit a wave-like pattern, instead following a trajectory similar to the f/H contours of planetary geostrophic case, though modified by relative vorticity. In general, the study of flow near topography, either in the shallow water or continuously stratified, introduces a wealth of dynamical behaviors where material invariance of potential vorticity provides an important tool to help unravel mechanisms.

FIGURE 40.6: Illustrating the implications of potential vorticity material invariance for a shallow water fluid on an f-plane. If mass converges into a region, thus stretching the fluid column, then potential vorticity material invariance implies the relative vorticity increases, $\partial\zeta/\partial t > 0$. This result is directly analogous to the rotating cylinder example considered in Figures 40.1 and 40.4. Namely, converging a region of constant mass reduces its moment of inertia so that angular momentum conservation leads to an increase in spin.

40.6 Circulation with non-conservative processes

We follow the discussion in Section 40.4 to study the evolution of circulation in the presence of non-conservative processes such as dia-surface transport and boundary stresses (Section 36.6). For this purpose, consider the velocity circulation around a closed horizontal area, $\mathcal{S}$ (see Figure 40.7)

$$\mathcal{C} = \int_{\mathcal{S}} \zeta \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{S}} \boldsymbol{u} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell. \tag{40.72}$$

In this equation, $\hat{\boldsymbol{t}}\,\mathrm{d}\ell$ is the vector line increment around the contour, and $\hat{\boldsymbol{t}}$ is the tangent vector orienting the contour integral in a counterclockwise direction. We assume the circulation contour extends vertically through the layer so that the unit outward normal, $\hat{\boldsymbol{n}}$, to the contour is strictly horizontal, as is the tangent vector, $\hat{\boldsymbol{t}}$. We now seek an evolution equation for this circulation by making use of the vorticty equation (40.55).

FIGURE 40.7: Illustrating the calculation of circulation around the contour, $\partial\mathcal{S}$, of a static horizontal area, $\mathcal{S}$, within a layer of shallow water fluid. The circulation theorem (40.76) provides the means to compute the time changes in circulation as a function of the advection of absolute vorticity crossing the contour plus the circulation of friction. Note that the contour has a vertical extent throughout the shallow water layer, so that the unit outward normal, $\hat{\boldsymbol{n}}$, and the unit tangent direction, $\hat{\boldsymbol{t}}$, are both horizontal vectors.

To develop an evolution equation for $\mathcal{C}$, integrate the vorticity equation (40.55) over the area

$\mathcal{S}$ to yield

$$\int_{\mathcal{S}} \frac{\partial \zeta}{\partial t} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}} [-\nabla \cdot (\zeta_{\mathrm{a}} \, \boldsymbol{u} + \hat{\boldsymbol{z}} \times \boldsymbol{F})] \, \mathrm{d}\mathcal{S} = - \oint_{\partial \mathcal{S}} [\zeta_{\mathrm{a}} \, \boldsymbol{u} + \hat{\boldsymbol{z}} \times \boldsymbol{F})] \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\ell, \tag{40.73}$$

where $\oint$ symbolizes an integral around the contour. To reach this equation we used the divergence theorem on the right hand side, with $\hat{\boldsymbol{n}}$ the *horizontal* unit outward normal vector along the contour, $\partial \mathcal{S}$, and $\mathrm{d}\ell$ is the line increment along the contour. We also set $\partial f / \partial t = 0$ as part of the time derivative of the absolute vorticity. The non-conservative forcing term can be written

$$(\hat{\boldsymbol{z}} \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} = (\hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}) \cdot \boldsymbol{F} = -\hat{\boldsymbol{t}} \cdot \boldsymbol{F}, \tag{40.74}$$

thus leading to

$$\int_{\mathcal{S}} \frac{\partial \zeta}{\partial t} \, \mathrm{d}\mathcal{S} = - \oint_{\partial \mathcal{S}} \zeta_{\mathrm{a}} \, \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\ell + \oint_{\partial \mathcal{S}} \boldsymbol{F} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell, \tag{40.75}$$

where $\oint$ is the counter-clockwise oriented closed contour integral. We next assume the area $\mathcal{S}$ is constant in time, so that the Eulerian time derivative can be pulled across the integral to render

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = - \oint_{\partial \mathcal{S}} \zeta_{\mathrm{a}} \, \boldsymbol{u} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\ell + \oint_{\partial \mathcal{S}} \boldsymbol{F} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell. \tag{40.76}$$

The first term on the right hand side arises from the horizontal advection of absolute vorticity across the contour. This term is not oriented and so the integral sign has no arrow. The second term arises from the counter-clockwise oriented circulation of any non-conservative accelerations. We refer to equation (40.76) as a *circulation theorem*. It has many uses under specific cases, some of which are described in the remainder of this chapter.

40.6.1 Circulation around a closed streamline in steady flow

As a particular example of the circulation theorem (40.76), consider a steady flow in the absence of boundary volume sources ($w^{(\dot{\eta})} = 0$). In this case, the thickness equation (36.19) reduces to $\nabla \cdot (h \, \boldsymbol{u}) = 0$ so that we can introduce a transport streamfunction, Ψ (with dimensions of $\mathrm{L}^3 \, \mathrm{T}^{-1}$)

$$h \, \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla \Psi. \tag{40.77}$$

In a bounded domain, the streamlines (contours of constant Ψ) are closed. Furthermore, the unit outward normal to a closed streamline is perpendicular to the velocity, $\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = 0$. We thus see that the steady state expression of the circulation theorem (40.76), computed around a closed streamline, leads to the following constraint on the non-conservative forces

$$\oint_{\text{streamline}} \boldsymbol{F} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell = \int_{\text{streamline area}} (\nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{z}} \, \mathrm{d}\mathcal{S} = 0, \tag{40.78}$$

where the second equality follows from Stokes' theorem applied over the area bounded by the streamline. Equation (40.78) provides a constraint on the non-conservative forcing that must be satisfied to enable a steady flow. For example, when integrated around a closed streamline, the wind stress forcing must balance dissipation. If the constraint (40.78) is not satisfied, then the flow cannot reach a steady state. Although we may not know explicit details of the streamlines, we can still make use of this constraint if we assume the flow is steady. The analysis in Section 40.7 offers an example application of these ideas for studies of circulation in steady ocean gyres.

40.6.2 Circulation from wind stress and Rayleigh drag

A particularly simple form for the non-conservative acceleration is given by

$$\boldsymbol{F} = -\gamma\, \boldsymbol{u} + \boldsymbol{\tau}^{\text{wind}}/(h\,\rho) \equiv -\gamma\, \boldsymbol{u} + \boldsymbol{F}^{\text{wind}}. \tag{40.79}$$

The first term is referred to as *Rayleigh drag* with $\gamma > 0$ a constant with dimensions of inverse time.[4] Rayleigh drag damps all flow to rest with γ^{-1} the e-folding time for the damping. The second term in equation (40.79) is the acceleration on the layer from wind stress,

$$\boldsymbol{F}^{\text{wind}} = \frac{\boldsymbol{\tau}^{\text{wind}}}{h\,\rho}, \tag{40.80}$$

with this form following from our discussion in Section 36.6.5. Namely, the homogeneity of the shallow water layer renders the contact stress from winds into a body stress applied throughout the layer.

Plugging the acceleration (40.79) into the time dependent circulation theorem (40.76) leads to

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} + \gamma\,\mathcal{C} = -\int_{\partial\mathcal{S}} \zeta_{\mathrm{a}}\, \boldsymbol{u}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\ell + \oint_{\partial\mathcal{S}} \boldsymbol{F}^{\text{wind}}\cdot\hat{\boldsymbol{t}}\,\mathrm{d}\ell. \tag{40.81}$$

Specializing to a steady state and choosing the contour as a closed streamline (along which $\boldsymbol{u}\cdot\hat{\boldsymbol{n}} = 0$), renders

$$\mathcal{C} = \gamma^{-1}\oint_{\text{streamline}} \boldsymbol{F}^{\text{wind}}\cdot\hat{\boldsymbol{t}}\,\mathrm{d}\ell = (\gamma\,\rho)^{-1}\oint_{\text{streamline}} (\boldsymbol{\tau}^{\text{wind}}/h)\cdot\hat{\boldsymbol{t}}\,\mathrm{d}\ell. \tag{40.82}$$

This equation says that velocity circulation around a closed streamline is determined by wind stress circulation around that streamline plus knowledge of the Rayleigh drag damping time scale γ^{-1}. This result supports our expectation that the steady circulation around a closed streamline is oriented with the same sense as the applied wind stress.

40.7 A primer on steady ocean gyres

Ocean gyres are a prominent feature of ocean circulation, with the North Atlantic and North Pacific middle-latitude gyres two canonical examples. A characteristic feature of ocean gyres is that they are not symmetric in the east-west direction, with a prominent western side where poleward flow is stronger than the more sluggish southward flow in the interior. As shown in this section, gyre asymmetry is not a response to the wind forcing, with the asymmetry found even without any zonal variations in the winds. Instead, it is a manifestation of the beta effect present for flow on a rotating spherical planet (or idealized as the β-plane from Section 25.5). The role of $\beta > 0$ in western intensification was first articulated by *Stommel* (1948). We discuss the beta effect more formally in Section 41.6. For the present discussion, it is sufficient to know that it arises from the meridional derivative of the planetary vorticity:

$$\beta = \partial_y f > 0. \tag{40.83}$$

As such, the beta effect encapsulates the leading order role of the earth's sphericity.

We have the basic tools in hand to understand the physical balances leading to western intensification in steady ocean gyres. We follow the traditional approach by focusing on vorticity balances. Vorticity budgets offer a more direct path towards understanding western intensification

[4] See Section 34.2.4 for more discussion of Rayleigh drag in the context of Ekman mechanics.

than the linear momentum or axial angular momentum balances used to explore channel flow in Sections 29.5 and 37.7.

40.7.1 Steady and large-scale vorticity balance

The steady circulation theorem (40.82) holds regardless the bottom topography or surface height undulations. Again, it says that circulation around a closed streamline is in the same sense as the wind circulation. However, we need more information to see how western intensification emerges as a property of the flow in ocean gyres. For that purpose, consider the steady absolute vorticity equation (40.55), again in the presence of wind forcing and Rayleigh drag

$$\nabla \cdot (\boldsymbol{u}\, \zeta_{\mathrm{a}}) = -\gamma\, \zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\mathrm{wind}}). \tag{40.84}$$

Introducting the shallow water potential vorticity, $Q = \zeta_{\mathrm{a}}/h$, allows us to write

$$\nabla \cdot (\boldsymbol{u}\, \zeta_{\mathrm{a}}) = \nabla \cdot (h\, \boldsymbol{u}\, Q). \tag{40.85}$$

The steady state thickness equation (36.19) means that $\nabla \cdot (h\, \boldsymbol{u}) = 0$, so that the vorticity equation (40.84) takes the form

$$h\, \boldsymbol{u} \cdot \nabla Q = -\gamma\, \zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\mathrm{wind}}). \tag{40.86}$$

This equation says that in the absence of the Rayleigh friction ($\gamma = 0$) and with a zero wind stress curl, the steady horizontal flow is aligned with potential vorticity contours. This result follows directly from the material invariance of potential vorticity in the absence of non-conservative processes. However, in the presence of Rayleigh drag and/or wind stress curl, the potential vorticity is modified when following the flow so that $\boldsymbol{u} \cdot \nabla Q \neq 0$, in which case the circulation does not follow Q contours.

40.7.2 Planetary geostrophic flow and the Sverdrup balance

For large-scale flow away from lateral boundaries, the flow has an absolute vorticity that is dominated by planetary vorticity so that

$$Q \approx Q_{\mathrm{PG}} = f/h, \tag{40.87}$$

which is the potential vorticity for planetary geostrophic flow (Section 32.5 and 44.4). Correspondingly, we assume the Rayleigh drag term is negligible in this region since the relative vorticity is small, so that the potential vorticity equation (40.86) takes the form

$$h\, \boldsymbol{u} \cdot \nabla Q_{\mathrm{PG}} = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\mathrm{wind}}). \tag{40.88}$$

Expanding the left hand side and introducing the planetary vorticity gradient renders the *shallow water Sverdrup balance*

$$\beta\, v = Q_{\mathrm{PG}}\, \boldsymbol{u} \cdot \nabla h + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\mathrm{wind}}) \qquad \text{shallow water Sverdrup balance.} \tag{40.89}$$

This balance states how horizontal advection of layer thickness (first right hand side term) plus the wind stress curl (second term) balance meridional motion for flow on a rotating sphere (beta effect on left hand side). Gradients in the layer thickness arise from free surface undulations as well as gradients in the bottom topography (see Figure 36.1). The traditional *Sverdrup balance* arises when we assume the flow takes place over a flat bottom and the free surface undulations

are negligible, in which case $\nabla h = 0$ so that

$$\beta\, v = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}) \qquad \text{traditional Sverdrup balance.} \tag{40.90}$$

This balance is also suited to a stratified ocean in regions where the upper ocean flow does not interact with the bottom, such as in regions far from the continental shelves, or in regions where vertical stratification (i.e., the pynocline) shields the upper ocean flows from bottom topography.

40.7.3 Sverdrup flow in a closed domain with anti-cyclonic wind stress

Consider a closed northern hemisphere middle latitude β-plane domain driven by an anti-cyclonic wind stress

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}) < 0 \qquad \text{northern hemisphere anti-cyclonic wind stress.} \tag{40.91}$$

This situation is depicted in Figure 40.8, where we also illustrate a commonly used wind stress profile that is purely zonal and has a co-sinusoidal meridional structure that is symmetric about the central latitude of the domain

$$\boldsymbol{F}^{\text{wind}} = -\hat{\boldsymbol{x}}\, A\, \cos[\pi\, (y - y_0 + L/2)/L] \tag{40.92a}$$

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}) = -(\pi\, A/L) \sin[\pi\, (y - y_0 + L/2)/L]. \tag{40.92b}$$

In these equations, $A > 0$ is the magnitude of the wind stress acceleration applied to the layer, and the domain extends meridionally from $y_0 - L/2 \leq y \leq y_0 + L/2$ with $y = y_0$ the central latitude. This wind stress has westerlies on the poleward side of the domain and easterlies (trade winds) on the equatorward side so that $\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{\tau}) < 0$ throughout the domain.

The Sverdrup balance (40.90) indicates that an anti-cyclonic wind stress curl drives an equatorward Sverdrup flow. We emphasize that this flow is *not* the result of meridional winds pushing the fluid to the south. Instead, it arises in response to the constraints of vorticity balance with an anti-cyclonic wind stress curl in the presence of the beta effect. Indeed, for the idealized wind stress (40.92a) there is no meridional wind component. Although water satisfying Sverdrup balance flows south, all the water in the domain cannot be moving to the south. Rather, volume conservation requires a poleward return flow somewhere outside the region of Sverdrup balance.

40.7.4 Western intensification and the role of beta

Volume conservation is a kinematic constraint that requires a return flow on either the eastern or western side of the domain, outside the region of Sverdrup balance. But what side? We offer the following arguments for the western side.

Inertial entry into a boundary layer region

Recall the discussion of Figure 39.4 where we considered how inviscid flow in a homogeneous fluid over a flat bottom region materially preserves absolute vorticity in the presence of a meridional barrier. To materially preserve absolute vorticity (and ignoring free surface undulations relative to the depth of the fluid), the flow can deviate meridionally, either northward or southward, when encountering a western wall. In contrast, such meridional deviation is prohibited for absolute vorticity preserving flow that encounters an eastern wall. So in referring to Figure 40.8, southward flow can make a turn westward towards the western boundary, enter the boundary layer, and move northward within the boundary layer. It cannot do so for the eastern side.

FIGURE 40.8: Illustrating the southward Sverdrup flow in response to an anti-cyclonic wind stress forcing in a bounded northern hemisphere domain. A northward return flow is required to satisfy volume conservation. As seen in Section 40.7.4, a linear vorticity balance between beta, winds, and friction lead to a western boundary return flow and corresponding western intensification.

Steady velocity circulation follows wind circulation

The steady circulation theorem (40.82) means that the flow circulation is in the same sense as the wind circulation. With an anti-cyclonic wind forcing, the circulation also must be anti-cyclonic. This result again leads us to conclude that the western boundary is the region for the return flow, in which case the full gyre circulation will be anti-cyclonic.

Steady vorticity balance and a role for dissipation

The two previous arguments point to the western side as the return flow region. But we have yet to provide an argument for western boundary intensification. For that purpose, recall that the return flow region is not in traditional Sverdrup balance. To see what terms can break that balance, consider again the steady vorticity balance (40.86). Continuing to assume a flat bottom and rigid lid surface leads to

$$\beta\, v = -\gamma\, \zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}), \tag{40.93}$$

where we dropped the nonlinear advection term $\boldsymbol{u} \cdot \nabla\zeta$ (the "inertial" term) since we wish to determine whether a linear balance can give rise to western intensification (we return to this assumption in Section 40.7.8). The Rayleigh drag on the right hand side breaks the Sverdrup balance in regions where the relative vorticity is nontrivial. Since we know there must be a return flow somewhere in the domain, we know there must be a region where dissipation is sufficiently strong to break Sverdrup balance.

What is required for the steady and linear dissipative vorticity balance (40.93) to be maintained in the northward return flow region? To answer this question, expose the signs on the terms in equation (40.93)

$$\underbrace{\beta\, v}_{\text{positive}} + \underbrace{\gamma\, \zeta}_{\text{unspecified}} = \underbrace{\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}})}_{\text{negative}}. \tag{40.94}$$

We have $\beta\, v > 0$ since we are concerned with the region of northward return flow, and $\hat{\boldsymbol{z}} \cdot (\nabla \times$

$\boldsymbol{F}^{\text{wind}}) < 0$ by assumption of anti-cyclonic wind stress over the full domain. Hence, for the balance (40.94) to be realized requires $\zeta < 0$, with the value large enough to balance both the winds and the meridional advection of planetary vorticity

$$\underbrace{\gamma\,\zeta}_{\text{negative}} = \underbrace{-\beta\,v}_{\text{negative}} + \underbrace{\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}})}_{\text{negative}}. \tag{40.95}$$

For anti-cyclonic gyre flow, as required by the circulation condition (40.82), the only way to realize $\zeta < 0$ of sufficient magnitude is to have an intensified flow along the western side of the gyre. In this region, $\zeta \approx \partial v/\partial x < 0$ can become sufficiently large in magnitude. Furthermore, since the wind stress is applied throughout the domain, all streamlines feel the winds and must pass through the western boundary region where vorticity is enhanced and Rayleigh drag is able to balance the winds and planetary advection. The required boundary current flow is depicted in Figure 40.8.

The importance of beta

In the absence of beta, there would be no interior region in Sverdrup balance driving southward flow. The flow would thus only be subject to the circulation condition (40.82) whereby linear flow can symmetrically dissipate the wind stress. Hence, the beta effect is the fundamental element that causes poleward flow to intensify along the western side of the gyre in response to the equatorward interior flow.

40.7.5 A role for bottom pressure torques

Recall the shallow water Sverdrup balance (40.89), here with the addition of Rayleigh drag

$$\beta\,v = Q_{\text{PG}}\,\boldsymbol{u} \cdot \nabla h - \gamma\,\zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}). \tag{40.96}$$

For the right hand side, we have thus far considered a flat bottom and ignored free surface undulations, in which case $\nabla h = 0$. In this case, the only way to balance meridional motion on a beta plane is to invoke non-conservative processes either from wind stress or Rayleigh drag.

Spatial variations in the bottom topography open up the possibility for an inviscid balance

$$\beta\,v = Q_{\text{PG}}\,\boldsymbol{u} \cdot \nabla h, \tag{40.97}$$

or more generally a balance where frictional vorticity sinks are unimportant except for regions very close to the boundary. For example, consider northward flow in the northern hemisphere along a shallow western continental shelf. Assume the bottom topography only has variations in the zonal direction, with $\partial_x h > 0$ reflecting deeper water to the east of the shelf. The inviscid vorticity balance (40.97) thus takes the form

$$\beta\,v = (f/h)\,u\,\partial_x h. \tag{40.98}$$

Since $\beta\,v > 0$ and $(f/h)\,\partial_x h > 0$, we must have $u > 0$. Hence, flow departs from purely northward motion by leaving the shelf and moving into deeper waters. This behavior is also revealed by the western shelf example in Figure 40.5, where the f/H contours deviate from contours of constant depth when there is a nonzero β. As examined in this section, the bottom pressure torque, arising from bottom topographic form stress, plays the lead role in the corresponding vorticity balance.

Curl of the form stresses

In the present analysis, we are only concerned with that portion of $\boldsymbol{u} \cdot \nabla h$ directly arising from pressure gradients. We thus consider just the geostrophic flow to arrive at

$$\boldsymbol{u} \cdot \nabla h = (g/f)\, \nabla h \cdot (\hat{\boldsymbol{z}} \times \nabla \eta) = (g/f)\, \hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla h). \tag{40.99}$$

It is this term that contains the various pressure torques arising from form stresses. But before unpacking those torques, briefly return to the above shelf example and note that with $\nabla h = \hat{\boldsymbol{x}}\, \partial_x h$ then there is a nonzero $\boldsymbol{u} \cdot \nabla h$ only with a nonzero $\partial_y \eta$, which in turn means there is a nonzero zonal geostrophic flow. As noted above, this zonal flow is a consequence of the sloping bottom topography.

Pressure torques

Returning to the general situation, we determine the expressions for the pressure torques contained in the term $\boldsymbol{u} \cdot \nabla h$ by making use of the hydrostatic relation $p_{\mathrm{b}} = p_{\mathrm{a}} + \rho\, g\, h$, and the layer thickness, $h = \eta - \eta_{\mathrm{b}}$ (see Figure 36.1), in which case

$$\begin{aligned}
\boldsymbol{u} \cdot \nabla h &= (g/f)\, \hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla h) && \text{(40.100a)}\\
&= 1/(\rho\, f)\, \hat{\boldsymbol{z}} \cdot [\nabla \times (p_{\mathrm{a}} \nabla \eta) + \nabla \eta \times \nabla p_{\mathrm{b}}] && \text{(40.100b)}\\
&= 1/(\rho\, f)\, \hat{\boldsymbol{z}} \cdot [\nabla \times (p_{\mathrm{a}} \nabla \eta) - \nabla \times (p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) + \nabla h \times \nabla p_{\mathrm{b}}] && \text{(40.100c)}\\
&= 1/(\rho\, f)\, \hat{\boldsymbol{z}} \cdot [\nabla \times (p_{\mathrm{a}} \nabla \eta) - \nabla \times (p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) + \nabla p_{\mathrm{b}} \times \nabla p_{\mathrm{a}}/(\rho\, g)]\,. && \text{(40.100d)}
\end{aligned}$$

The first and second terms are the curls of the pressure form stresses applied to the surface (atmospheric) and bottom boundaries (Section 29.2), respectively, which we refer to as the atmospheric and bottom pressure torques. The third term is a torque arising from misalignment of the applied pressure and bottom pressure. Inserting equation (40.100d) in the vorticity balance (40.96) leads to the steady balance

$$\beta\, \rho\, h\, v = \hat{\boldsymbol{z}} \cdot [\nabla \times (p_{\mathrm{a}} \nabla \eta) - \nabla \times (p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) + \nabla p_{\mathrm{b}} \times \nabla p_{\mathrm{a}}/(\rho\, g)] + \rho\, h\, [-\gamma\, \zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\mathrm{wind}})]\,. \tag{40.101}$$

We consider a few special cases to see how the pressure torques affect the meridional flow in a gyre circulation, with a focus on bottom pressure torque since this term is generally far larger than those torques involving the atmospheric pressure.

Inviscid balance between meridional flow and bottom pressure torque

In the absence of friction and wind forcing, and with a uniform atmospheric pressure ($\nabla p_{\mathrm{a}} = 0$), then β times the depth integrated meridional mass transport in equation (40.101) is balanced by the bottom pressure torque (i.e., curl of the topographic form stress)

$$\beta\, \rho\, h\, v = -\hat{\boldsymbol{z}} \cdot (\nabla \times p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) \qquad \text{linear inviscid and unforced.} \tag{40.102}$$

Again consider the example of northward flow along a western continental shelf. In this case, $\nabla \eta_{\mathrm{b}} = \hat{\boldsymbol{x}}\, \partial_x \eta_{\mathrm{b}} < 0$, so that the balance (40.102) reduces to

$$\beta\, \rho\, h\, v = \partial_y p_{\mathrm{b}}\, \partial_x \eta_{\mathrm{b}}. \tag{40.103}$$

This balance says that if the bottom depth increases eastward away from the shelf, so that $\partial_x \eta_{\mathrm{b}} < 0$, then northward flow corresponds to a northward decrease in the bottom pressure,

$\partial_y p_{\rm b} < 0$. That is, the northward flow is directed down the bottom pressure gradient.

Association rather than causality

The inviscid planetary geostrophic balance (40.102) does not express causality. Rather, it expresses a balance or association that is maintained by steady linear flows in the presence of sloping topography. Hence, it is incorrect to say that bottom pressure torque gives rise to (i.e., causes) inviscid planetary geostrophic flow. Rather, the balance (40.102) says for planetary geostrophic flow, there is no bottom pressure torque without a meridional flow, and conversely there is no meridional flow without bottom pressure torque.

Vanishing topographic form stress curl for geostrophic f-plane motion

From the balance (40.102), we find that a linear inviscid and unforced geostrophic flow on an f-plane satisfies

$$\hat{\boldsymbol{z}} \cdot (\nabla \times p_{\rm b} \nabla \eta_{\rm b}) = \hat{\boldsymbol{z}} \cdot (\nabla p_{\rm b} \times \nabla \eta_{\rm b}) = 0 \quad \beta = 0. \tag{40.104}$$

When we can ignore the applied surface pressure, $p_{\rm a} = 0$, then the bottom pressure is given by $p_{\rm b} = g\,\rho\,h = g\,\rho\,(\eta - \eta_{\rm b})$, in which case $\hat{\boldsymbol{z}} \cdot (\nabla p_{\rm b} \times \nabla \eta_{\rm b}) = \hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla \eta_{\rm b})$. Evidently, linear inviscid and unforced geostrophic flow on an f-plane means that $\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla \eta_{\rm b}) = 0$. That is, isolines of surface height align with isolines of bottom topography. Conversely, surface height contours that deviate from bottom topography contours signal the role of friction and/or β acting on the planetary geostrophic flow.

Local generation of bottom pressure torque

The beta effect provides an inviscid means to balance a misalignment between the surface height and the bottom topography, with misalignment required to generate a nonzero topographic form stress curl, which we have been referring to as the bottom pressure torque. We discussed an analogous misalignment is Section 37.7 when studying the force balances in a steady zonally re-entrant channel with bottom topography. Wind stress forcing and dissipation offer another means to balance $(\eta, \eta_{\rm b})$-misalignment, as seen merely by rewriting the vorticity balance (40.101) as an expression for the bottom pressure torque

$$\begin{aligned} &\hat{\boldsymbol{z}} \cdot (\nabla \times p_{\rm b} \nabla \eta_{\rm b}) = \\ &\qquad - \beta\,\rho\,h\,v + \hat{\boldsymbol{z}} \cdot [\nabla \times (p_{\rm a} \nabla \eta) + \nabla p_{\rm b} \times \nabla p_{\rm a}/(\rho\,g)] + \rho\,h\,[-\gamma\,\zeta + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\rm wind})]\,. \end{aligned} \tag{40.105}$$

In our discussion of western intensification in Section 40.7.4, we ignored the role of bottom pressure torque. However, as seen by this balance, bottom pressure torque plays a role when topography and surface height are misaligned, with that role in some locations more important than friction. Ssee *Becker and Salmon* (1997), *Hughes* (2000), *Hughes and de Cueves* (2001), *Jackson et al.* (2006) and *Patmore et al.* (2019) for examples.

40.7.6 Properties of area integrated bottom pressure torques

Consider a simply connected fluid domain bounded by an isobath. Stokes' theorem reveals that the integral of the bottom pressure torque, $\hat{\boldsymbol{z}} \cdot (\nabla \times p_{\rm b} \nabla \eta_{\rm b})$, vanishes when computed over the area bounded by any isobath

$$\int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot (\nabla \times p_{\rm b} \nabla \eta_{\rm b})\, {\rm d}\mathcal{S} = \oint_{\partial \mathcal{S}} p_{\rm b} \nabla \eta_{\rm b} \cdot \hat{\boldsymbol{t}}\, {\rm d}\ell = 0. \tag{40.106}$$

The integrand for the line integral vanishes pointwise since, by construction, the boundary, $\partial\mathcal{S}$, is determined by an isobath so its the tangent vector, $\hat{\boldsymbol{t}}$, is orthogonal to $\nabla\eta_{\mathrm{b}}$. The identical argument holds for an area bounded by an isobar of bottom pressure since, for any region,

$$\int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot (\nabla \times p_{\mathrm{b}} \nabla \eta_{\mathrm{b}})\, \mathrm{d}\mathcal{S} = -\int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot (\nabla \times \eta_{\mathrm{b}} \nabla p_{\mathrm{b}})\, \mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{S}} \eta_{\mathrm{b}} \nabla p_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}\ell. \tag{40.107}$$

Now if the region is bounded by an isobar, then $\nabla p_{\mathrm{b}} \cdot \hat{\boldsymbol{t}} = 0$ at each point along the region boundary. With a bit more work, we can show that the area integral of the bottom pressure torque vanishes for an annular region bounded by any two isobaths or any two bottom pressure isobars. The proof is presented in the caption to Figure 40.9.

These mathematical identities mean that bottom pressure torque plays no role in the area integrated vorticity budget for regions bounded by isobaths or bottom pressure isobars. In particular, taking a contour that encircles the global ocean reveals that bottom pressure torque does not alter the global area integrated vorticity. Equivalently, topographic form stresses integrated around a closed contour defined by an isobath or isobar do not alter the circulation around that contour. Evidently, topographic form stress cannot spin-up or spin-down the circulation around a contour determined by isobaths or bottom pressure isobars. Other processes, such as flow nonlinearities, viscous friction, and/or boundary stresses, must play role in determining the circulation since their contour integrals are unconstrained. As studied by *Stewart et al.* (2021), these very special properties of bottom pressure torque and topographic form stress introduce a variety of nuances when interpreting the area integrated vorticity budget.

FIGURE 40.9: Stokes' theorem is generally applicable in a simply connected region. However, an annulus region, $\mathcal{S}$, is not simply connected since it has a hole. To apply Stokes' theorem over an annulus we imagine snipping the outer contour, $\partial\mathcal{S}_1$, and inner contour, $\partial\mathcal{S}_2$, and then connecting the two ends of the snipped contours as shown here. In this manner we convert the non-simply connected annulus into a simply connected region, over which we can apply Stokes' theorem in the naive manner. Importantly, we see that the the two segments connecting the inner and outer contour are traversed in opposite directions when performing the contour integral. Assuming all functions are smooth, we can take the limit as these two contours get infinitesimally close, in which they cancel identically. This limit also recovers the connected outer and inner contours. If the outer and inner contours are defined by isobaths or bottom pressure isobars, then the bottom pressure torque identically vanishes on the contours. In this manner we have proven that the bottom pressure torque vanishes within the annulus region. We make use of this method in Exercise 41.8 when considering the circulation in an ocean domain with islands.

40.7.7 Advection-diffusion of the steady streamfunction[5]

Since the steady state flow satisfies $\nabla \cdot (h\,\boldsymbol{u}) = 0$, we can introduce a streamfunction

$$h\,\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla \Psi, \tag{40.108}$$

in which case the relative vorticity becomes

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \nabla \cdot (h^{-1}\,\nabla \psi), \tag{40.109}$$

and the steady vorticity equation (40.86) can be written

$$\hat{\boldsymbol{z}} \cdot (\nabla \Psi \times \nabla Q) = -\gamma\,\nabla \cdot (h^{-1}\,\nabla \Psi) + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}). \tag{40.110}$$

Following *Welander* (1968), we interpret equation (40.110) as a steady advection-diffusion equation for Ψ. Namely, introduce the horizontally non-divergent vector

$$\boldsymbol{u}^{(\text{Q})} = \hat{\boldsymbol{z}} \times \nabla Q, \tag{40.111}$$

in which case the streamfunction equation (40.110) becomes

$$\boldsymbol{u}^{(\text{Q})} \cdot \nabla \Psi = \gamma\,\nabla \cdot (h^{-1}\,\nabla \Psi) - \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}^{\text{wind}}). \tag{40.112}$$

With zero wind stress curl and zero Rayleigh drag, the contours of the steady streamfunction are aligned with $\boldsymbol{u}^{(\text{Q})}$; that is, Ψ and Q contours are parallel. In the presence of Rayleigh drag, the streamfunction deviates from the Q contours, as it does in the presence of a wind stress curl.

These results represent a mere repackaging of results found earlier. Even so, the advection-diffusion interpretation offers complementary insights into the patterns of the steady streamfunction. Indeed, as we see in Section 40.8, the advective-diffusive interpretation proves very useful when studying patterns of steady sea level in planetary geostrophic gyres.

40.7.8 Comments and further study

Friction is needed to close the vorticity budget in a flat bottom linear ocean

This video from SciencePrimer provides a concise summary of the dynamics of ocean gyres and western boundary intensification due to the beta effect. Chapter 19 of *Vallis* (2017) provides a lucid treatment of ocean gyre dynamics by working through the key features of the *Stommel* (1948) model, as well as variants such as that from *Munk* (1950), who considered a viscous closure (most important next to side boundaries) rather than the Rayleigh drag used by Stommel. The Stommel model and its variants are themselves very idealized renditions of the ocean gyres occuring in Nature. Notable further factors become important in studying Nature's gyres, such as topography (briefly discussed in Section 40.7.5), flow nonlinearities and instabilities (recall we dropped the inertial term in Section 40.7.4, thus focusing on linear balances), turbulent boundary layers, and coupled air-sea processes. Each of these processes render the study of western boundary currents one of the most complex and timeless areas of physical oceanography.

[5] We study the physics of advection and diffusion in Chapter 64. For Section 40.7.7 we only require a few basic features of this equation.

Distinguishing beta-induced western boundary currents from frictional boundary layers

Western intensification of the gyre, implied by $\beta > 0$, is distinct from a frictional boundary layer, implied by a no-slip side boundary (e.g., Section 26.8). Namely, a frictional western boundary layer, supported by a no-slip solid earth boundary, leads to cyclonic flow within the boundary layer. In contrast, as discussed in this section, planetary β-induced western intensification gives rise to anti-cyclonic flow in the western boundary current. This distinction emphasizes the importance of the side boundary condition, be it no-slip, free-slip, or partial slip. Namely, the free-slip boundary does not support the cyclonic boundary layer of the no-slip. As explored in *Kiss* (2002) and *Kiss* (2004), these distinct boundary conditions lead to distinct boundary current properties, with impacts on the dynamics of how the boundary current separates from the side.

Topographic form stress reduces the fundamental role of friction

Friction plays a central role in the Stommel and Munk models of western intensification. As described in Chapter 19 of *Vallis* (2017), there have been attempts to produce an inviscid (and unforced) gyre solution, with the study from *Fofonoff* (1954) of particular note. We consider elements of the Fofonoff gyre in Exercise 39.12. Additionally, we raised the importance of sloping sides in Section 40.7.5 and in the earlier discussion of axial angular momentum in Section 29.5. Sloping sides enable bottom topographic form stress and bottom pressure torques to dominate over bottom turbulent stresses and turbulent torques. In so doing, sloping sides play a leading role in gyre balances, though we did note in the discussion surrounding equation (40.106) that friction remains essential to close the vorticity balance integrated around the gyre. The role of sloping sides for gyre circulations was emphasized by *Hughes* (2000), *Hughes and de Cueves* (2001), with *Stewart et al.* (2021) identifying further nuances related to the integrated properties in Section 40.7.6.

Flow nonlinearities also reduce the role of friction

Furthermore, we ignored the role of nonlinearities, which generally require the use of numerical models to investigate. Indeed, one of the first numerical simulations was from *Bryan* (1963), who showed that western boundary currents in a flat bottom gyre generally experience hydrodynamical instabilities when the flows become strong enough. *Becker and Salmon* (1997) and *Becker* (1999) further studied the case of a nonlinear gyre circulation in the presence of a sloping side shelf, thus allowing for the role of both nonlinearities and topographic form stress in the vorticity balance. These, and many other, studies allow for inviscid contributions to the vorticity balance, thus alleviating the need for invoking strong frictional effects found in the models of Stommel and Munk.

40.8 Free surface patterns in steady ocean gyres

We here consider basic features of steady free surface patterns realized by a shallow water fluid, with inspiration from *Minobe et al.* (2017), *Wise et al.* (2018), *Wise et al.* (2020a) and *Wise et al.* (2020b), and making use of the advection-diffusion interpretation of *Welander* (1968) introduced in Section 40.7.7. The basic question is how to relate the free surface near the coast to that in the interior of an ocean gyre. We formulate the steady linear case following *Wise et al.* (2018), who considered sloping bottom topography rather than the vertical walls assumed by *Minobe et al.* (2017). The transient case, which involves coastal boundary waves, is considered by *Hughes et al.* (2019), *Wise et al.* (2020a) and *Wise et al.* (2020b).

40.8.1 Formulating the free surface equation

We make use of the steady frictional geostrophic equations, with the velocity equation given by the linearized version of equation (40.128)

$$f\,\hat{\boldsymbol{z}} \times h\,\boldsymbol{u} = -g\,h\,\nabla\eta + \boldsymbol{f}^{\mathrm{nc}}. \tag{40.113}$$

Here, $\boldsymbol{f}^{\mathrm{nc}}$ is the thickness weighted acceleration from non-conservative processes, such as the wind stress, viscous friction, and bottom drag, with details provided in Section 40.9.1. Since the flow is steady, the layer thickness equation (36.20) leads to the non-divergence condition

$$\nabla \cdot (h\,\boldsymbol{u}) = 0. \tag{40.114}$$

We now formulate a vorticity-like equation. Yet rather than taking the curl of equation (40.113), thus emulating the work from Section 40.9, we first divide by the Coriolis parameter to write

$$\hat{\boldsymbol{z}} \times h\,\boldsymbol{u} = -(g\,h/f)\,\nabla\eta + \boldsymbol{f}^{\mathrm{nc}}/f, \tag{40.115}$$

so that the curl leads to

$$\hat{\boldsymbol{z}} \cdot [\nabla(g\,h/f) \times \nabla\eta] = \hat{\boldsymbol{z}} \cdot \nabla \times (\boldsymbol{f}^{\mathrm{nc}}/f), \tag{40.116}$$

where we used the non-divergence condition (40.114). Dividing by the Coriolis parameter limits the analysis to regions bounded away from the equator, which is not a problem for our focus on middle or high latitude planetary geostrophic ocean gyres. We are motivated to pursue this formulation since it supports the use of equation (40.116) next to sloping boundaries, in which the layer thickness vanishes ($h = 0$) at the shoreline edge of the domain.

40.8.2 Advecting the free surface

To help interpret the conservative portion of the free surface equation (40.116), we introduce the streamfunction[6]

$$\psi^{(\eta)} \equiv -g\,h/f, \tag{40.117}$$

so that equation (40.116) takes the form

$$\boldsymbol{u}^{(\eta)} \cdot \nabla\eta = -\hat{\boldsymbol{z}} \cdot \nabla \times (\boldsymbol{f}^{\mathrm{nc}}/f), \quad \text{with} \quad \boldsymbol{u}^{(\eta)} = \hat{\boldsymbol{z}} \times \nabla\psi^{(\eta)} = -\hat{\boldsymbol{z}} \times \nabla(g\,h/f). \tag{40.118}$$

The left hand side is written as the advection of the free surface by the horizontally non-divergent velocity, $\boldsymbol{u}^{(\eta)}$. That is, the velocity, $\boldsymbol{u}^{(\eta)}$, advects the free surface, whereas the fluid velocity, $\boldsymbol{u}$, advects matter. In the absence of non-conservative forces ($\boldsymbol{f}^{\mathrm{nc}} = 0$), the free surface is aligned with isolines of $h/f = 1/Q_{\mathrm{PG}}$, or equivalently with lines of constant planetary geostrophic potential vorticity, Q_{PG} (recall that $Q_{\mathrm{PG}} = f/h$ as defined by (40.87)). For free surface contours to deviate from Q_{PG} contours requires non-conservative forces, such as those from wind stresses and frictional dissipation. This discussion is related to that given in Section 40.5.2 where we introduced the notion of f/H contours for planetary geostrophic flow.

[6] We follow the sign convention of *Wise et al.* (2018) by introducing $\psi^{(\eta)} = -g\,h/f$ in equation (40.117). The alternative choice of $\psi^{(\eta)} = +g\,h/f$ is less convenient for interpreting the direction of the velocity induced by topographic slopes. Additionally, in equation (40.125) we introduce Rayleigh drag and interpret the resulting equation as an advective-diffusion balance. If we take $\psi^{(\eta)} = +g\,h/f$ then it would be an advective-anti-diffusive balance, which is far less physically satisfying.

The advection operator

The layer thickness is the difference between the free surface and bottom topography, $h = \eta - \eta_{\rm b} \geq 0$ (see Figure 36.1), in which case the advection operator takes on the form

$$\nabla\psi \times \nabla\eta = -(g/f)\,\nabla(\eta - \eta_{\rm b}) \times \nabla\eta + (g\,h/f^2)\,\beta\,\hat{\boldsymbol{y}} \times \nabla\eta \tag{40.119a}$$
$$= (g/f)\,[\nabla\eta_{\rm b} + (h\,\beta/f)\,\hat{\boldsymbol{y}}] \times \nabla\eta. \tag{40.119b}$$

This result motivates decomposing $\boldsymbol{u}^{(\eta)}$ into two terms

$$\boldsymbol{u}^{(\rm b)} = (g/f)\,\hat{\boldsymbol{z}} \times \nabla\eta_{\rm b} = (g/f)\,(-\hat{\boldsymbol{x}}\,\partial_y\eta_{\rm b} + \hat{\boldsymbol{y}}\,\partial_x\eta_{\rm b}) \tag{40.120a}$$
$$\boldsymbol{u}^{(\beta)} = \hat{\boldsymbol{z}} \times (g\,h\,\beta/f^2)\,\hat{\boldsymbol{y}} = -(g\,h\,\beta/f^2)\,\hat{\boldsymbol{x}}, \tag{40.120b}$$

so that the free surface equation (40.118) takes on the form

$$(\boldsymbol{u}^{(\rm b)} + \boldsymbol{u}^{(\beta)}) \cdot \nabla\eta = -\hat{\boldsymbol{z}} \cdot \nabla \times (\boldsymbol{f}^{\rm nc}/f). \tag{40.121}$$

As so defined, $\boldsymbol{u}^{(\rm b)}$ arises from gradients in the bottom topography and it is directed with shallow water to the right in the northern hemisphere and to the left in the southern hemisphere (just as the phase velocity for a coastally trapped Kelvin wave; see Section 53.7). The velocity, $\boldsymbol{u}^{(\beta)}$, arises from the planetary vorticity gradient and is always directed to the west, just as the phase velocity of a Rossby wave (Section 53.9). Notably, $\boldsymbol{u}^{(\eta)}$ has a meridional component only so long as there is a zonal topographic slope, $\partial_x\eta_{\rm b} \neq 0$.

Free surface trajectories in the absence of non-conservative forcing

In the absence of non-conservative forces the steady free surface equation (40.121) is

$$(\boldsymbol{u}^{(\rm b)} + \boldsymbol{u}^{(\beta)}) \cdot \nabla\eta = 0 \Longrightarrow [\hat{\boldsymbol{z}} \times \nabla\eta_{\rm b} - (h\,\beta/f)\,\hat{\boldsymbol{x}}] \cdot \nabla\eta = 0. \tag{40.122}$$

For the case of a flat bottom domain, so that $\boldsymbol{u}^{(\rm b)} = 0$, free surface contours are purely zonal ($\partial_x\eta = 0$). Conversely, on an f-plane, so that $\boldsymbol{u}^{(\beta)} = 0$, free surface contours are aligned with the bottom topography, $\hat{\boldsymbol{z}} \cdot (\nabla\eta_{\rm b} \times \nabla\eta) = 0$. In the general case, the unforced steady free surface contours are aligned according to the interplay between planetary beta and bottom topography according to equation (40.122).

It is instructive to imagine a free surface "trajectory" as defined by integral curves of $\boldsymbol{u}^{(\eta)}$. Consider one such trajectory that moves from the interior of a northern hemisphere gyre onto the continental shelf, such as in the example depicted in Figure 40.5. In the interior we assume the bottom topography is nearly flat, so that $\boldsymbol{u}^{(\rm b)} \approx 0$ and the corresponding free surface trajectory is along a constant latitude line. As we reach the continental slope, the trajectory becomes southwestward with a trajectory slope determined by the zonal slope of the topography. Finally, as the continental shelf is reached, which is relatively flat, the trajectory returns to a near constant latitude contour.

40.8.3 Rayleigh drag and free surface diffusion

The free surface equation (40.121) indicates that any non-conservative acceleration, $\boldsymbol{f}^{\rm nc}$, causes the free surface to deviate from contours of constant streamfunction, $\psi^{(\eta)} = -g\,h/f$. The dominant contribution to $\boldsymbol{f}^{\rm nc}$ arises from wind stress. Here, we consider the role of a thickness weighted

Rayleigh drag assumed to take the form given by equation (40.130)

$$\boldsymbol{f}^{\rm nc} = -\gamma\, h\, \boldsymbol{u}_{\rm g}, \tag{40.123}$$

where γ has dimensions of inverse time and $\boldsymbol{u}_{\rm g}$ is the geostrophic flow given by

$$\boldsymbol{u}_{\rm g} = (g/f)\, \hat{\boldsymbol{z}} \times \nabla \eta. \tag{40.124}$$

Substituting into the free surface equation (40.121) leads to

$$\underbrace{(\boldsymbol{u}^{(\rm b)} + \boldsymbol{u}^{(\beta)}) \cdot \nabla \eta}_{\text{advection}} = \underbrace{\nabla \cdot [(\gamma\, h\, g/f^2)\, \nabla \eta]}_{\text{diffusion}} \; \underbrace{-\hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}^{\rm wind}/(\rho\, f)]}_{\text{source from } \nabla \times \boldsymbol{\tau}^{\rm wind}/f}. \tag{40.125}$$

In the absence of a wind stress, the free surface satisfies an advective-diffusive balance.[7] Evidently, the Rayleigh drag, acting as a sink to the geostrophic momentum also acts to diffuse the free surface and so to cause the free surface contours to deviate from contours of constant $g\, h/f$. Notice that the diffusion coefficient,

$$\kappa = \gamma\, h\, g/f^2 = -(\gamma/f)\, \psi^{(\eta)}, \tag{40.126}$$

gets larger moving toward the equator. Hence, free surface contours can more readily deviate from contours of constant $\psi^{(\eta)}$ when moving towards the equator.

40.9 Column vorticity

Throughout this chapter we have focused on vorticity as defined by the curl of the horizontal velocity, $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u})$. Since flow within a shallow water layer moves in coherent and extensible vertical columns (Section 36.2), the shallow water vorticity measures the spin of a shallow water column.

We can also measure the column spin by considering the curl of the thickness weighted velocity

$$\Sigma = \hat{\boldsymbol{z}} \cdot \nabla \times (h\, \boldsymbol{u}) = h\, \zeta + \hat{\boldsymbol{z}} \cdot \nabla h \times \boldsymbol{u}. \tag{40.127}$$

We refer to Σ as the *column vorticity*, though note that it has the dimensions of a velocity due to the thickness weighting. In addition to the thickness weighted relative vorticity, the column vorticity measures the misalignment between the layer thickness gradient and the velocity, with $\hat{\boldsymbol{z}} \cdot \nabla h \times \boldsymbol{u}$ generally nonzero especially for geostrophic flows. Hence, the second term offers an extra measure of the spin for the fluid column beyond the relative vorticity measure.[8] The layer thickness factor ensures that Σ directly probes stresses acting at the layer interfaces, as well as stresses within the fluid layer. Besides its intrinsic interest, this analysis is motivated by studies of the depth integrated flow commonly pursued in oceanography, with examples studied in Chapter 45.

[7] We study advection and diffusion in Chapter 64.

[8] Exercise 40.7 offers a particular example of a geostrophic flow that is aligned perpendicular to ∇h, as found in a geostrophic shallow water front.

40.9.1 Formulating the column vorticity equation

To formulate the dynamical equation for Σ, we start from the momentum equation (37.29)

$$\frac{\partial(h\,\boldsymbol{u})}{\partial t} + \nabla\cdot(h\,\boldsymbol{u}\otimes\boldsymbol{u}) + f\,\hat{\boldsymbol{z}}\times(h\,\boldsymbol{u}) = -g\,h\,\nabla\eta^{\text{eff}} + \boldsymbol{f}^{\text{nc}} \tag{40.128}$$

where

$$\boldsymbol{f}^{\text{nc}} = h\,\boldsymbol{F} \tag{40.129}$$

is the thickness weighted acceleration (dimension of squared velocity) arising from non-conservative processes, such as from horizontal strains in the presence of viscosity and the boundary transfer of turbulent momentum such as through winds and bottom drag (see Section 36.6). For example, recall the acceleration given by equation (40.79), which is built from Rayleigh drag plus wind stress, in which case

$$\boldsymbol{f}^{\text{nc}} = -\gamma\,h\,\boldsymbol{u} + \boldsymbol{\tau}^{\text{wind}}/\rho = -\gamma\,h\,\boldsymbol{u} + h\,\boldsymbol{F}^{\text{wind}}. \tag{40.130}$$

Taking the vertically projected curl of equation (40.128) leads to

$$\partial_t\Sigma + \hat{\boldsymbol{z}}\cdot\nabla\times[\nabla\cdot(h\,\boldsymbol{u}\otimes\boldsymbol{u})] + \nabla\cdot(f\,h\,\boldsymbol{u}) = -g\,\hat{\boldsymbol{z}}\cdot(\nabla h\times\nabla\eta^{\text{eff}}) + \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{f}^{\text{nc}}). \tag{40.131}$$

Let us now examine each of these terms and offer physical interpretations.

Frictional torques and boundary pressure torques

The term $\hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{f}^{\text{nc}})$ in equation (40.131) provides a torque from boundary stresses and interior viscous stresses. The term $g\,\nabla h\times\nabla\eta^{\text{eff}}$ provides a torque whenever the thickness gradients are not aligned with the gradients in the effective surface height. We can write this term in the equivalent form based on the following identities

$$\begin{aligned}
\rho\,g\,\nabla h\times\nabla\eta^{\text{eff}} &= \rho\,g\,\nabla h\times\nabla\eta + \nabla h\times\nabla p_{\text{a}} && (40.132\text{a})\\
&= -\nabla p_{\text{a}}\times\nabla\eta + \nabla p_{\text{b}}\times\nabla\eta + \nabla(p_{\text{b}}-p_{\text{a}})\times\nabla p_{\text{a}}/(\rho\,g) && (40.132\text{b})\\
&= -\nabla p_{\text{a}}\times\nabla\eta + \nabla p_{\text{b}}\times\nabla[\eta + p_{\text{a}}/(\rho\,g)] && (40.132\text{c})\\
&= -\nabla p_{\text{a}}\times\nabla\eta + \nabla p_{\text{b}}\times\nabla[\eta_{\text{b}} + h + p_{\text{a}}/(\rho\,g)] && (40.132\text{d})\\
&= -\nabla p_{\text{a}}\times\nabla\eta + \nabla p_{\text{b}}\times\nabla\eta_{\text{b}} && (40.132\text{e})\\
&= \nabla\times(-p_{\text{a}}\,\nabla\eta + p_{\text{b}}\,\nabla\eta_{\text{b}}), && (40.132\text{f})
\end{aligned}$$

where we made use of the hydrostatic relation $p_{\text{b}} = p_{\text{a}} + \rho\,g\,h$. We thus see that $-g\,\nabla h\times\nabla\eta^{\text{eff}} = \rho^{-1}\nabla\times(p_{\text{a}}\,\nabla\eta - p_{\text{b}}\,\nabla\eta_{\text{b}})$ arises from pressure torques acting on the surface and bottom of the shallow water column. These torques spin the column if there is a misalignment between the boundary pressure gradients and the boundary surface slopes. Notably, it is commonly the case that the torque associated with the applied surface pressure is far smaller than that from the bottom pressure, in which case

$$-g\,\nabla h\times\nabla\eta^{\text{eff}} \approx -\rho^{-1}\nabla\times(p_{\text{b}}\,\nabla\eta_{\text{b}}) = -\rho^{-1}\nabla p_{\text{b}}\times\nabla\eta_{\text{b}}. \tag{40.133}$$

Torque from the nonlinear transport

The nonlinear term $\hat{\boldsymbol{z}} \cdot \nabla \times [\nabla \cdot (h\, \boldsymbol{u} \otimes \boldsymbol{u})]$ can be written

$$\begin{aligned}
\hat{\boldsymbol{z}} \cdot \nabla \times [\nabla \cdot (h\, \boldsymbol{u} \otimes \boldsymbol{u})] &= \hat{z}_m\, \epsilon_{mst}\, \partial_s[\partial_n\, (h\, u_n\, u_t)] && (40.134a)\\
&= \partial_n\, \partial_s[(h\, u_n)\, \epsilon_{mst}\, \hat{z}_m\, u_t] && (40.134b)\\
&= \partial_n[\partial_s(h\, u_n)\, \epsilon_{mst}\, \hat{z}_m\, u_t + h\, u_n\, \zeta] && (40.134c)\\
&= -\partial_n[\epsilon_{smt}\, \hat{z}_m\, u_t\, \partial_s(h\, u_n)] + \nabla \cdot (h\, \zeta\, \boldsymbol{u}), && (40.134d)
\end{aligned}$$

which exposes the divergence of the thickness weighted advective flux of relative vorticity. Further manipulations lead to

$$\begin{aligned}
-\partial_n[\epsilon_{smt}\, \hat{z}_m\, u_t\, \partial_s(h\, u_n)] &= -\partial_n[\epsilon_{smt}\, \hat{z}_m\, u_t\, u_n\, \partial_s h + \epsilon_{smt}\, \hat{z}_m\, u_t\, h\, \partial_s u_n] && (40.135a)\\
&= \partial_n[\hat{z}_m\, (\epsilon_{mst}\, \partial_s h\, u_t)\, u_n - h\, \epsilon_{smt}\, \hat{z}_m\, u_t\, \partial_s u_n] && (40.135b)\\
&= \nabla \cdot [\hat{\boldsymbol{z}} \cdot (\nabla h \times \boldsymbol{u})\, \boldsymbol{u}] - \partial_n[h\, (\hat{\boldsymbol{z}} \times \boldsymbol{u}) \cdot \nabla u_n] && (40.135c)\\
&= \nabla \cdot [\hat{\boldsymbol{z}} \cdot (\nabla h \times \boldsymbol{u})\, \boldsymbol{u}] + \nabla \cdot [h\, (v\, \partial_x - u\, \partial_y) \boldsymbol{u}], && (40.135d)
\end{aligned}$$

so that the nonlinear term takes the form

$$\hat{\boldsymbol{z}} \cdot \nabla \times [\nabla \cdot (h\, \boldsymbol{u} \otimes \boldsymbol{u})] = \nabla \cdot [\Sigma\, \boldsymbol{u} + h\, (v\, \partial_x - u\, \partial_y)\, \boldsymbol{u}] = \nabla \cdot [\Sigma\, \boldsymbol{u} + h\, (\boldsymbol{u}_{\text{clock}} \cdot \nabla)\, \boldsymbol{u}] \qquad (40.136)$$

The first term inside the square bracket is the advective flux of Σ. The second term is the thickness weighted transport of $\boldsymbol{u}$ by the clockwise rotated horizontal velocity

$$\boldsymbol{u}_{\text{clock}} = -\hat{\boldsymbol{z}} \times \boldsymbol{u}. \qquad (40.137)$$

40.9.2 Summary of the column vorticity equation

The above manipulations bring the Σ equation (40.131) into the flux-form

$$\partial_t \Sigma = -\nabla \cdot \boldsymbol{J}^{\Sigma} + \rho^{-1}\, \hat{\boldsymbol{z}} \cdot \nabla \times [-p_{\text{a}} \nabla \eta + p_{\text{b}} \nabla \eta_{\text{b}} + \rho\, \boldsymbol{f}^{\text{nc}}], \qquad (40.138)$$

where

$$\boldsymbol{J}^{\Sigma} \equiv [h\, f + \Sigma + h\, (v\, \partial_x - u\, \partial_y)]\, \boldsymbol{u} = h\, \zeta_{\text{a}}\, \boldsymbol{u} + [v\, (\partial_x h + h\, \partial_x) - u\, (\partial_y h + h\, \partial_y)]\, \boldsymbol{u} \qquad (40.139)$$

is the total flux of Σ. The corresponding material time derivative form of equation (40.138) is given by

$$\frac{\mathrm{D}\Sigma}{\mathrm{D}t} + \Sigma\, \nabla \cdot \boldsymbol{u} + \nabla \cdot [h\, f\, \boldsymbol{u} + h\, (v\, \partial_x - u\, \partial_y)\, \boldsymbol{u}] = \rho^{-1}\, \hat{\boldsymbol{z}} \cdot \nabla \times [-p_{\text{a}} \nabla \eta + p_{\text{b}} \nabla \eta_{\text{b}} + \rho\, \boldsymbol{f}^{\text{nc}}]. \qquad (40.140)$$

The thickness equation (36.118)

$$\frac{\mathrm{D}h}{\mathrm{D}t} = -h\, \nabla \cdot \boldsymbol{u} + w^{(\dot{\eta})}, \qquad (40.141)$$

brings equation (40.140) into the form

$$h\, \frac{\mathrm{D}(\Sigma/h)}{\mathrm{D}t} + \nabla \cdot [h\, f\, \boldsymbol{u} - h\, \hat{\boldsymbol{z}} \cdot (\boldsymbol{u} \times \nabla)\, \boldsymbol{u}] = -\frac{\Sigma\, w^{(\dot{\eta})}}{h} + \rho^{-1}\, \hat{\boldsymbol{z}} \cdot \nabla \times [-p_{\text{a}} \nabla \eta + p_{\text{b}} \nabla \eta_{\text{b}} + \rho\, \boldsymbol{f}^{\text{nc}}], \qquad (40.142)$$

where we wrote

$$v\, \partial_x - u\, \partial_y = -\hat{\boldsymbol{z}} \cdot (\boldsymbol{u} \times \nabla). \qquad (40.143)$$

40.9.3 Steady linear column vorticity balance and the island rule

To garner experience with the column vorticity equation (40.138), consider the steady state and assume $\boldsymbol{J}^{\Sigma}$ is dominated by the planetary vorticity

$$\boldsymbol{J}^{\Sigma} \approx h\, f\, \boldsymbol{u}, \tag{40.144}$$

in which case the budget equation (40.138) reduces to the balance

$$\nabla \cdot (h\, f\, \boldsymbol{u}) = \rho^{-1}\, \hat{\boldsymbol{z}} \cdot \nabla \times [-p_{\mathrm{a}} \nabla \eta + p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} + \rho\, \boldsymbol{f}^{\mathrm{nc}}]. \tag{40.145}$$

Hence, torques due to interface pressures and turbulent stresses are balanced by the divergence of the thickness weighted advective flux of planetary vorticity. Furthermore, since $\nabla \cdot (h\, \boldsymbol{u}) = 0$ in the steady state, equation (40.145) takes the form

$$\rho\, h\, \beta\, v = \hat{\boldsymbol{z}} \cdot \nabla \times (-p_{\mathrm{a}} \nabla \eta + p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} + \rho\, \boldsymbol{f}^{\mathrm{nc}}), \tag{40.146}$$

which connects to the discussion of pressure torques given in Section 40.7.5. It says that for planetary geostrophic flow, meridional transport in the presence of $\beta \neq 0$ is balanced by the torques arising from form atmospheric and bottom form stresses, as well as from non-conservative processes such as wind stress, viscous friction, and bottom drag.

Formulating an integral balance

The local balance (40.145) holding for planetary geostrophic flow leads to an integral balance through an area integral over an arbitrary closed domain

$$\oint_{\mathcal{S}} \nabla \cdot (h\, f\, \boldsymbol{u})\, \mathrm{d}\mathcal{S} = \rho^{-1} \oint_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot \nabla \times [-p_{\mathrm{a}} \nabla \eta + p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} + \rho\, \boldsymbol{f}^{\mathrm{nc}}]\, \mathrm{d}\mathcal{S}. \tag{40.147}$$

Making use of Gauss' divergence theorem on the left hand side and Stokes' theorem on the right hand side renders

$$\oint_{\partial \mathcal{S}} h\, f\, \boldsymbol{u} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\ell = \rho^{-1} \oint_{\partial \mathcal{S}} [-p_{\mathrm{a}} \nabla \eta + p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} + \rho\, \boldsymbol{f}^{\mathrm{nc}}] \cdot \hat{\boldsymbol{t}}\, \mathrm{d}\ell. \tag{40.148}$$

The left hand side is a contour integral with $\hat{\boldsymbol{n}}$ the unit outward normal along the contour. The right hand side is also a contour integral, yet with $\hat{\boldsymbol{t}}$ the unit tangent along the contour oriented in the counter-clockwise sense. The integral balance (40.148) says that the advective transport of planetary vorticity leaving the closed region (left hand side) is balanced by the oriented contour integral of the pressure and turbulent stresses. If the contour follows a closed streamline, on which $\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = 0$, then the right hand side contour integral must vanish.

The integral balance (40.148) is a rather remarkable statement that equates the transport leaving a region to pressure and turbulent stresses integrated along the region boundary. *Godfrey* (1989) chose a particularly clever contour, such as that depicted in Figure 40.10, and made some assumptions about the stresses that then allowed for an estimate of the transport. We here present the arguments.

Assumptions about the stresses

A portion of the red contour in Figure 40.10 traverses the eastern boundary on both Island A and Island B. As shown in Section 40.7, friction in the eastern boundary region of an ocean gyre is much less than the western boundary, motivating us to ignore friction (either viscous or

bottom drag) along the eastern boundary portions of the contour. Likewise, friction is generally small for the open ocean portion along the two latitudinal lines. Hence, wind stress is the only non-conservative process that affects the right hand side of equation (40.148).

Godfrey (1989) furthermore ignored pressure form stresses and their associated torques. This assumption is reasonable for the atmospheric form stress, $-p_{\rm a}\nabla\eta$, which is generally quite small (it is zero for a rigid lid approximation). However, the bottom form stress, $p_{\rm b}\nabla\eta_{\rm b}$, and the associated bottom pressure torque, can be larger than the wind stress and wind stress curl, especially near the continential margins and with strong currents. Hence, ignoring bottom pressure torque is an unsatisfying assumption.

The island rule

FIGURE 40.10: Illustrating the island rule with two land masses ("islands"). The red contour surrounds all of Island A and traverses along the eastern side of both Island A and Island B. The northern contour extends along a constant latitude line with a corresponding Coriolis parameter $f_{\rm north}$, whereas the southern contour has Coriolis parameter $f_{\rm south}$. Ignoring any precipitation or evaporation crossing the surface, steady state volume conservation means that the same meridional transport, $\mathcal{T}$, crosses both the southern and northern contours. Godfrey's island rule (40.151) provides an estimate for this transport when given the wind stress along the contour.

The islands are material surfaces so that $\boldsymbol{u}\cdot\hat{\boldsymbol{n}} = 0$ along those portions of the contour that are adjacent to the coasts. Integrating along the northern latitude, with $\hat{\boldsymbol{n}} = \hat{\boldsymbol{y}}$, yields

$$f_{\rm north}\int_{y_{\rm north}} h\,v\,{\rm d}x \equiv f_{\rm north}\,\mathcal{T}\,, \tag{40.149}$$

where $\mathcal{T}$ is the meridional transport. Ignoring any volume transport through the layer surface (e.g., $w^{(\dot\eta)} = 0$), the steady transport crossing the northern boundary equals to that crossing the southern boundary, so that

$$f_{\rm south}\int_{y_{\rm south}} h\,v\,{\rm d}x \equiv f_{\rm south}\,\mathcal{T}\,. \tag{40.150}$$

Making use of these results in the integral balance (40.148), and following the above assumptions about the boundary stresses, leads to *Godfrey's island rule*

$$\rho\,\mathcal{T} = \frac{1}{f_{\rm north} - f_{\rm south}}\oint_{\partial\mathcal{S}} \boldsymbol{\tau}^{\rm wind}\cdot\hat{\boldsymbol{t}}\,{\rm d}\ell, \tag{40.151}$$

where $\boldsymbol{\tau}^{\rm wind}$ is the wind stress, and where the minus sign on $f_{\rm south}$ arises since $\hat{\boldsymbol{n}} = -\hat{\boldsymbol{y}}$ along the southern latitude contour. This expression provides an approximation to the flow around Island A, noting that the only nonzero flow normal to the contour is through the two latitudinal segments.

40.9.4 Further study

Godfrey (1989) applied the island rule (40.151) to estimate transport around Austral-Asia, New Zealand, and Malagasy. Further discussion of Godfrey's island rule can be found in *Tomczak and Godfrey* (1994), *Pedlosky et al.* (1997), and *Klinger and Haine* (2019).

40.10 Exercises

EXERCISE 40.1: FLOW NEAR A TOPOGRAPHIC BUMP IN A REDUCED GRAVITY MODEL
Elements of this exercise are motivated by Figure 2 from *Adcock and Marshall* (2000) and Figure 1 from *Marshall et al.* (2012), where we consider a reduced gravity model with a dynamic lower layer and stagnant upper layer. Place a topographic bump (e.g., seamount or mountain) fully within the lower layer as shown in Figure 40.11.

(a) Following Exercise 36.6, derive the momentum and thickness equations for a reduced gravity model with a stagnant upper layer. Then derive the potential vorticity equation for the dynamical layer.

(b) Now assume an f-plane. If the lower layer potential vorticity is (somehow) horizonally homogenized (e.g., some form of mixing produces a horizontally constant potential vorticity), draw the resulting layer interface $\eta_{3/2}$. Assume the relative vorticity is negligible compared to the planetary vorticity so that the flow satisfies the planetary geostrophic scaling introduced in Section 40.5.2 and further pursued in Section 44.4. Also, ignore any non-steady processes; we are only interested here in the steady flow.

(c) For the case of horizontally homogenized potential vorticity from the previous part, what is the direction for a geostrophically balanced flow: cyclonic or anti-cyclonic? Hint: make use of Exercise 36.6 for the momentum equation of an inverted reduced gravity model.

FIGURE 40.11: A reduced gravity model (see Section 36.3) with a stagnant upper layer and a dynamic lower layer as in Exercise 36.6. A seamount sits fully within the lower layer.

EXERCISE 40.2: POTENTIAL VORTICITY FOR TWO SHALLOW WATER LAYERS
Consider the inviscid Boussinesq two-layer shallow water model as discussed in Section 36.4. Derive the potential vorticity equation for each layer, showing the mathematical steps used in the derivation. Hint: the answer is given in Section 40.3.6.

EXERCISE 40.3: AVERAGE VORTICITY IN A SHALLOW WATER LAYER
Consider a single layer of shallow water fluid on a rotating plane with rotation rate $\boldsymbol{\Omega} = \hat{\boldsymbol{z}}\,\Omega$. Assume the fluid is contained in an arbitrary horizontal region and that it has a constant total volume given by

$$\mathcal{V} = \int \left[\int \mathrm{d}z \right] \mathrm{d}\mathcal{S} = \int h \, \mathrm{d}\mathcal{S} = \int (H + \Delta\eta - \eta_\mathrm{b}) \, \mathrm{d}\mathcal{S} = H \, \mathcal{S}, \tag{40.152}$$

where $\mathcal{S}$ is the horizontal area of the domain, $h(x, y, t) = H + \Delta\eta(x, y, t) - \eta_\mathrm{b}(x, y)$ is the layer thickness, H is the resting depth relative to $z = 0$, $\Delta\eta$ is the sea level deviation from resting, and η_b is the undulation of the bottom topography (see Figure 36.1). Additionally, recall that $z = 0$ is set according to

$$\int \eta_\mathrm{b} \, \mathrm{d}\mathcal{S} = 0, \tag{40.153}$$

and volume conservation ensures that

$$\int \Delta\eta \, \mathrm{d}\mathcal{S} = 0. \tag{40.154}$$

(a) Determine the volume average of the vorticity $\hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_\mathrm{rigid}$ arising from the rigid-body rotation

$$\langle \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_\mathrm{rigid} \rangle = \mathcal{V}^{-1} \int \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_\mathrm{rigid} \, \mathrm{d}V. \tag{40.155}$$

(b) Determine the area average of the relative vorticity,

$$\overline{\zeta} = \mathcal{S}^{-1} \int \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega} \, \mathrm{d}\mathcal{S}, \tag{40.156}$$

in terms of the circulation around the boundary of the domain.

(c) Determine the volume average of the relative vorticity

$$\langle \zeta \rangle = \mathcal{V}^{-1} \int \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega} \, \mathrm{d}V. \tag{40.157}$$

Write the expression in terms of the area average vorticity, $\overline{\zeta}$, and the correlation, $\overline{\zeta' h'}$, where primes are deviations from the area mean.

EXERCISE 40.4: APPLICATION OF THE MATERIAL INVARIANCE OF POTENTIAL VORTICITY
In an adiabatic shallow water fluid in a rotating reference frame, show that the potential vorticity satisfies

$$\frac{\mathrm{D}}{\mathrm{D}t} \left[\frac{\zeta + f}{\eta - \eta_b} \right] = 0, \tag{40.158}$$

where η is the height of the free surface and η_b is the height of the bottom topography (see Figure 36.1). For both of the following questions, assume constant volume for the fluid column. Also, assume the column rotates coherently about its axis.

(a) A cylindrical column of air at 30° latitude with radius 100 km expands horizontally to twice its original radius. If the air is initially at rest, what is the mean tangential velocity at the perimeter after the expansion?

(b) An air column at 60°N with zero relative vorticity ($\zeta = 0$) stretches from the surface to the tropopause, which we assume is a rigid lid at 10 km. The air column moves zonally onto a plateau 2.5 km high. What is its relative vorticity? Suppose it then moves southward along the plateau to 30°N, starting from the relative vorticity it obtained from the plateau. What is its new relative vorticity?

EXERCISE 40.5: APPLICATION OF THE MATERIAL INVARIANCE OF POTENTIAL VORTICITY
An air column at 60°N with $\zeta = 0$ initially reaches from the surface to a fixed tropopause at 10 km height. If the air column moves across a mountain 2.5 km high at 45°N, what is its absolute vorticity and relative vorticity as it passes the mountaintop? Hint: Use the material invariance of shallow water potential vorticity, and assume the top of the column remains at 10 km.

EXERCISE 40.6: PROPERTIES OF THE STEADY STATE SHALLOW WATER FLUID
Consider a single layer of shallow water fluid in steady state (i.e., all Eulerian time derivatives vanish).

(a) Show that there exists a streamfunction for the steady state thickness weighted horizontal flow

$$h\,\boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla\Psi. \tag{40.159}$$

(b) What are the physical dimensions of Ψ?

(c) Show that the shallow water potential vorticity is a constant along the steady state streamlines of the thickness weighted flow

$$Q = Q(\Psi). \tag{40.160}$$

(d) Show that the Bernoulli function,

$$B = g\,\eta + \boldsymbol{u}\cdot\boldsymbol{u}/2 \tag{40.161}$$

is also a constant along the same streamlines; i.e.,

$$B = B(\Psi). \tag{40.162}$$

(e) What is the functional relation between the Bernoulli function and the potential vorticity? Hint: make use of the physical dimensions for Q, B, and Ψ to be sure that your solution is dimensionally consistent.

EXERCISE 40.7: ZONALLY SYMMETRIC SHALLOW WATER FRONT
Consider a single layer of shallow water fluid on a β-plane ($f = f_0 + \beta\,y$) with a flat bottom. Assume all fields possess zonal symmetry as in the zonal front shown in Figure 40.12. Since the zonal pressure gradient vanishes under the assumption of zonal symmetry, the geostrophic portion of the meridional velocity vanishes. However, there is generally a non-zero ageostrophic component to this velocity, and we retain that possibility throughout this exercise.

(a) Write the potential vorticity, Q, assuming the zonal flow is in geostrophic balance. Write Q terms of meridional derivatives of the layer thickness.

FIGURE 40.12: Schematic of a zonally symmetric front in a shallow water layer in the northern hemisphere ($f > 0$), here used for Exercise 40.7. The thickness decreases to the north. If the zonal flow is in geostrophic balance, then the northward pressure gradient is in geostrophic balance with a southward Coriolis acceleration arising from an eastward (out of the page) geostrophic current (see also Figure 37.1). The geostrophic component of the meridional flow vanishes due to zonal symmetry, but the full meridional flow need not vanish if there are ageostrophic processes. We allow for the possibility of a nonzero meridional velocity throughout this exercise.

(b) From the shallow water equations, explicitly show that the potential vorticity is materially constant (i.e., it is a Lagrangian invariant). To do so, work through the usual shallow water potential vorticity material conservation derivation yet make use of the zonally symmetric equations of motion. Allow for a nonzero ageostrophic meridional flow. Show all relevant steps.

(c) Show that the potential vorticity can be written as $Q = -(\partial_y M)/h$, where h is the layer thickness. What is the expression for M? Hint: recall our discussion of potential momentum in Section 14.4.

(d) Potential vorticity is not the only material constant for this system. Due to the zonal symmetry, Noether's Theorem indicates there is another. Show that M is materially constant. Again, continue to allow for a nonzero meridional velocity component.

EXERCISE 40.8: RAYLEIGH DRAG AND GALILEAN INVARIANCE

Recall the discussion of Galilean invariance from Section 18.9. Is the Rayleigh drag used in equation (40.79) Galilean invariant? Why? If not, then should that be of concern for its use in studying flow in a closed and bounded domain?

EXERCISE 40.9: GYRES IN THE PRESENCE OF CYCLONIC WINDS

Consider the ocean gyre discussion in Section 40.7. Rather than anti-cyclonic winds, now apply a cyclonic wind stress to the domain. As per the circulation theorem (40.82), the gyre flow will have a cyclonic sense. Will the resulting gyre exhibit eastern intensification or western? Appeal to whatever arguments you wish.

EXERCISE 40.10: SHALLOW WATER EQUATIONS WITH DIVERGENCE-DAMPING

When breaking the continous symmetry of the equations of motion, a discretized numerical simulation admits unphysical flow features sometimes referred to as *computational modes*. Some computational modes can evolve in time with energy accumulating at high wave numbers, in which case the numerical simulation produces unphysical grid noise and becomes of little physical use. To suppress grid noise, numerical models commonly introduce numerical dissipation, even if the continuous equations have zero dissipation. The formulation of numerical dissipation is largely an art guided by the dual needs of suppressing grid noise without otherwise damaging

physical properties of the simulated flow. We here consider physical properties of a specific form of numerical dissipation known as *divergence-damping*. We work within the framework of the continuous equations so to develop generic physical properties of the divergence-damping operator. No knowledge of numerical methods is required to solve this problem.

Divergence-damping is motivated by the desire to leave the vorticity equation untouched while damping divergent motion that can arise in numerical simulations. This motivation is based on noting that much of the large-scale circulation in a rotating fluid has a nontrivial absolute vorticity yet a relatively small horizontal divergence. For example, geostrophic flow on an f-plane has vorticity dominated by planetary vorticity f, while it is has zero horizontal divergence (see Section 32.4 or the 2d barotropic equation in Section 39.1). The divergence-damping operator is thus designed to reduce the magnitude of the horizontal divergence while leaving the vorticity untouched.

We here examine the impacts of divergence-damping on mechanical energy and angular momentum. For this purpose, consider a single layer of shallow water fluid with divergence-damping. This system is described by the momentum and thickness equations

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\left(g\,\eta + \alpha\,\Gamma\right) \tag{40.163a}$$

$$\frac{\mathrm{D}h}{\mathrm{D}t} = -h\,\nabla\cdot\boldsymbol{u}. \tag{40.163b}$$

The parameter $\alpha > 0$ is a constant and the field Γ is given by the Laplacian of the horizontal flow divergence

$$\Gamma = \nabla^2\mathscr{D}, \tag{40.164}$$

where

$$\mathscr{D} = \nabla\cdot\boldsymbol{u}. \tag{40.165}$$

The divergence has physical dimensions of inverse time (T^{-1}), so that its Laplacian, Γ, has dimensions of $L^{-2}\,T^{-1}$, and the coefficient α has dimensions $L^4\;T^{-1}$.

Divergence damping leads to a modification to the horizontal pressure gradient. We may think of this modification as arising from the horizontal gradient of a modified free surface height

$$\tilde{\eta} = \eta + \frac{\alpha\,\Gamma}{g}. \tag{40.166}$$

Notably, mass conservation remains the same since the thickness equation is unchanged. Hence, momentum evolution is modified by changing the pressure gradient, yet the thickness equation remains the same.

(a) Show that the vorticity equation (40.9) remains unchanged in the presence of divergence-damping.

(b) Show that the potential vorticity equation (40.29) remains unchanged in the presence of divergence-damping.

(c) Show that the horizontal divergence evolves according to

$$\frac{\partial\mathscr{D}}{\partial t} = \left[\frac{\partial\mathscr{D}}{\partial t}\right]_{\alpha=0} - \alpha\nabla^2\Gamma. \tag{40.167}$$

(d) Show that the evolution of gravitational potential energy per horizontal area

$$\mathscr{P} = g\,\rho \int_{\eta_b}^{\eta} z \,\mathrm{d}z \tag{40.168}$$

remains unchanged from that determined in Section 37.5.1.

(e) Show that the kinetic energy per horizontal area evolves according to

$$\frac{\partial \mathscr{K}}{\partial t} + \nabla \cdot (\boldsymbol{u}\,\mathscr{K}) = -h\rho\, g\, \boldsymbol{u} \cdot \nabla \tilde{\eta}, \tag{40.169}$$

where

$$\mathscr{K} = \frac{1}{2} \int_{\eta_b}^{\eta} \rho\, \mathbf{u}^2 \,\mathrm{d}z = \rho\, h\, \mathbf{u}^2/2, \tag{40.170}$$

is the horizontal kinetic energy per area (Section 37.5.2).

(f) Determine the evolution equation for global integrated kinetic energy

$$\frac{\partial}{\partial t}\left[\int \mathscr{K}\,\mathrm{d}A\right] = \frac{\partial}{\partial t}\left[\int \int_{\eta_b}^{\eta} (\rho\, \boldsymbol{u} \cdot \boldsymbol{u}/2)\,\mathrm{d}z\,\mathrm{d}A\right]. \tag{40.171}$$

Hint: drop all lateral boundary terms by assuming either solid lateral walls or periodicity.

(g) Consider a single shallow water layer in a rotating tank as in Section 37.8. Show that the material evolution of angular momentum relative to the vertical rotational axis is given by

$$\frac{1}{\delta M}\frac{\mathrm{D}L^z}{\mathrm{D}t} = -g\,\frac{\partial \eta}{\partial \phi} + \mathscr{T}. \tag{40.172}$$

What is the mathematical form for $\mathscr{T}$? Hint: check your answer with the next part of this exercise.

(h) Show that the domain integrated angular momentum satisfies the equation

$$\frac{\partial}{\partial t}\int L^z = \alpha\,\rho \int \Gamma\,\frac{\partial \eta}{\partial \phi}\,\mathrm{d}A. \tag{40.173}$$

where we assume the bottom topography is flat so that $h = \eta$.

(i) The linearized thickness equation (see Section 53.5) for a flat bottom is given by

$$\frac{\partial \eta}{\partial t} + H\,\nabla \cdot \boldsymbol{u} = 0, \tag{40.174}$$

where H is the thickness of the resting fluid layer. Show that the time change for the global integrated angular momentum is given by

$$\frac{\partial}{\partial t}\int L^z = -\frac{\alpha\,\rho}{H}\int \left[\frac{\partial}{\partial t}\nabla^2 \eta\right]\frac{\partial \eta}{\partial \phi}\,\mathrm{d}A. \tag{40.175}$$

Chapter 41

Vorticity and circulation mechanics

In this chapter we study the kinematics and dynamics of vorticity and circulation, extending our introductory study in Chapter 38 and shallow water study in Chapter 40. An understanding of vorticity mechanics offers many insights into the nature of fluid flow and how that flow is constrained. Hence, vorticity is a central feature in nearly all theories of geophysical fluid mechanics. To ground the conceptual presentation, we include sample applications of particular importance to atmosphere and ocean flows.

In making use of vorticity for geophysical fluids, it can be useful to move beyond the vorticity of a fluid element as defined by the curl of the velocity field. For example, as a means to summarize facets of the vorticity contained within a three-dimensional fluid, we study the depth integral of the vorticity equation in Section 41.8 for a hydrostatic and Boussinesq fluid and in Section 45.4 for a planetary geostrophic flow. This analysis has proven to be quite useful in understanding facets of ocean circulation, where vertical fluid columns extend from the bottom at $z = \eta_{\mathrm{b}}$ to the surface at $z = \eta$. Relatedly, there are occasions to study vorticity of the depth integrated flow (i.e., vorticity of the transport) or depth averaged flow (i.e., vorticity of the barotropic flow), and we do so in Section 41.9. Such studies emphasize the importance of boundary forces and their curls ("torques") for the vorticity of a fluid column. Details of the terms affecting such vorticities depend on the form of the vorticity, with somewhat complementary features emphasized.

CHAPTER GUIDE

This chapter assumes an understanding of vorticity developed in earlier chapters in this part of the book. We also make use of fluid kinematics from Part III and fluid dynamics from Part V. As for the shallow water vorticity discussed in Chapter 40, we here make use of vector calculus identities for Cartesian coordinates as detailed in Chapter 2. The concepts and methods developed in this chapter are fundamental to the notions of vorticity and circulation, with elements encountered in the remainder of this part of the book as well as in the study of balanced models in Part VIII.

Throughout this chapter, when considering spherical geometry, we make use of the planetary Cartesian coordinates from Figure 10.1. Since the sphere is assumed to be embedded in Euclidean space, we can naively perform integrals of vectors over the Euclidean space.

41.10 Exercises 1151

41.1 Loose threads

- Rewrite Section 41.8 using the full vertical vorticity equation derived in Section 41.3.4. The only difference is the presence of a component of baroclinicity, $-\hat{\boldsymbol{z}} \times \rho^{-1} \nabla p$.

- Summarize the various forms of the vorticity budget as per *McWilliams et al.* (2024) Section 2.

41.2 Kelvin's circulation theorem

Kelvin's circulation theorem is concerned with the evolution of circulation around a closed loop that follows the flow, or equivalently (through Stokes' theorem) with the change in vorticity penetrating the area enclosed by the loop

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x} = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}(\boldsymbol{v})} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{41.1}$$

where $\mathcal{S}(\boldsymbol{v})$ designates a surface whose points all move with the fluid flow. We here consider the case of a non-rotating reference frame, with the straightforward extension to rotating reference frames in Section 41.6. Note that Kelvin's theorem typically refers to the case of a perfect barotropic fluid, where we see that the circulation remains invariant when following the flow. The treatment here, however, is more general, thus seeing how circulation evolves for more general flows.

We emphasize that our concern is with circulation computed around closed loops that follow the flow. For single-component fluids, such loops are material (i.e., the same fluid particles are fixed to the loop). Correspondingly, we can make use of Kelvin's circulation theorem for any material loop, including loops next to static material boundaries such as that considered in Exercise 41.9. For multi-component fluids there is no perfectly material loop in the presence of diffusion, and yet we can still make use of Kelvin's theorem for loops that follow the barycentric velocity, $\boldsymbol{v}$.

41.2.1 Formulation

Since the circulation is computed following the flow, the time derivative in equation (41.1) moves inside the integral as a material/Lagrangian time derivative[1]

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \frac{\mathrm{D}(\boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x})}{\mathrm{D}t}. \tag{41.2}$$

The material evolution of $\boldsymbol{v}$ is determined by Newton's law of motion, which for a non-rotating reference frame is given by (see Section 27.13)

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\frac{1}{\rho}\nabla p - \nabla\Phi + \boldsymbol{F}. \tag{41.3}$$

In this equation, p is the pressure, ρ is the mass density, Φ is the geopotential (and/or the potential for any conservative force), and $\boldsymbol{F}$ is the acceleration from any non-conservative forces such as from viscous stresses and/or boundary interactions.

The material time derivative of the differential line element moving around the circuit equals to the differential of the velocity on the circuit

$$\frac{\mathrm{D}(\mathrm{d}\boldsymbol{x})}{\mathrm{D}t} = \mathrm{d}\boldsymbol{v}. \tag{41.4}$$

This result follows since all points along the circuit follow the flow, by construction. Consequently,

[1] In Section 21.2, we studied how to take derivatives of flow-following integrals.

evolution of circulation following a loop becomes

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\left(-\rho^{-1}\,\nabla p - \nabla\Phi + \boldsymbol{F}\right)\cdot \mathrm{d}\boldsymbol{x} + \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{v}\right] \tag{41.5a}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\left(-\rho^{-1}\,\nabla p + \boldsymbol{F}\right)\cdot \mathrm{d}\boldsymbol{x} + \mathrm{d}(-\Phi + \boldsymbol{v}\cdot\boldsymbol{v}/2)\right] \tag{41.5b}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} (-\rho^{-1}\,\nabla p + \boldsymbol{F})\cdot \mathrm{d}\boldsymbol{x} \tag{41.5c}$$

$$= \int_{\mathcal{S}(\boldsymbol{v})} \left[-\nabla\times\left(\rho^{-1}\,\nabla p\right) + \nabla\times\boldsymbol{F}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \tag{41.5d}$$

$$= \int_{\mathcal{S}(\boldsymbol{v})} (\boldsymbol{B} + \nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{41.5e}$$

We noted that when integrating over space at a particular time, $\nabla\Phi\cdot\mathrm{d}\boldsymbol{x} = \mathrm{d}\Phi$ is an exact spatial differential, and so is $\mathrm{d}\boldsymbol{v}^2$. Hence, they both have a zero line integral around a closed circuit in space[2]

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}\Phi = 0 \quad\text{and}\quad \oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}\boldsymbol{v}^2 = 0. \tag{41.6}$$

41.2.2 Two processes affecting circulation

Equation (41.5e) says that the circulation around a flow-following loop is affected by two processes, whose form depends on whether considering their line integral or surface integral expressions. The irreversible process arises from frictional acceleration

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}(\boldsymbol{v})} (\nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{41.7}$$

with the line integral form expressing the mechanical work per unit mass (acceleration times distance) done by friction around the closed loop.[3] Friction dissipates kinetic energy, so that friction generally reduces the magnitude of the circulation. The surface integral form expresses the curl of friction as integrated over the surface.

The reversible process affecting circulation in equation (41.5e) arises from the pressure gradient acceleration

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} (-\rho^{-1}\,\nabla p)\cdot\mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}(\boldsymbol{v})} \rho^{-2}(\nabla\rho\times\nabla p)\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{S}(\boldsymbol{v})} \boldsymbol{B}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{41.8}$$

As for friction, the line integral form expresses the mechanical work per unit mass (acceleration times distance) done by the pressure gradient acceleration as integrated around the circuit. The vector $\boldsymbol{B}$ is referred to as the *baroclinicity*

$$\boldsymbol{B} = -\nabla\times(\rho^{-1}\,\nabla p) = \rho^{-2}\,\nabla\rho\times\nabla p, \tag{41.9}$$

and it has physical dimensions of inverse squared time, T^{-2}. Its appearance in the circulation theorem arises from the non-alignment of density and pressure isolines.

Work done by pressure around an arbitrary loop does not generally vanish, nor does it have a specific sign. However, there are a variety of special loops around which the pressure work

[2]See Section 2.8 for more on exact differentials.

[3]We introduced the notions of mechanical work in Section 11.1.4.

does vanish. For example, the pressure work vanishes for closed contours on surfaces of constant density or constant pressure. However, such contours are generally not flow-following, and so their circulation is less interesting dynamically. In the remainder of this section, we consider some further cases where baroclinicity vanishes.

41.2.3 Barotropic flow

The solenoidal/baroclinicity vector vanishes for a constant density fluid, in which $\nabla\rho = 0$ such as for a single layer of shallow water fluid. More generally, the baroclinicity vector vanishes for barotropic flow, in which

$$p = p(\rho) \Longrightarrow \text{barotropic flow.} \tag{41.10}$$

Kelvin's circulation theorem then follows, which states that for inviscid barotropic flow the circulation around any closed flow-following circuit remains constant

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t}\oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{v}\cdot\mathrm{d}\boldsymbol{x} = \frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}(\boldsymbol{v})} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = 0 \qquad \Longleftarrow \text{inviscid barotropic flow.} \tag{41.11}$$

That is, the circulation around any vortex tube in a perfect barotropic fluid moves in a manner that keeps the circulation materially constant. This remarkable result greatly constrains the motion of a perfect barotropic fluid.

Another way to recognize that baroclinicity vanishes for a barotropic flow is to note that the curl of the pressure gradient acceleration vanishes

$$\nabla\times(\rho^{-1}\,\nabla p) = -\rho^{-2}\,\nabla\rho\times\nabla p = -\rho^{-2}\,(\partial p/\partial\rho)\,\nabla\rho\times\nabla\rho = 0. \tag{41.12}$$

Hence, for a barotropic fluid there is a scalar potential whereby

$$\nabla\Phi_{\mathrm{p}} = \rho^{-1}\nabla p, \tag{41.13}$$

with integration leading to

$$\Phi_{\mathrm{p}} = \int_{p_0}^{p}\frac{\mathrm{d}p'}{\rho(p')}, \tag{41.14}$$

where p_0 is an arbitrary reference pressure.[4] The identity (41.13) means that the pressure gradient acceleration for a barotropic flow is an exact spatial differential

$$\rho^{-1}\nabla p\cdot\mathrm{d}\boldsymbol{x} = \rho^{-1}\,\mathrm{d}p \equiv \mathrm{d}\Phi_{\mathrm{p}}. \tag{41.15}$$

Since the closed loop integral of an exact differential vanishes, we again see that the pressure gradient acceleration has no impact on circulation around flow-following loops in a barotropic flow. Stated alternatively, with $\nabla\Phi_{\mathrm{p}} = \rho^{-1}\nabla p$, then the Euler equation takes on the form

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} = -\nabla(\Phi_{\mathrm{p}} + \Phi), \tag{41.16}$$

which renders a materially constant circulation.

41.2.4 Pressure contribution to circulation in an ideal gas

Building on the notions from a barotropic flow in Section 41.2.3, we here determine an important class of contours for an ideal gas where baroclinicity vanishes even if the flow is not barotropic.

[4] We make use of the scalar potential, Φ_{p}, in Exercise 41.10.

To start, recall from Exercise 24.3 that we derived equation (24.106) for an ideal gas

$$\rho^{-1}\,\nabla p = \theta\,\nabla\Pi, \tag{41.17}$$

where θ is the potential temperature (equation (24.92)) and Π is the Exner function (equation (24.93)). This equation says that the pressure gradient acceleration, for an ideal gas, is equal to the potential temperature times the gradient of the Exner function. We can thus write the pressure gradient acceleration contribution in equation (41.5c) as

$$-\oint_{\partial\mathcal{S}(\boldsymbol{v})} \rho^{-1}\,\nabla p\cdot \mathrm{d}\boldsymbol{x} = -\oint_{\partial\mathcal{S}(\boldsymbol{v})} \theta\,\nabla\Pi\cdot\mathrm{d}\boldsymbol{x} = -\oint_{\partial\mathcal{S}(\boldsymbol{v})} \theta\,\mathrm{d}\Pi = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \Pi\,\mathrm{d}\theta, \tag{41.18}$$

where the final step noted that the closed loop integral of an exact differential vanishes

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}(\theta\,\Pi) = 0. \tag{41.19}$$

Hence, the contribution from baroclinicity (i.e., pressure gradient acceleration) vanishes for closed contours drawn either on a constant Π surface or a constant θ surface. For an ideal gas, changes in θ are directly related to changes in specific entropy (see equation (27.200) from Exercise 27.4). Hence, for a perfect fluid flow of an ideal gas, where specific entropy is materially invariant, so too is potential temperature: $\mathrm{D}\theta/\mathrm{D}t = 0$. It follows that a contour drawn on a potential temperature surface remains a flow-following contour for a perfect fluid. We have thus deduced that isentropic flow of an ideal gas has a flow-following circulation that is unaffected by baroclinicity.

41.2.5 Circulation around a loop with constant entropy and concentration

We here make use of the expression (27.69) for the pressure gradient acceleration in terms of thermodynamic functions

$$-\rho^{-1}\,\nabla p = -\nabla\mathcal{H} + T\,\nabla\mathcal{S} + \mu\,\nabla C, \tag{41.20}$$

where $\mathcal{H}$ is the specific enthalpy, $\mathcal{S}$ is the specific entropy, T is the thermodynamic (Kelvin) *in situ* temperature, and μ is the chemical potential for a binary fluid such as commonly assumed for the ocean (freshwater and salt) and atmosphere (dry air and water vapor). Equation (41.20) holds for a compressible fluid, in which the thermodynamic pressure and mechanical pressure are the same (Section 26.8.1).

The identity (41.20) brings the pressure gradient contribution to Kelvin's circulation theorem (41.5e) into

$$-\oint_{\partial\mathcal{S}(\boldsymbol{v})} \rho^{-1}\,\nabla p\cdot\mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} (T\,\nabla\mathcal{S} + \mu\,\nabla C)\cdot\mathrm{d}\boldsymbol{x}, \tag{41.21}$$

where we set

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \nabla\mathcal{H}\cdot\mathrm{d}\boldsymbol{x} = 0, \tag{41.22}$$

which holds since $\mathcal{H}$ is a state function so that for any time instance,

$$\nabla\mathcal{H}\cdot\mathrm{d}\boldsymbol{x} = \mathrm{d}\mathcal{H} \tag{41.23}$$

is an exact spatial differential. The decomposition (41.21) reveals that the pressure contribution to circulation vanishes when computing circulation for an isentropic and constant concentration

loop[5]

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \rho^{-1}\,\nabla p\cdot \mathrm{d}\boldsymbol{x} = 0 \quad \text{if } \mathrm{d}\mathcal{S}=0 \text{ and } \mathrm{d}C=0. \tag{41.24}$$

Such loops follow the flow in those cases where specific entropy and matter concentration are materially invariant

$$\frac{\mathrm{D}\mathcal{S}}{\mathrm{D}t} = 0 \quad \text{and} \quad \frac{\mathrm{D}C}{\mathrm{D}t} = 0. \tag{41.25}$$

It follows that for the special case of a homogeneous fluid (C = constant) undergoing isentropic quasi-static changes, pressure plays no role in the circulation computed around an isentropic loop.

41.2.6 Circulation around a loop with constant S and Θ

Rather than invoking the gradient form of the fundamental thermodynamic relation (41.20), consider an ocean application where equation (31.10) says that the *in situ* density, ρ, takes on the functional form

$$\rho = \rho(S,\Theta,p), \tag{41.26}$$

with S the salinity and Θ the Conservative Temperature. It follows that along a contour that maintains fixed S and Θ, the pressure gradient acceleration is a function just of the pressure, in which case we write

$$\rho^{-1}\,\nabla p\cdot \mathrm{d}\boldsymbol{x} = \rho^{-1}(S_{\mathrm{const}},\Theta_{\mathrm{const}},p)\,\mathrm{d}p \equiv \mathrm{d}\Psi_{\mathrm{p}} \quad \text{if } S \text{ and } \Theta \text{ are fixed}, \tag{41.27}$$

where we followed the barotropic case of equation (41.14) to write

$$\Psi_{\mathrm{p}}(S_{\mathrm{const}},\Theta_{\mathrm{const}},p) = \int_{p_0}^{p} \frac{\mathrm{d}p'}{\rho(S_{\mathrm{const}},\Theta_{\mathrm{const}},p')}, \tag{41.28}$$

with p_0 an arbitrary reference pressure. As in Section 41.2.5, we conclude that pressure plays no role in affecting circulation around loops with fixed S and Θ

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \rho^{-1}\,\nabla p\cdot \mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}\Psi_{\mathrm{p}}(S,\Theta,p) = 0 \quad \text{if } S=S_{\mathrm{const}} \text{ and } \Theta=\Theta_{\mathrm{const}}, \tag{41.29}$$

which follows since $\mathrm{d}\Psi_{\mathrm{p}}$ is an exact spatial differential. Such closed loop contours follow the flow if S and Θ are materially invariant

$$\frac{\mathrm{D}S}{\mathrm{D}t} = 0 \quad \text{and} \quad \frac{\mathrm{D}\Theta}{\mathrm{D}t} = 0, \tag{41.30}$$

which is the case in the absence of mixing and/or sources of S and Θ.

41.2.7 Comments and further reading

There is no guarantee that the closed flow-following contours discussed in Sections 41.2.5 and 41.2.6 exist in any particular flow. Rather, all we showed is that *if* such closed contours exist, and if the flow maintains materially invariant specific entropy and concentration (Section 41.2.5) or salinity and Conservative Temperature (Section 41.2.6), then the circulation around such loops is unaffected by the pressure gradient acceleration.

[5] For the ocean, an isentropic and constant salt concentration process maintains a constant Conservative Temperature.

Our presentation of Kelvin's circulation theorem anticipates analogous considerations encountered with potential vorticity in Chapter 42, with portions of the discussion motivated by *Kooloth et al.* (2022).

41.3 Vorticity dynamics

We now move from the circulation around a macroscopic circuit to the vorticity at a point. In particular, we seek information for how vorticity changes in time. What physical processes lead to these changes? We considered this question in Chapter 40 when studying shallow water vorticity. Here, we consider the general case of a stratified flow with friction. As for Kelvin's theorem, we make use of Newton's law of motion, written here in the form for a rotating fluid (see Section 27.13)

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v} = -\rho^{-1}\,\nabla p - \nabla\Phi + \boldsymbol{F}, \tag{41.31}$$

where $\boldsymbol{\Omega}$ is the angular velocity of the rotating reference frame.

41.3.1 Vector-invariant velocity equation

As for the shallow water fluid in Section 40.1, we find it useful to convert the advective-form momentum equation to vector-invariant velocity equation. For this purpose, make use of the vector identity (see Section 2.3.4)

$$\boldsymbol{\omega} \times \boldsymbol{v} = -(1/2)\,\nabla(\boldsymbol{v}\cdot\boldsymbol{v}) + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{v} \tag{41.32}$$

to eliminate velocity self-advection in favor of vorticity

$$\partial_t \boldsymbol{v} + \boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v} = -\rho^{-1}\,\nabla p - \nabla(\boldsymbol{v}^2/2 + \Phi) + \boldsymbol{F}. \tag{41.33}$$

We here introduced the absolute vorticity

$$\boldsymbol{\omega}_{\mathrm{a}} = \nabla \times (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) = \boldsymbol{\omega} + 2\,\boldsymbol{\Omega}, \tag{41.34}$$

which is the curl of the absolute (inertial frame) velocity, and which equals to the sum of the relative vorticity plus the planetary vorticity (see Section 38.6.1).

41.3.2 Basic form of the vorticity equation

Taking the curl of the vector-invariant momentum equation (41.33) removes the mechanical energy per mass, $\boldsymbol{v}^2/2 + \Phi$, thus leaving

$$\partial_t \boldsymbol{\omega} + \nabla \times (\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v}) = \rho^{-2}\,(\nabla\rho \times \nabla p) + \nabla \times \boldsymbol{F}. \tag{41.35}$$

For geophysical fluids we generally assume that $\boldsymbol{\Omega}$ has zero time tendency, so that

$$\partial_t \boldsymbol{\omega}_{\mathrm{a}} = \partial_t\,(\boldsymbol{\omega} + 2\,\boldsymbol{\Omega}) = \partial_t \boldsymbol{\omega}, \tag{41.36}$$

in which case equation (41.35) can be written as an equation for absolute vorticity

$$\partial_t \boldsymbol{\omega}_{\mathrm{a}} + \nabla \times (\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v}) = \boldsymbol{B} + \nabla \times \boldsymbol{F}, \tag{41.37}$$

where $\boldsymbol{B}$ is the baroclinicity vector given by equation (41.9).

41.3.3 Massaged form of the vorticity equation

Physical interpretation of the term $\nabla \times (\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v})$ appearing in the prognostic equation (41.37) can be made more transparent by using the following vector identity

$$\nabla \times (\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v}) = (\boldsymbol{v} \cdot \nabla)\boldsymbol{\omega}_{\mathrm{a}} - (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\boldsymbol{v} + \boldsymbol{\omega}_{\mathrm{a}} \nabla \cdot \boldsymbol{v} - \boldsymbol{v} \nabla \cdot \boldsymbol{\omega}_{\mathrm{a}} \tag{41.38a}$$

$$= (\boldsymbol{v} \cdot \nabla)\boldsymbol{\omega}_{\mathrm{a}} - (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\boldsymbol{v} - \frac{\boldsymbol{\omega}_{\mathrm{a}}}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t}. \tag{41.38b}$$

The second equality required the continuity equation

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho \nabla \cdot \boldsymbol{v}, \tag{41.39}$$

and the non-divergent nature of the absolute vorticity

$$\nabla \cdot \boldsymbol{\omega}_{\mathrm{a}} = \nabla \cdot (\nabla \times \boldsymbol{v} + 2\boldsymbol{\Omega}) = 0. \tag{41.40}$$

Equation (41.37) thus takes the form

$$\frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}}{\mathrm{D}t} - \frac{\boldsymbol{\omega}_{\mathrm{a}}}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\boldsymbol{v} + \frac{1}{\rho^2}(\nabla\rho \times \nabla p) + \nabla \times \boldsymbol{F}, \tag{41.41}$$

which can be written

$$\rho\,\frac{\mathrm{D}(\boldsymbol{\omega}_{\mathrm{a}}/\rho)}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v} + \boldsymbol{B} + \nabla \times \boldsymbol{F}. \tag{41.42}$$

Each term on the right hand side of the material evolution equation (41.42) represents a distinct physical process that affects $\boldsymbol{\omega}_{\mathrm{a}}/\rho$ of a fluid element. The first term, $(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v}$, embodies stretching and twisting and is explored in Section 41.5 in the simplified context of a barotropic fluid. The second term arises from baroclinicity as introduced in equation (41.9) and given a mechanical interpretation in Section 41.4. The third term arises from the curl of the friction vector, which contributes especially in boundary layer regions where friction curls are relatively large in magnitude.

41.3.4 Evolution of Cartesian vorticity components

The terms appearing on the right hand side of the vorticity equation (41.42) provide sources for the vorticity of a fluid element. However, these sources are quite special in that they can be written as the convergence of a flux corresponding to each component of the vorticity. We here expose that property by deriving flux-form conservation equations that are separately satisfied by each of the vorticity components.

For this purpose, consider the equation for the vertical component of the absolute vorticity

$$\rho\,\frac{\mathrm{D}(\zeta_{\mathrm{a}}/\rho)}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,w + \hat{\boldsymbol{z}} \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}) \quad \text{with } \zeta_{\mathrm{a}} = \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_{\mathrm{a}}. \tag{41.43}$$

Making use of the identities

$$\rho \frac{\mathrm{D}(\zeta_{\mathrm{a}}/\rho)}{\mathrm{D}t} = \frac{\partial \zeta_{\mathrm{a}}}{\partial t} + \nabla \cdot (\boldsymbol{v}\, \zeta_{\mathrm{a}}) \tag{41.44a}$$

$$(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\, w = \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, w) \tag{41.44b}$$

$$\hat{\boldsymbol{z}} \cdot \boldsymbol{B} = -\hat{\boldsymbol{z}} \cdot [\nabla \times (\rho^{-1}\, \nabla p)] = \nabla \cdot (\hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p) \tag{41.44c}$$

$$\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}) = -\nabla \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{F}), \tag{41.44d}$$

brings equation (41.43) into the flux-form

$$\frac{\partial \zeta_{\mathrm{a}}}{\partial t} = -\nabla \cdot \boldsymbol{J}_{\zeta} \quad \text{with} \quad \boldsymbol{J}_{\zeta} = \boldsymbol{v}\, \zeta_{\mathrm{a}} - \boldsymbol{\omega}_{\mathrm{a}}\, w - \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{z}} \times \boldsymbol{F}. \tag{41.45}$$

This budget equation says that ζ_{a} evolves at a point according to the convergence of a flux, $\boldsymbol{J}_{\zeta}$. There are no source terms appearing outside of the flux. This vorticity flux is comprised of an advective flux of vertical vorticity, $\boldsymbol{v}\, \zeta_{\mathrm{a}}$; a contribution from absolute vorticity transported vertically, $-\boldsymbol{\omega}_{\mathrm{a}}\, w$; a contribution from the pressure gradient acceleration rotated clockwise by $\pi/2$ radians around the vertical axis, $-\hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p$; and the $\pi/2$ counter-clockwise rotated friction acceleration, $\hat{\boldsymbol{z}} \times \boldsymbol{F}$. Note that there is no vertical component to the vorticity flux:

$$\hat{\boldsymbol{z}} \cdot \boldsymbol{J}_{\zeta} = \hat{\boldsymbol{z}} \cdot [\boldsymbol{v}\, \zeta_{\mathrm{a}} - \boldsymbol{\omega}_{\mathrm{a}}\, w - \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{z}} \times \boldsymbol{F}] = 0, \tag{41.46}$$

so that ζ_{a} is only affected by the convergence of a purely horizontal flux. We offer a schematic of this property in Figure 41.1.

FIGURE 41.1: Tendency for the vertical component to the absolute vorticity arises from the convergence of the vorticity flux, $\boldsymbol{J}_{\zeta}$, given by equation (41.45). This vorticity flux is strictly horizontal, $\boldsymbol{J}_{\zeta} \cdot \hat{\boldsymbol{z}} = 0$. This result generalizes for any arbitrary Cartesian component of the absolute vorticity, whereby the corresponding vorticity flux is orthogonal to its vorticity component. Generalization of this result leads to the impermeability theorem of potential vorticity studied in Section 43.2.

Mathematically, there is nothing special about the vertical vorticity component. Hence, we readily find that the horizontal vorticity components also satisfy their own respective flux-form conservation equations, thus leading to the general result

$$\partial_t (\hat{\boldsymbol{e}} \cdot \boldsymbol{\omega}_{\mathrm{a}}) = -\nabla \cdot [\boldsymbol{v}\, (\hat{\boldsymbol{e}} \cdot \boldsymbol{\omega}_{\mathrm{a}}) - \boldsymbol{\omega}_{\mathrm{a}}\, (\hat{\boldsymbol{e}} \cdot \boldsymbol{v}) - \hat{\boldsymbol{e}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{e}} \times \boldsymbol{F}], \tag{41.47}$$

where $\hat{\boldsymbol{e}}$ is any one of the Cartesian unit vectors $\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}}$. Furthermore, we readily see that the vorticity flux satisfies

$$\hat{\boldsymbol{e}} \cdot [\boldsymbol{v}\, (\hat{\boldsymbol{e}} \cdot \boldsymbol{\omega}_{\mathrm{a}}) - \boldsymbol{\omega}_{\mathrm{a}}\, (\hat{\boldsymbol{e}} \cdot \boldsymbol{v}) - \hat{\boldsymbol{e}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{e}} \times \boldsymbol{F}] = 0, \tag{41.48}$$

so that the time tendency for $\hat{\boldsymbol{e}} \cdot \boldsymbol{\omega}_{\mathrm{a}}$ is affected by a flux in the directions orthogonal to $\hat{\boldsymbol{e}}$. This property of the vorticity flux is generalized via the impermeability theorem of potential vorticity studied in Section 43.2, with particular connection to the present discussion given in Section 43.2.2.

41.3.5 Evolution of the normal component of absolute vorticity

As a further examination of vorticity components, we here consider the material evolution of vorticity projected onto the unit normal vector, $\hat{\boldsymbol{n}}$, for an infinitesimal material area, $\delta\mathcal{S}$. This discussion leads to an infinitesimal version of Kelvin's circulation theorem, thus explicitly linking the evolution equations for vorticity and circulation. In the process we make use of some kinematics from Chapter 19.

The unit normal vector to a material surface evolves according to equation (19.75e)

$$\frac{\mathrm{D}\hat{n}_m}{\mathrm{D}t} = -\hat{\boldsymbol{n}} \cdot \partial_m^{\mathrm{surf}} \boldsymbol{v}, \tag{41.49}$$

where the surface derivative, and corresponding surface divergence, are given from equation (19.71)

$$\partial_m^{\mathrm{surf}} = \partial_m - \hat{n}_m \, (\hat{\boldsymbol{n}} \cdot \nabla) \quad \text{and} \quad \nabla^{\mathrm{surf}} = \nabla - \hat{\boldsymbol{n}} \, (\hat{\boldsymbol{n}} \cdot \nabla). \tag{41.50}$$

Making use of the vorticity equation in the form (41.41), along with the continuity equation (41.39), leads to

$$\hat{\boldsymbol{n}} \cdot \frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}}{\mathrm{D}t} = -(\hat{\boldsymbol{n}} \cdot \boldsymbol{\omega}_{\mathrm{a}}) \, \nabla \cdot \boldsymbol{v} + \hat{n}_j \, (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla) \, v_j + \hat{\boldsymbol{n}} \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}). \tag{41.51}$$

Likewise, taking the dot product of $\boldsymbol{\omega}_{\mathrm{a}}$ with the evolution equation (41.49) yields

$$\boldsymbol{\omega}_{\mathrm{a}} \cdot \frac{\mathrm{D}\hat{\boldsymbol{n}}}{\mathrm{D}t} = \hat{n}_j \, [-(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla) + (\hat{\boldsymbol{n}} \cdot \boldsymbol{\omega}_{\mathrm{a}}) \, (\hat{\boldsymbol{n}} \cdot \nabla)] \, v_j. \tag{41.52}$$

Adding these two equations renders the material time evolution

$$\frac{\mathrm{D}(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})}{\mathrm{D}t} = -(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}) \, \nabla^{\mathrm{surf}} \cdot \boldsymbol{v} + \hat{\boldsymbol{n}} \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}). \tag{41.53}$$

The surface divergence of the velocity measures, via equation (19.72), the evolution of the material surface area

$$\frac{1}{\delta S} \frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} = \nabla^{\mathrm{surf}} \cdot \boldsymbol{v}, \tag{41.54}$$

so that the material evolution equation for the $\hat{\boldsymbol{n}}$ component of absolute vorticity is

$$\frac{\mathrm{D}(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})}{\mathrm{D}t} = -\frac{(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})}{\delta S} \frac{\mathrm{D}\delta\mathcal{S}}{\mathrm{D}t} + \hat{\boldsymbol{n}} \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}). \tag{41.55}$$

The area term arises from the familiar "ice-skater" effect that reflects angular momentum conservation for the column (Section 40.2.2), whereas the other terms are the projection of the baroclinicity and friction curl onto $\hat{\boldsymbol{n}}$. Bringing the area term onto the left hand side then renders the infinitesimal form of Kelvin's circulation theorem (41.5e)

$$\frac{\mathrm{D}}{\mathrm{D}t}(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}) = (\boldsymbol{B} + \nabla \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{41.56}$$

Note the presence of the absolute vorticity, $\boldsymbol{\omega}_{\mathrm{a}}$, in equation (41.55) rather than the relative vorticity considered in Section 41.2. We return in Section 41.6 to the question of circulation arising from planetary rotation, where we derive the finite version of the circulation theorem (41.55).

41.3.6 Vorticity, angular momentum, and torques

Both vorticity and angular momentum offer measures of the rotational motion of a fluid flow. However, there are key distinctions as detailed in Section 38.9. Perhaps the most fundamental distinction is that vorticity measures the rotation or spin without reference to an origin, whereas angular momentum is computed relative to a subjectively chosen origin. Vorticity is thus an intrinsic property of the fluid flow, whereas angular momentum depends on the chosen origin and is affected by fluid strains. Consequently, there is a direct connection between angular momentum and vorticity only for the special case of flow exhibiting rigid-body motion.

Angular momentum of motion relative to an origin changes in the presence of torques computed about the chosen origin, with the torque equal to the crosss product of the position vector of a point and the force vector acting at that point. In contrast, vorticity at a point is affected by the curl of the force per mass acting at the point. Furthermore, angular momentum is a property of any mechanical system, including point particles and rigid bodies, whereas vorticity is a property only of a continuous media where we can compute spatial derivatives of the velocity field.

When the curl of a force per mass is applied to a fluid and thus changes its vorticity, we commonly use the term "torque" in reference to this force curl. For example, in Section 41.4 we explore baroclinicity, which is the key mechanism for how inviscid torques from pressure modify vorticity. In that discussion, we see that baroclinicity provides a vorticity source when the pressure force acting on a fluid element does not pass through the center of mass of that element. When there is baroclinicity, the pressure force spins the fluid element thus affecting vorticity. Analogous inviscid and viscous force curls act on boundaries, such as when a fluid interacts with the solid earth. It is within this context that we use the term "torque" when referring to a vorticity source. Correspondingly, the torques providing a vorticity source have the dimension of force per mass per length, whereas the torques altering angular momentum have the dimension of force times length.[6]

41.4 Mechanics of baroclinicity

Baroclinicity is present in most geophysical flows, thus affecting the material evolution of circulation and vorticity. Flow with a nonzero baroclinicity vector is generally referred to as *baroclinic flow*, whereas *barotropic* flows have zero baroclinicity. We illustrate the basic distinction between barotropic and baroclinic fluids in Figure 41.2. We observe that a baroclinic fluid is associated with fluid motion that is a function of depth. In contrast, a barotropic fluid in the special case of pressure and density surfaces aligned with geopotentials, supports no motion. We further develop these points as we here explore the mechanics of baroclinicity.

41.4.1 Curl of the pressure gradient body force

Baroclinicity is the curl of the pressure gradient body force

$$\boldsymbol{B} = \nabla \times \boldsymbol{F}_{\text{press}} = \nabla \times (-\rho^{-1}\,\nabla p) = -\nabla \rho^{-1} \times \nabla p = \frac{\nabla \rho \times \nabla p}{\rho^2}. \tag{41.57}$$

As discussed in Section 41.3.6, the curl of a force provides a torque that spins the fluid, thus rendering a vorticity source. Geometrically, baroclinicity arises when there is nonzero change in pressure along contours of constant density, or conversely changes in density along contours of

[6] See Section 2 of *Hughes* (2000) for a similar perspective on usage of the term "torque" for processes affecting vorticity.

FIGURE 41.2: Left panel: a barotropic fluid, whereby density is a function just of pressure, $\rho = \rho(p)$, so that density surfaces (dashed lines) and pressure surfaces (solid lines) are parallel. Horizontal density and pressure surfaces in a barotropic fluid support no motion. Right panel: a baroclinic fluid, whereby density and pressure surfaces generally differ so that density is a function of more than just the pressure. A baroclinic fluid is associated with fluid motion.

constant pressure.[7] It can be useful to introduce the notion of a *solenoid*, which is a tube region in the fluid that is perpendicular to both $\nabla\rho$ and ∇p. There are no solenoids for barotropic flows, whereby $p = p(\rho)$ (see equation (41.10)). For baroclinic flow, solenoids are associated with a torque that affects vorticity.

To further understand the mechanical interpretation of solenoids in terms of a torque, consider the cross product

$$\rho\,\boldsymbol{B} = \boldsymbol{F}^{\text{press}} \times \nabla\rho = (-\rho^{-1}\,\nabla p) \times \nabla\rho. \tag{41.58}$$

The first term on the right hand side is the pressure gradient acceleration that is oriented down the pressure gradient. Now consider a tiny fluid element such as shown in Figure 41.3. By construction, the pressure force acts at the geometric center of the element. However, the nonzero density gradient means that the center of mass for the fluid element is not at the geometric center. Since the pressure gradient force does not pass through the center of mass, it imparts a torque to the fluid element. This torque then modifies the vorticity and hence the circulation around the boundary of the element. Only when the pressure gradient force is aligned with the density gradient (barotropic flow), or if the density is spatially uniform (e.g., constant density homogeneous fluid) does the pressure gradient force pass through the center of mass, thus creating no torque and inducing no vorticity.

41.4.2 Kelvin's circulation theorem and contact pressure forces

We are afforded another means to understand baroclinicity by returning to the formulation of Kelvin's circulation theorem in Section 41.2.1. Focusing just on the baroclinicity contribution in equation (41.5e) we have

$$\left[\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t}\right]_{\text{baroclinicity}} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} -\rho^{-1}\,\nabla p \cdot \mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \rho^{-2}\,(-p\,\nabla\rho) \cdot \mathrm{d}\boldsymbol{x}, \tag{41.59}$$

which follows since, at any particular instance,

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \nabla(p/\rho) \cdot \mathrm{d}\boldsymbol{x} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}(p/\rho) = 0. \tag{41.60}$$

The term $-p\,\nabla\rho$ in equation (41.59) is proportional to the compressive contact pressure force (Section 26.2) acting normal to a constant density surface. Consequently, if the material surface

[7] See Exercise 7.1 for a two-dimensional example of this geometry.

FIGURE 41.3: A mechanical interpretation of the baroclinicity vector. We consider a tiny fluid element bounded by surfaces of constant pressure and density. By construction, the pressure gradient force acts at the geometric center of the element, whereas the center of mass for the element is off-center due to the density gradient across the element. The pressure gradient force thus provides a torque for the fluid element, with the moment-arm for the torque determined by the distance between the geometric center and the center of mass. This torque modifies the vorticity of the fluid element, and in turn modifies the circulation computed around the element's boundary. As depicted here, the baroclinicity vector points into the page (right hand rule for $(-\rho^{-1}\,\nabla p)\times\nabla\rho$), so that this baroclinicity spins-up a clockwise circulation around the element, or equivalently a clockwise vorticity. This figure is adapted from Figure 14.9 of *Thorne and Blandford* (2017).

on which we are computing circulation happens to be parallel to a constant density surface, then pressure cannot generate any circulation around that material circuit. The left circuit in Figure 41.4 illustrates this situation. For the more general case where a material surface crosses constant density surfaces, pressure modifies circulation computed around such circuits (right circuit in Figure 41.4).

FIGURE 41.4: The material circuit on the left is assumed to be within a constant density surface. In this case, $\nabla\rho\cdot\mathrm{d}\boldsymbol{x}=0$ so that pressure cannot modify the circulation around this circuit. However, if a material circuit is not contained fully within constant density surface, such as depicted on the right, then pressure is able to modify the circulation computed around the circuit.

41.4.3 Bottom pressure contributions at the solid-earth boundary

As an application of the above ideas, consider a fluid region that intersects the solid-earth boundary. The solid-earth boundary is material so that we can apply Kelvin's circulation theorem to a circuit on the boundary. Consider the situation in Figure 41.5, which shows a vertical slice next to a sloping bottom with constant density surfaces intersecting the bottom. As in our considerations in Section 41.4.2, any material circuit that sits within the bottom boundary crosses density

surfaces, in which case circulation is affected by the bottom pressure. Indeed, even if the bottom is flat, so long as density is not constant along the bottom, then a material circuit within the bottom has circulation modified by bottom pressure.

To develop the mathematics of the above ideas, write the differential line element within the bottom circuit as

$$\mathrm{d}\boldsymbol{x} = \hat{\boldsymbol{x}}\,\mathrm{d}x + \hat{\boldsymbol{y}}\,\mathrm{d}y + \hat{\boldsymbol{z}}\,\mathrm{d}z = (\hat{\boldsymbol{x}} + \hat{\boldsymbol{z}}\,\partial_x\eta_\mathrm{b})\mathrm{d}x + (\hat{\boldsymbol{y}} + \hat{\boldsymbol{z}}\,\partial_y\eta_\mathrm{b})\mathrm{d}y. \tag{41.61}$$

To reach this result we set $z = \eta_\mathrm{b}(x, y)$ since the circuit is along the bottom boundary, which in turn means that[8]

$$\mathrm{d}z = \mathrm{d}\eta_\mathrm{b} = \nabla\eta_\mathrm{b} \cdot (\hat{\boldsymbol{x}}\,\mathrm{d}x + \hat{\boldsymbol{y}}\,\mathrm{d}y) = \nabla\eta_\mathrm{b} \cdot \mathrm{d}\boldsymbol{x}_\mathrm{horz}. \tag{41.62}$$

Consequently, the projection of the density gradient onto the circuit is given by

$$\nabla\rho \cdot \mathrm{d}\boldsymbol{x} = (\nabla_z\rho + \partial_z\rho\,\nabla\eta_\mathrm{b}) \cdot \mathrm{d}\boldsymbol{x}_\mathrm{horz}. \tag{41.63}$$

Making use of this result in Kelvin's circulation theorem and focusing on the pressure contribution, as in equation (41.59), leads to

$$\left[\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t}\right]_\mathrm{bottom} = -\oint_{\partial\mathcal{S}_\mathrm{bottom}} p\,\rho^{-2}\,\nabla\rho \cdot \mathrm{d}\boldsymbol{x} = -\oint_{\partial\mathcal{S}_\mathrm{bottom}} \frac{p_\mathrm{b}}{\rho^2}(\nabla_z\rho + \partial_z\rho\,\nabla\eta_\mathrm{b}) \cdot \mathrm{d}\boldsymbol{x}_\mathrm{horz}. \tag{41.64}$$

There are two contributions to the circulation changes revealed by equation (41.64). The first arises from the sloped density surfaces next to the bottom, and the second arises from the sloped bottom multiplied by the vertical density gradient. These two contributions are weighted by the bottom pressure, p_b, which is normalized by the squared density. Circulation modifications are enhanced by increased horizontal density gradients next to the bottom, as well as increased topographic slopes. For the special case of flat topography and flat density there are no bottom pressure-induced changes to the circulation around a bottom material circuit.

FIGURE 41.5: Constant density surfaces intersecting a sloped solid-earth boundary. Any circuit that sits along the boundary is material since the bottom is material. For circuits that cross density surfaces, the bottom pressure acts to modify circulation computed for this circuit.

41.4.4 Further study

This video from Prof. Shapiro provides a lucid discussion of baroclinicity and its role in affecting

[8] Since $\eta_\mathrm{b} = \eta_\mathrm{b}(x, y)$, its gradient is horizontal: $\nabla\eta_\mathrm{b} = \hat{\boldsymbol{x}}\,\partial_x\eta_\mathrm{b} + \hat{\boldsymbol{y}}\,\partial_y\eta_\mathrm{b}$.

vorticity and circulation.

41.5 Vortex lines and material lines

We here study the physics of the source term

$$(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\, \boldsymbol{v} = f\, \partial_z \boldsymbol{v} + (\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v} \tag{41.65}$$

appearing in the vorticity equation (41.42). The contribution from $\hat{\boldsymbol{z}}\, f\, \partial_z w$ to the first term is further explored when studying the planetary geostrophic equations in Sections 32.5 and 45.3, given its importance for large-scale meridional motion on a spherical planet. The second term, $(\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v}$, is the focus of this section.

41.5.1 Vortex lines evolve through the strain rate tensor

To help unpack the physics of the source, $(\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v}$, write it in the following form found by exposing Cartesian tensor labels

$$\omega_m\, \partial_m v_n = (\omega_m/2)\, [(\partial_m v_n + \partial_n v_m) + (\partial_m v_n - \partial_n v_m)] \tag{41.66a}$$

$$= \omega_m\, \mathbb{S}_{mn} - \omega_m\, \mathbb{R}_{mn}, \tag{41.66b}$$

where $\mathbb{S}_{mn} = (1/2)\, (\partial_n v_m + \partial_m v_n)$ are components to the strain rate tensor and $\mathbb{R}_{mn} = (1/2)\, (\partial_n v_m - \partial_m v_n)$ are components to the rotation tensor. These tensors were introduced in Section 19.3 when studying the kinematics of line elements. As shown in that discussion, the rotation tensor is related to the vorticity by the identity (19.55), whose use leads to

$$2\, \omega_m\, \mathbb{R}_{mn} = -\omega_m\, \epsilon_{mnp}\, \omega_p = \epsilon_{nmp}\, \omega_m\, \omega_p = (\boldsymbol{\omega} \times \boldsymbol{\omega})_n = 0. \tag{41.67}$$

Recalling that the rotation tensor generates rotations about the axis defined by vorticity, we can understand why $\boldsymbol{\omega} \cdot \mathbb{R} = 0$. Namely, there is no rotation generated when a vector is rotated about its own axis. We are thus left just with

$$(\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v} = \boldsymbol{\omega} \cdot \mathbb{S}. \tag{41.68}$$

That is, the source, $(\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v}$, appearing in the vorticity equation is determined by the projection of the vorticity onto the strain rate tensor. This result highlights the fundamental role of flow strains in affecting vorticity.

41.5.2 Frozen-in nature of vorticity

Consider an inviscid barotropic fluid in the absence of planetary rotation and whose flow is non-divergent, in which case the vorticity equation (41.42) reduces to

$$\frac{\mathrm{D}\boldsymbol{\omega}}{\mathrm{D}t} = (\boldsymbol{\omega} \cdot \nabla)\, \boldsymbol{v}, \tag{41.69}$$

and recall the evolution equation for a material line element as detailed in Section 19.3

$$\frac{\mathrm{D}(\delta \boldsymbol{x})}{\mathrm{D}t} = (\delta \boldsymbol{x} \cdot \nabla)\, \boldsymbol{v}. \tag{41.70}$$

Now recall from Section 38.7.1 that a vortex line is a line drawn through the fluid that is everywhere parallel to the vorticity. Such a line connects material fluid particles, so that a vortex line constitutes a particular case of a material line. At some initial time, $t = 0$, let the vorticity on an infinitesimal vortex line be related to the material line element according to

$$\delta \boldsymbol{x}(0) = \Gamma\, \boldsymbol{\omega}(\boldsymbol{x}, 0), \tag{41.71}$$

where Γ has dimensions $L\,T$ and is determined by the initial vorticity and initial line element. Since the vorticity equation (41.69) has precisely the same mathematical form as the material line element equation (41.70), the difference vector

$$\boldsymbol{A} \equiv \delta \boldsymbol{x} - \Gamma\, \boldsymbol{\omega}, \tag{41.72}$$

evolves according to

$$\frac{\mathrm{D}\boldsymbol{A}}{\mathrm{D}t} = (\boldsymbol{A} \cdot \nabla)\boldsymbol{v}. \tag{41.73}$$

But since $\boldsymbol{A}$ vanishes at $t = 0$, we conclude that it vanishes for all time

$$\frac{\mathrm{D}\boldsymbol{A}}{\mathrm{D}t} = 0. \tag{41.74}$$

Consequently, the relation (41.71) holds for all time with Γ a constant. That is, the vortex line and its corresponding line element remain parallel as they both evolve according to their projection onto the strain rate tensor. We thus say that vorticity is a *frozen-in* property as illustrated by Figure 41.6. Although we established this property only for the case of an inviscid, barotropic fluid with non-divergent flow, it offers insight into the more general situation occuring in real fluids.

FIGURE 41.6: For the non-divergent flow of a perfect barotropic fluid, vortex lines are also material lines. This property means that for an arbitrary vortex line drawn in the fluid, the fluid particles that are initially on the vortex line remain on the line as it moves through the fluid according to the strain rate tensor. We here show two instances of the same vortex line along with sample test fluid particles. The left configuration stretches into the right configuration, with the vorticity increasing as the vortex line stretches according to the discussion in Section 41.5.3. This property of a vortex line is known as its *frozen-in nature*. The frozen-in nature of vortex lines strictly holds only for perfect barotropic fluid exhibiting non-divergent flow, yet it offers useful insights into the vortex dynamics of more general fluids.

41.5.3 Stretching and tilting of vortex tubes

Vorticity responds when vortex lines or tubes are stretched or bent by the strain rate tensor. To help understand the response, consider again the perfect fluid barotropic vorticity equation with a non-divergent flow (equation (41.69)) and focus on the material evolution of the vertical vorticity

component

$$\frac{\mathrm{D}\omega_z}{\mathrm{D}t} = \omega_x \frac{\partial w}{\partial x} + \omega_y \frac{\partial w}{\partial y} + \omega_z \frac{\partial w}{\partial z} = \boldsymbol{\omega} \cdot \nabla w = \nabla \cdot (w\, \boldsymbol{\omega}). \tag{41.75}$$

The following discussion closely emulates that given for a material line element in Section 19.4.3.

Stretching

Consider the vortex tube to be initially aligned with the $\hat{\boldsymbol{z}}$-axis, so that $\omega_x = \omega_y = 0$, in which case there is only a single term impacting the material evolution of vertical vorticity[9]

$$\frac{\mathrm{D}\omega_z}{\mathrm{D}t} = \omega_z \frac{\partial w}{\partial z}. \tag{41.76}$$

Since the flow is non-divergent, the volume of an infinitesimal portion of the vortex tube is materially constant

$$\frac{\mathrm{D}(\delta V)}{\mathrm{D}t} = 0, \tag{41.77}$$

which means that the vertical extent, δz, and cross-sectional area, δA, are constrained

$$\frac{1}{\delta z}\frac{\mathrm{D}(\delta z)}{\mathrm{D}t} + \frac{1}{\delta A}\frac{\mathrm{D}(\delta A)}{\mathrm{D}t} = 0. \tag{41.78}$$

As the tube stretches vertically, its horizontal area reduces, and vice versa. Making use of the expression for the evolution of a material line segment (equation (41.70)) allows us to write

$$\frac{1}{\delta z}\frac{\mathrm{D}(\delta z)}{\mathrm{D}t} = \frac{\partial w}{\partial z}, \tag{41.79}$$

so that the vorticity equation (41.76) becomes

$$\frac{\mathrm{D}\omega_z}{\mathrm{D}t} = \omega_z \frac{\partial w}{\partial z} = \omega_z \left[\frac{1}{\delta z}\frac{\mathrm{D}(\delta z)}{\mathrm{D}t}\right] = -\omega_z \left[\frac{1}{\delta A}\frac{\mathrm{D}(\delta A)}{\mathrm{D}t}\right]. \tag{41.80}$$

Rearrangement leads to

$$\frac{\mathrm{D}(\omega_z\, \delta A)}{\mathrm{D}t} = 0, \tag{41.81}$$

which is an expression of Kelvin's circulation theorem (equation (41.11)) for a horizontal cross-section of the vortex tube.

The above manipulations suggest the following interpretation for the *stretching* term, $\omega_z\,(\partial w/\partial z)$, appearing in the vertical vorticity equation (41.75) and illustrated in Figure 41.7. Namely, as the vortex tube is stretched and its cross-sectional area is compressed, the vorticity magnitude increases so to maintain a constant circulation around the tube, as per Kelvin's theorem (or equivalently as per Helmholtz's first theorem discussed in Section 38.7.3). Stretching a vortex tube increases the magnitude of the vorticity in the direction of the stretching whereas compressing a tube reduces the vorticity magnitude. This result accords with our understanding of angular momentum conservation as discussed for the rotating cylinder in Section 40.2.2 and depicted by Figure 40.1.

[9] Be mindful to distinguish the symbols for the vertical component of vorticity, ω_z, and the vertical component of velocity, w.

FIGURE 41.7: Ilustrating how stretching and tilting of a vortex tube impacts on the vorticity. Top panels: As the cross-sectional area of the vortex tube shrinks, and the vertical extent of the tube stretches, the magnitude of the vorticity along the axis of the tube increases. This result accords with our understanding of angular momentum conservation as discussed for the rotating cylinder in Section 40.2.2 and depicted by Figure 40.1, as well as with Helmholtz's first theorem in Section 38.7.3 and Figure 38.7. Lower panels: The initial vortex tube is assumed to be aligned parallel to the x-axis, so that it has zero projection in the vertical direction. A horizontal shear of the vertical velocity ($\partial w/\partial x \neq 0$) deforms the vortex tube. Upon deforming (or tilting), the tube picks up a nonzero projection in the vertical, which means that it now has a nonzero vertical component to vorticity.

Tilting

Now consider an initially horizontal vortex tube as in the lower left panel of Figure 41.7 so that $\omega_z = 0$. Furthermore, to focus on just one of the two horizontal directions we set $\omega_y = 0$ so that equation (41.75) for the vertical vorticity becomes

$$\frac{\mathrm{D}\omega_z}{\mathrm{D}t} = \omega_x \frac{\partial w}{\partial x}. \tag{41.82}$$

If there is no horizontal shear in the vertical velocity ($\partial w/\partial x = 0$), then the vortex tube remains horizontal. However, in the presence of $\partial w/\partial x \neq 0$, the vorticity vector picks up a nonzero vertical projection. To help visualize this process, recall the frozen-in nature of vortex lines, and consider the evolution of an infinitesimal line segment on the vortex tube. With the vortex tube initially aligned parallel to the x-axis, the evolution of a material line segment (equation (41.70)) is given by

$$\frac{\mathrm{D}(\delta \boldsymbol{x})}{\mathrm{D}t} = \delta x \frac{\partial \boldsymbol{v}}{\partial x}. \tag{41.83}$$

The initially horizontal line segment thus picks up a projection in the vertical so long as $\partial w/\partial x \neq 0$. Correspondingly, the vorticity picks up a vertical component. We can think of this process as a tilting or deforming of the initially horizontal vortex tube, with the tilted tube having a nonzero vertical projection.

41.5.4 Shallow water vorticity revisited

We here revisit our discussion of the shallow water vorticity from Chapter 40 in light of the vorticity equation (41.42). Notably, an inviscid shallow water fluid has zero baroclinicity, so that only stretching and tilting affect shallow water vorticity.

Vortex tubes never close in a shallow water layer

The absolute vorticity vector in a shallow water layer is given by equation (36.105d)

$$\boldsymbol{\omega}_{\mathrm{a}} = \nabla \times \boldsymbol{v} + \hat{\boldsymbol{z}}\, f = \boldsymbol{\omega}_{\mathrm{h}} + \hat{\boldsymbol{z}}\,(\zeta + f) = \hat{\boldsymbol{x}}\,\partial_y w - \hat{\boldsymbol{y}}\,\partial_x w + \hat{\boldsymbol{z}}\,\zeta_{\mathrm{a}} = -\hat{\boldsymbol{z}} \times \nabla w + \hat{\boldsymbol{z}}\,\zeta_{\mathrm{a}}, \tag{41.84}$$

where we set $\partial_z u = \partial_z v = 0$ for the horizontal velocity within a shallow water layer. Since the shallow water fluid is hydrostatic, the horizontal vorticity component is much smaller in magnitude than the vertical component,

$$|\partial_x w, \partial_y w| \ll |\zeta|. \tag{41.85}$$

Vortex tubes in a shallow water fluid do not close, since to close requires breaking this inequality. Hence, shallow water vortex tubes reach from the bottom of the layer to the top, with only a slight tilt relative to the vertical.

Material time evolution of shallow water vorticity

To determine how shallow water vorticity evolves, we make use of the stretching and tilting term in the form of equation (41.68) so that

$$\frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v} \Longrightarrow \frac{\mathrm{D}\omega_{\mathrm{a}n}}{\mathrm{D}t} = \omega_{\mathrm{a}m}\,\mathbb{S}_{mn}. \tag{41.86}$$

The strain rate tensor for the shallow water fluid is

$$\mathbb{S} = \frac{1}{2}\begin{bmatrix} 2\,\partial_x u & \partial_y u + \partial_x v & \partial_z u + \partial_x w \\ \partial_x v + \partial_y u & 2\,\partial_y v & \partial_z v + \partial_y w \\ \partial_x w + \partial_z u & \partial_y w + \partial_z v & 2\,\partial_z w \end{bmatrix} = \frac{1}{2}\begin{bmatrix} 2\,\partial_x u & \partial_y u + \partial_x v & \partial_x w \\ \partial_x v + \partial_y u & 2\,\partial_y v & \partial_y w \\ \partial_x w & \partial_y w & 2\,\partial_z w \end{bmatrix}, \tag{41.87}$$

so that material time evolution of the vertical vorticity component, is given by

$$\begin{aligned} \frac{\mathrm{D}(\zeta + f)}{\mathrm{D}t} &= \omega_1\,\mathbb{S}_{13} + \omega_2\,\mathbb{S}_{23} + \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_{\mathrm{a}}\,\mathbb{S}_{33} && (41.88\mathrm{a}) \\ &= (1/2)\,(\omega_1\,\partial_x w + \omega_2\,\partial_y w) + \omega_{\mathrm{a}3}\,\partial_z w && (41.88\mathrm{b}) \\ &= (\zeta + f)\,\partial_z w && (41.88\mathrm{c}) \\ &= -(\zeta + f)\,\nabla \cdot \boldsymbol{u}, && (41.88\mathrm{d}) \end{aligned}$$

which agrees with the shallow water vorticity equation (40.9). For the zonal vorticity component we have

$$\begin{aligned} \frac{\mathrm{D}\omega_1}{\mathrm{D}t} &= \omega_1\,\mathbb{S}_{11} + \omega_2\,\mathbb{S}_{21} + \hat{\boldsymbol{z}} \cdot \boldsymbol{\omega}_{\mathrm{a}}\,\mathbb{S}_{31} && (41.89\mathrm{a}) \\ &= \omega_1\,\partial_x u + \omega_2\,(\partial_x v + \partial_y u)/2 + \omega_3\,\partial_x w, && (41.89\mathrm{b}) \end{aligned}$$

and a similar expression for the meridional component.

Flux-form evolution of Cartesian vorticity components

In Section 41.3.4, we showed how each of the three Cartesian vorticity components evolves according to a flux-form equation. For the vertical component to the vorticity, the vorticity flux, $\boldsymbol{J}_\zeta$, is given by equation (41.45) and it takes on the following form for a shallow water layer

$$\boldsymbol{J}_\zeta = \boldsymbol{v}\,\zeta_{\mathrm{a}} - w\,\boldsymbol{\omega}_{\mathrm{a}} = \boldsymbol{u}\,\zeta_{\mathrm{a}} - w\,\boldsymbol{\omega}_{\mathrm{h}} = \boldsymbol{u}\,\zeta_{\mathrm{a}} + w\,\hat{\boldsymbol{z}} \times \nabla w = \boldsymbol{u}\,\zeta_{\mathrm{a}} + \hat{\boldsymbol{z}} \times \nabla w^2/2. \tag{41.90}$$

The term

$$\hat{\boldsymbol{z}} \times \nabla w^2/2 = -\nabla \times \hat{\boldsymbol{z}}\, w^2/2 \tag{41.91}$$

has a zero divergence and so has no contribution to the convergence of the vorticity flux. Hence, the vorticity flux, $\boldsymbol{J}_\zeta$, derived here differs by a gauge from the purely advective flux, $\boldsymbol{u}\,\zeta_{\rm a}$, considered in the shallow water vorticity equation (40.7).

For the zonal component to the vorticity, the vorticity flux, $\boldsymbol{J}_{\omega_1}$, is given by equation (41.47) and it takes on the following form for a shallow water layer

$$\boldsymbol{J}_{\omega_1} = \boldsymbol{v}\,\omega_{\rm a1} - u\,\boldsymbol{\omega}_{\rm a} = (\hat{\boldsymbol{y}}\,v + \hat{\boldsymbol{z}}\,w)\,\omega_1 - \hat{\boldsymbol{y}}\,\omega_2 - \hat{\boldsymbol{z}}\,(\zeta + f) = \hat{\boldsymbol{y}}\,(v\,\omega_1 - u\,\omega_2) + \hat{\boldsymbol{z}}\,[w\,\omega_1 - u\,(\zeta + f)], \tag{41.92}$$

with a similar form for the flux of the meridional vorticity component, $\boldsymbol{J}_{\omega_2}$.

41.5.5 Concerning three-dimensional turbulence

As a vortex tube is stretched in the presence of straining motion, it spins faster as its radius decreases. Hence, its kinetic energy moves from larger to smaller spatial scales. This process of downscale energy cascade (i.e., the movement of kinetic energy from large to small scales) is a fundamental property of three dimensional turbulence, and vortex stretching is the dominant mechanism for the cascade. In contrast, two dimensional turbulence, which occurs in horizontal non-divergent flows, does not support vortex stretching and consequently does not support the downscale energy cascade. Instead, two dimensional turbulence supports an inverse cascade whereby there is a net flow of energy to larger scales, with that flow related to the material conservation of vorticity in two dimensional non-divergent flows (see Chapter 39). *Vallis* (2017) provides a lucid discussion of energy cascades in both two and three dimesional turbulence.

41.6 Circulation viewed in a rotating reference frame

We here tie up an important loose end by studying circulation and vorticity for fluids in a rotating reference frame, such as those on a rotating planet. It turns out that incorporating rotation is straightforward, and yet the implications are quite profound for the motion of geophysical fluids. In this section we are careful to make use of planetary Cartesian coordinates, whereby the origin of the coordinate system is at the center of the planet (see Figure 10.1).

Start by recalling the expression from Section 13.7.1 for the inertial or absolute velocity (i.e., velocity measured in an inertial frame)

$$\boldsymbol{v}_{\rm a} = \boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}, \tag{41.93}$$

where $\boldsymbol{v}$ is the velocity measured in the rotating frame (relative velocity), and $\boldsymbol{x}$ is the position vector relative to the origin (e.g., center of earth). The absolute circulation around an arbitrary circuit (a circuit that is not necessarily material) is thus given by

$$\mathcal{C}_{\rm a} = \oint_{\partial\mathcal{S}} (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) \cdot {\rm d}\boldsymbol{x} = \mathcal{C} + \mathcal{C}_{\rm planet}, \tag{41.94}$$

where the circulation measured in the rotating reference frame is

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v} \cdot {\rm d}\boldsymbol{x} \tag{41.95}$$

and the circulation associated with the rotating planet is

$$\mathcal{C}_{\text{planet}} = \oint_{\partial\mathcal{S}} (\boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x}. \tag{41.96}$$

A fluid element at rest in the rotating reference frame still has a nonzero absolute circulation as given by the planetary circulation. Making use of Stokes' theorem leads to the equivalent forms for the circulations

$$\mathcal{C} = \oint_{\partial\mathcal{S}} \boldsymbol{v} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{relative circulation} \tag{41.97a}$$

$$\mathcal{C}_{\text{planet}} = \oint_{\partial\mathcal{S}} (\boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} \boldsymbol{\omega}_{\text{planet}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{planetary circulation} \tag{41.97b}$$

$$\mathcal{C}_{\text{a}} = \oint_{\partial\mathcal{S}} \boldsymbol{v}_{\text{a}} \cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} \boldsymbol{\omega}_{\text{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{absolute circulation,} \tag{41.97c}$$

where

$$\boldsymbol{\omega} = \nabla \times \boldsymbol{v} \qquad \text{relative vorticity} \tag{41.98a}$$

$$\boldsymbol{\omega}_{\text{planet}} = \nabla \times (\boldsymbol{\Omega} \times \boldsymbol{x}) = 2\,\boldsymbol{\Omega} \qquad \text{planetary vorticity} \tag{41.98b}$$

$$\boldsymbol{\omega}_{\text{a}} = \nabla \times (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) = \boldsymbol{\omega} + \boldsymbol{\omega}_{\text{planet}} \qquad \text{absolute vorticity.} \tag{41.98c}$$

Thus far we have merely substituted in the expression (41.93) for the inertial velocity and then decomposed the vorticity and circulation into its relative and planetary components. Next we consider how circulation evolves, in which case we see how the relative and planetary circulations interact.

41.6.1 Material evolution of absolute circulation

We now consider how the absolute circulation evolves for a material circuit that moves with the fluid

$$\frac{\mathrm{d}\mathcal{C}_{\text{a}}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t} \oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{v}_{\text{a}} \cdot \mathrm{d}\boldsymbol{x} = \frac{\mathrm{d}}{\mathrm{d}t} \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x}. \tag{41.99}$$

We measure fluid motion in the rotating frame so that the material time derivative is computed with the velocity, $\boldsymbol{v}$, rather than the absolute velocity, $\boldsymbol{v}_{\text{a}}$. We now follow the derivation of Kelvin's circulation theorem in a non-rotating reference frame from Section 41.2 so that

$$\frac{\mathrm{d}\mathcal{C}_{\text{a}}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t} \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{x} \tag{41.100a}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + \boldsymbol{\Omega} \times \frac{\mathrm{D}\boldsymbol{x}}{\mathrm{D}t}\right] \cdot \mathrm{d}\boldsymbol{x} + \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{v} \tag{41.100b}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + \boldsymbol{\Omega} \times \boldsymbol{v}\right] \cdot \mathrm{d}\boldsymbol{x} + \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{\Omega} \times \boldsymbol{x}) \cdot \mathrm{d}\boldsymbol{v} \tag{41.100c}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega} \times \boldsymbol{v}\right] \cdot \mathrm{d}\boldsymbol{x}. \tag{41.100d}$$

To reach this result we set

$$\boldsymbol{v} = \frac{\mathrm{D}\boldsymbol{x}}{\mathrm{D}t}, \tag{41.101}$$

for the velocity of a fluid particle on the circuit. We also used the identity

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{v} = \frac{1}{2}\oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}(\boldsymbol{v}\cdot\boldsymbol{v}) = 0 \tag{41.102}$$

as well as

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{\Omega}\times\boldsymbol{x})\cdot\mathrm{d}\boldsymbol{v} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}\left[(\boldsymbol{\Omega}\times\boldsymbol{x})\cdot\boldsymbol{v}\right] - \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{\Omega}\times\mathrm{d}\boldsymbol{x})\cdot\boldsymbol{v} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} (\boldsymbol{\Omega}\times\boldsymbol{v})\cdot\mathrm{d}\boldsymbol{x}, \tag{41.103}$$

where we set

$$\oint_{\partial\mathcal{S}(\boldsymbol{v})} \mathrm{d}\left[(\boldsymbol{\Omega}\times\boldsymbol{x})\cdot\boldsymbol{v}\right] = 0 \tag{41.104}$$

since, as for equation (41.102), the closed loop integral of an exact spatial differential vanishes. We also noted that $\boldsymbol{\Omega}$ is a constant vector so that $\mathrm{d}\boldsymbol{\Omega} = 0$. Now insert the momentum equation (41.31) into equation (41.100d) to yield

$$\frac{\mathrm{d}\mathcal{C}_{\mathrm{a}}}{\mathrm{d}t} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + 2\,\boldsymbol{\Omega}\times\boldsymbol{v}\right]\cdot\mathrm{d}\boldsymbol{x}. \tag{41.105a}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[-\frac{1}{\rho}\nabla p - \nabla\Phi + \boldsymbol{F}\right]\cdot\mathrm{d}\boldsymbol{x}. \tag{41.105b}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[-\frac{\mathrm{d}p}{\rho} + \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{x}\right]. \tag{41.105c}$$

Making use of Stokes' theorem leads to the evolution of absolute circulation around a material loop

$$\frac{\mathrm{d}\mathcal{C}_{\mathrm{a}}}{\mathrm{d}t} = \oint_{\partial\mathcal{S}(\boldsymbol{v})} \left[-\frac{\mathrm{d}p}{\rho} + \boldsymbol{F}\cdot\mathrm{d}\boldsymbol{x}\right] = \int_{S(\boldsymbol{v})} (\boldsymbol{B} + \nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{41.106}$$

where $\boldsymbol{B} = \rho^{-2}\,\nabla\rho\times\nabla p$ is the baroclinicity vector from equation (41.57).

The circulation theorem (41.106) is the same as obtained for Kelvin's circulation theorem in a non-rotating reference frame as discussed in Section 41.2 (see equation (41.5e)). As such, we find that time changes to the absolute circulation are affected by the work applied by pressure and friction when integrated around the material circuit. Evidently, the formalism confirms that absolute circulation is a frame invariant property of the fluid, in which its evolution is unchanged when moving to a non-inertial rotating frame.

41.6.2 The beta effect

As given by equation (41.94), the absolute circulation around an arbitrary circuit equals to the circulation of fluid measured in the rotating frame (relative circulation) plus circulation of the rotating frame itself (planetary circulation)

$$\mathcal{C}_{\mathrm{a}} = \mathcal{C} + \mathcal{C}_{\mathrm{planet}} = \mathcal{C} + 2\int_{\mathcal{S}} \boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} \Longleftrightarrow \frac{\mathrm{d}\mathcal{C}_{\mathrm{a}}}{\mathrm{d}t} = \frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} + \frac{\mathrm{d}\mathcal{C}_{\mathrm{planet}}}{\mathrm{d}t}. \tag{41.107}$$

We can determine the processes that affect the absolute circulation around a material loop by using the circulation theorem (41.106)

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = -\frac{\mathrm{d}\mathcal{C}_{\text{planet}}}{\mathrm{d}t} + \frac{\mathrm{d}\mathcal{C}_{\text{a}}}{\mathrm{d}t} \tag{41.108a}$$

$$= -2\,\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{S}(\boldsymbol{v})} \boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}\right] + \int_{\mathcal{S}(\boldsymbol{v})} (\boldsymbol{B} + \nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{41.108b}$$

We generally assume that the planetary rotation is a constant in time and points through the north pole of the sphere[10] $\boldsymbol{\Omega} = \Omega\,\hat{\boldsymbol{Z}}$, so that

$$\int_{\mathcal{S}(\boldsymbol{v})} \boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \Omega\int_{\mathcal{S}(\boldsymbol{v})} \hat{\boldsymbol{Z}}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \Omega\,A_{\perp}. \tag{41.109}$$

The area, $A_{\perp}$, is the projection of the spherical area enclosed by the circuit onto the horizontal equatorial plane, with Figure 41.8 illustrating the geometry. This result has profound impact on large scale geophysical fluid motion, whereby relative circulation around a material circuit in the rotating frame changes according to

$$\frac{\mathrm{d}\mathcal{C}}{\mathrm{d}t} = \underbrace{-2\,\Omega\,\frac{\mathrm{d}A_{\perp}}{\mathrm{d}t}}_{\text{beta effect}} + \underbrace{\int_{\mathcal{S}} (\boldsymbol{B} + \nabla\times\boldsymbol{F})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}(\boldsymbol{v})}_{\text{baroclinicity plus friction curl}}. \tag{41.110}$$

Equation (41.110) is sometimes referred to as the *Bjerknes circulation theorem* (see *Holton* (1992) equation (4.5)). The second term, comprised of baroclinicity and friction, also appears in case of a non-rotating reference frame that we studied in Sections 41.2 and 41.4.

FIGURE 41.8: Geometry of the beta effect on a rotating sphere. According to the Bjerknes circulation theorem (41.110), the circulation for a material loop on the surface of a rotating sphere is affected by baroclinicity and friction, as for a non-rotating sphere, as well as latitudinal motion of the loop. The latitudinal motion alters the area of the loop as projected onto the equatorial plane, with the projected area increasing as the loop moves poleward. When multiplied by the magnitude of the planetary vorticity, $2\,\Omega$, the area contribution is termed *planetary induction* (i.e., relative circulation is induced by latitudinal motion), or more commonly it is called the *beta effect*. The beta effect requires both rotation ($2\,\Omega$) and curvature of the sphere ($\partial_y f = \beta$); it is therefore absent on the f-plane.

[10] We follow the notational conventions of Figure 10.1 with one exception. Here, the vertical Cartesian direction through the north pole is written $\hat{\boldsymbol{Z}}$ to avoid confusion with the local vertical direction $\hat{\boldsymbol{z}}$ determined by the geopotential.

The first term in the circulation theorem (41.110) is fundamentally new. It is nonzero in the presence of both rotation and curvature of the sphere. The spherical effect arises from latitudinal movement of a material circuit, with the area, $A_\perp$, changing under such motion. When the circuit moves poleward, the projected area $A_\perp$ increases whereas it decreases to zero as it moves equatorward. The material change in $A_\perp$, when multiplied by the planetary vorticity, modifies the relative circulation around the material circuit. We refer to *planetary induction* as the process whereby relative circulation is modified by latitudinal motion of a material circuit on a rotating sphere. Or more commonly, planetary induction is referred to as the *beta effect*, given its connection to the latitudinal gradient of the Coriolis parameter, $\beta = \partial_y f$. Notably, longitudinal motion of the circuit has no impact on $A_\perp$, so that longitudinal motion imparts no planetary induction of relative circulation.

In theories of large-scale laminar planetary flows, the baroclinicity and friction terms are typically sub-dominant. For these flows, the material evolution of relative circulation is dominated by the beta effect. Planetary geostrophic flow is the canonical example of such flow, as studied in Section 32.5 as well as Chapters 44 and 45. In such flows, forces that lead to meridional motion also give rise to changes in the relative circulation. Conversely, forces that change the circulation around a material loop affect meridional motion of the loop.

41.6.3 The case of two-dimensional non-divergent flow

To garner further insight into the nature of the beta effect, consider a perfect two-dimensional and non-divergent flow (zero vertical velocity) on a rotating sphere. In this case there is only a vertical component to vorticity and both baroclinicity and friction have no role in vorticity dynamics. Hence, vorticity is affected only via the beta effect. In addition, the fluid flow materially preserves the area of any material region. This *two-dimensional non-divergent barotropic flow* is discussed in more detail in Chapter 39. We here use it as an example to expose essential features of the beta effect (see also Section 39.2.2).

In the rotating frame, circulation around an infinitesimal closed material loop is

$$\mathcal{C} = A\,\zeta, \tag{41.111}$$

where ζ is the relative vorticity and A is the area enclosed by the loop. Because the fluid flow is non-divergent, the loop area A remains constant even as the loop becomes contorted (see Section 22.6). This area preservation property simplifies the evolution equation for the circulation, which is given by

$$\frac{\mathrm{D}\mathcal{C}}{\mathrm{D}t} = \frac{\mathrm{D}(A\,\zeta)}{\mathrm{D}t} = A\,\frac{\mathrm{D}\zeta}{\mathrm{D}t}. \tag{41.112}$$

Equating this result to the circulation change implied by Bjerknes' circulation theorem (41.110) renders

$$\frac{\mathrm{D}\mathcal{C}}{\mathrm{D}t} = A\,\frac{\mathrm{D}\zeta}{\mathrm{D}t} = -2\,\Omega\,\frac{\mathrm{D}A_\perp}{\mathrm{D}t}. \tag{41.113}$$

Let the material circuit be at a latitude, ϕ, so that the projection of the loop area onto the equatorial plane is (see Figure 41.8)

$$A_\perp = A\sin\phi. \tag{41.114}$$

Hence, material evolution of the circulation is

$$\frac{\mathrm{D}\mathcal{C}}{\mathrm{D}t} = A\,\frac{\mathrm{D}\zeta}{\mathrm{D}t} \tag{41.115a}$$

$$= -2\,\Omega\,\frac{\mathrm{D}A_\perp}{\mathrm{D}t} \tag{41.115b}$$

$$= -2\,A\,\Omega\,\frac{\mathrm{D}\sin\phi}{\mathrm{D}t} \tag{41.115c}$$

$$= -2\,A\,\Omega\,\cos\phi\,\frac{\mathrm{D}\phi}{\mathrm{D}t} \tag{41.115d}$$

$$= -A\left[\frac{2\,\Omega\,\cos\phi}{R}\right]\left[R\frac{\mathrm{D}\phi}{\mathrm{D}t}\right] \tag{41.115e}$$

$$= -A\,\beta\,v, \tag{41.115f}$$

where we introduced the meridional velocity component

$$v = R\,\frac{\mathrm{D}\phi}{\mathrm{D}t} \tag{41.116}$$

and the meridional derivative of the planetary vorticity

$$\beta = \frac{\mathrm{d}f}{\mathrm{d}y} = \frac{1}{R}\frac{\mathrm{d}}{\mathrm{d}\phi}(2\,\Omega\,\sin\phi) = \frac{2\,\Omega\,\cos\phi}{R}. \tag{41.117}$$

The result (41.115f)

$$\frac{1}{A}\,\frac{\mathrm{D}\mathcal{C}}{\mathrm{D}t} = \frac{\mathrm{D}\zeta}{\mathrm{D}t} = -\beta\,v, \tag{41.118}$$

shows how meridional motion on a rotating sphere induces relative circulation, and thus relative vorticity. It furthermore motivates the name *beta effect* for the planetary induction.

41.6.4 Planetary circulation, planetary vorticity, and the Coriolis acceleration

From equation (41.98b) we know that the planetary vorticity is given by the constant vector

$$\boldsymbol{\omega}_{\text{planet}} = \nabla\times(\boldsymbol{\Omega}\times\boldsymbol{x}) = 2\,\boldsymbol{\Omega}. \tag{41.119}$$

As a constant vector, it is the same everywhere in space. However, its impact on the fluid circulation and vorticity depends on what latitude the rotation vector is sampled. We here focus on the radial component of the planetary vorticity by measuring the circulation per area for fixed radius circuits, with reference to Figure 41.9.

Planetary circulation centered on the pole and on the equator

Equation (41.109) leads to the planetary circulation

$$\mathcal{C}_{\text{planet}} = 2\,\Omega\,A_\perp, \tag{41.120}$$

for an arbitrary constant radius circuit. Stokes' theorem then says that the planetary vorticity, as projected onto the local radial direction (outward normal to the surface), has value

$$\boldsymbol{\omega}_{\text{planet}}\cdot\hat{\boldsymbol{n}} \approx \mathcal{C}_{\text{planet}}/\mathcal{S} = 2\,\Omega\,A_\perp/\mathcal{S}, \tag{41.121}$$

where $\mathcal{S} = \int_{\mathcal{S}} \mathrm{d}\mathcal{S}$ is the area enclosed by the circuit. In the limit that the circuit becomes infinitesimal, then $A_\perp \to \mathcal{S}$ when the circuit is centered on the north pole, whereas $A_\perp \to 0$ for an equatorially centered circuit. Correspondingly, the planetary vorticity, when projected into the radial direction, is $2\,\Omega$ at the north pole (and $-2\,\Omega$ at the south pole), whereas it vanishes at the equator. We emphasize that it is not the planetary vorticity that vanishes at the equator, which is obvious since $\boldsymbol{\omega}_{\text{planet}} = 2\,\boldsymbol{\Omega}$ is a constant vector. Rather, it is the radial projection, $\boldsymbol{\omega}_{\text{planet}} \cdot \hat{\boldsymbol{r}}$, that vanishes at the equator.

FIGURE 41.9: Area mean of the planetary vorticity as computed around two closed circular loops with area $\mathcal{S}$. One circuit is centered on the north pole, in which case the area mean planetary circulation, $\mathcal{C}_{\text{planet}}/\mathcal{S} \approx 2\,\Omega$. The other circuit is centered on the equator so that $\mathcal{C}_{\text{planet}}/\mathcal{S} \approx 0$. Stokes' theorem says that the planetary vorticity, as projected onto the local radial direction (outward normal), has value $\boldsymbol{\omega}_{\text{planet}} \cdot \hat{\boldsymbol{r}} \approx \mathcal{C}_{\text{planet}}/\mathcal{S}$. Hence, the planetary vorticity equals $2\,\Omega$ at the north pole (and $-2\,\Omega$ at the south pole), whereas it vanishes at the equator.

Comments on the Coriolis acceleration

Although $\boldsymbol{\omega}_{\text{planet}} \cdot \hat{\boldsymbol{r}} = 0$ at the equator, the Coriolis acceleration does not generally vanish there. That is, recall the discussion in Section 13.9.8 where the Coriolis acceleration in spherical coordinates is written

$$\boldsymbol{A}_{\text{Coriolis}} = -2\,\Omega\left[\hat{\boldsymbol{\lambda}}\,(w\cos\phi - v\sin\phi) + \hat{\boldsymbol{\phi}}\,u\sin\phi - \hat{\boldsymbol{r}}\,u\cos\phi\right], \tag{41.122}$$

which, at $\phi = 0$, is

$$\boldsymbol{A}_{\text{Coriolis}}(\phi = 0) = -2\,\Omega\,(w\,\hat{\boldsymbol{\lambda}} - u\,\hat{\boldsymbol{r}}). \tag{41.123}$$

Evidently, a nonzero Coriolis acceleration at the equator arises since it depends on $\boldsymbol{\Omega} = \boldsymbol{\omega}_{\text{planet}}/2$ rather than just its radial projection, $\boldsymbol{\omega}_{\text{planet}} \cdot \hat{\boldsymbol{r}}$. For large-scale flows, we commonly ignore $\boldsymbol{A}_{\text{Coriolis}}(\phi = 0)$ since its radial term is tiny relative to the gravitational acceleration, and the longitudinal term is small for large-scale flows where the vertical velocity is typically small.[11] Indeed, these points were made in Section 13.9.8, whereby the Coriolis acceleration for large-scale

[11] *Stewart and Dellar* (2011) argue for the importance of the full expression of the Coriolis acceleration (41.122) for the dynamics of cross-equatorial abyssal ocean flows.

planetary flows is approximated by equation (13.101)

$$\boldsymbol{A}_{\text{Coriolis}}^{\text{large-scale}} \equiv -2\,\Omega \sin\phi\,(-\hat{\boldsymbol{\lambda}}\,v + \hat{\boldsymbol{\phi}}\,u) \equiv -f\,\hat{\boldsymbol{r}} \times \boldsymbol{v}. \tag{41.124}$$

This approximate Coriolis acceleration does vanish at the equator, and it is the form resulting from the Traditional Approximation used for the hydrostatic primitive equations in Section 28.1.3.

41.6.5 Further study

The beta effect and its role in vorticity is nicely summarized in this video from Science Primer in the context of Rossby waves.

41.7 Vorticity budget for a primitive equation Boussinesq ocean

In this section we develop the vorticity budget for a hydrostatic primitive equation Boussinesq ocean in the presence of diabatic sources and frictional forcing. This system is of particular importance for ocean circulation models. The governing primitive equations, as derived in Section 30.1.6, are given by

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{v} = -\nabla_z \varphi + \boldsymbol{F} \tag{41.125a}$$

$$\frac{\partial \varphi}{\partial z} = b \tag{41.125b}$$

$$\nabla \cdot \boldsymbol{v} = 0 \tag{41.125c}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = \dot{b}, \tag{41.125d}$$

with the non-divergent velocity field written

$$\boldsymbol{v} = (\boldsymbol{u}, w) = \boldsymbol{u} + w\,\hat{\boldsymbol{z}}. \tag{41.126}$$

The perturbation pressure is given by

$$\rho_0\,\varphi = \delta p = p - p_0, \tag{41.127}$$

with the reference pressure, $p_0 = p_0(z)$, in hydrostatic balance with the constant reference density

$$\frac{\mathrm{d}p_0}{\mathrm{d}z} = -g\,\rho_0, \tag{41.128}$$

and p the hydrostatic pressure satisfying the local hydrostatic balance

$$\frac{\partial p}{\partial z} = -g\,\rho. \tag{41.129}$$

The globally referenced Archimedean buoyancy is given by

$$b = -g\,(\rho - \rho_0)/\rho_0, \tag{41.130}$$

with this field discussed in Section 31.4.2. As mentioned at the end of Section 41.6.4, we here assume the Coriolis acceleration of the form relevant to the Traditional approximation (Section 28.1.3), in which we are only concerned with the local vertical component of planetary rotation

so that

$$f\,\hat{\boldsymbol{z}}\times\boldsymbol{v} = f\,\hat{\boldsymbol{z}}\times\boldsymbol{u}. \tag{41.131}$$

Finally, the friction acceleration vector is horizontal

$$\boldsymbol{F} = (F^x, F^y, 0) \tag{41.132}$$

and the gradient operator is decomposed into its horizontal plus vertical contribution.

$$\nabla = \nabla_z + \hat{\boldsymbol{z}}\,\partial_z. \tag{41.133}$$

41.7.1 Deriving the vorticity equation

Vector invariant velocity equation

To derive the vorticity equation, it is useful to combine the horizontal momentum equation with the hydrostatic balance, in which case

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{v} = -\nabla\varphi + b\,\hat{\boldsymbol{z}} + \boldsymbol{F}. \tag{41.134}$$

As for the non-hydrostatic case (Section 41.3.1), we rewrite the self-advection operator, $(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{u}$, before taking the curl. In turn, we introduce the hydrostatic relative vorticity given by the curl of the horizontal velocity

$$\boldsymbol{\omega}^{\mathrm{hy}} = \nabla\times\boldsymbol{u} = \hat{\boldsymbol{z}}\times\partial_z\boldsymbol{u} + \hat{\boldsymbol{z}}\,\zeta = -\hat{\boldsymbol{x}}\,\partial_z v + \hat{\boldsymbol{y}}\,\partial_z u + \hat{\boldsymbol{z}}\,\zeta, \tag{41.135}$$

where

$$\zeta = \partial_x v - \partial_y u \tag{41.136}$$

is the vertical component to the relative vorticity, and the hydrostatic vorticity is non-divergent

$$\nabla\cdot\boldsymbol{\omega}^{\mathrm{hy}} = 0. \tag{41.137}$$

It is then straightforward to show that

$$\boldsymbol{\omega}^{\mathrm{hy}}\times\boldsymbol{v} = \hat{\boldsymbol{x}}\,(w\,\partial_z u - v\,\partial_x v + v\,\partial_y u) + \hat{\boldsymbol{y}}\,(w\,\partial_z v - u\,\partial_y u + u\,\partial_x v) - \hat{\boldsymbol{z}}\,\partial_z(u^2+v^2)/2 \tag{41.138a}$$

$$= w\,\partial_z\boldsymbol{u} + \zeta\,(-v\,\hat{\boldsymbol{x}} + u\,\hat{\boldsymbol{y}}) - \hat{\boldsymbol{z}}\,\partial_z(u^2+v^2)/2, \tag{41.138b}$$

in which case

$$\nabla(\boldsymbol{u}^2/2) + \boldsymbol{\omega}^{\mathrm{hy}}\times\boldsymbol{v} = \nabla\,(u^2+v^2)/2 - \hat{\boldsymbol{z}}\,\partial_z\,(u^2+v^2)/2 + w\,\partial_z\boldsymbol{u} + \zeta\,(-v\,\hat{\boldsymbol{x}} + u\,\hat{\boldsymbol{y}}) \tag{41.139a}$$

$$= (u\,\partial_x + v\,\partial_y + w\,\partial_z)\,\boldsymbol{u} \tag{41.139b}$$

$$= (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{u}. \tag{41.139c}$$

The material time derivative of the horizontal velocity can thus be written

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} = \frac{\partial\boldsymbol{u}}{\partial t} + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{u} = \frac{\partial\boldsymbol{u}}{\partial t} + \boldsymbol{\omega}^{\mathrm{hy}}\times\boldsymbol{v} + \nabla(\boldsymbol{u}^2/2), \tag{41.140}$$

which then leads to the vector invariant horizontal velocity equation

$$\partial_t\boldsymbol{u} + (f\,\hat{\boldsymbol{z}} + \boldsymbol{\omega}^{\mathrm{hy}})\times\boldsymbol{v} = -\nabla(\varphi + \boldsymbol{u}^2/2) + b\,\hat{\boldsymbol{z}} + \boldsymbol{F}, \tag{41.141}$$

which can be written in the equivalent form[12]

$$(\partial_t + w\,\partial_z)\,\boldsymbol{u} + (f+\zeta)\,\hat{\boldsymbol{z}}\,\times\boldsymbol{u} = -\nabla_z\,(\varphi + \boldsymbol{u}^2/2) - (\partial_z\varphi - b)\,\hat{\boldsymbol{z}} + \boldsymbol{F}. \tag{41.142}$$

Curl of the velocity equation to render the vorticity equation

Now take the curl of the vector invariant velocity equation (41.141), and make use of the identity

$$\nabla\times(\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}\times\boldsymbol{v}) = (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} - (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}\cdot\nabla)\,\boldsymbol{v}, \tag{41.143}$$

where we introduced the absolute vorticity for a hydrostatic fluid

$$\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = f\,\hat{\boldsymbol{z}} + \boldsymbol{\omega}^{\mathrm{hy}}. \tag{41.144}$$

The result is the vorticity equation

$$\partial_t\boldsymbol{\omega}^{\mathrm{hy}} + (\boldsymbol{v}\cdot\nabla)\,\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}\cdot\nabla)\,\boldsymbol{v} + \nabla\times\hat{\boldsymbol{z}}\,b + \nabla\times\boldsymbol{F}. \tag{41.145}$$

Since the Coriolis parameter is time independent, we can add it to the time derivative to yield and equation for absolute vorticity

$$\frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}}{\mathrm{D}t} = \underbrace{(\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}\cdot\nabla)\,\boldsymbol{v}}_{\text{stretching + tilting}} + \underbrace{\nabla\times\hat{\boldsymbol{z}}\,b}_{\text{baroclinicity}} + \underbrace{\nabla\times\boldsymbol{F}}_{\text{friction curl}}. \tag{41.146}$$

It is notable that the pressure gradient is eliminated from the Boussinesq vorticity equation. Even so, the vorticity is affected by baroclinicity as manifested through horizontal gradients in the buoyancy field, which we discuss next.

41.7.2 Boussinesq baroclinicity

Let us compare the Boussinesq vorticity equation (41.146) to the vorticity equation (41.42) for a non-hydrostatic and non-Boussinesq fluid. One difference concerns the form of the vorticity, which differs due to the use of only the horizontal velocity, $\boldsymbol{\omega}^{\mathrm{hy}} = \nabla\times\boldsymbol{u}$, for the hydrostatic fluid whereas the full velocity is used for the non-hydrostatic case, $\boldsymbol{\omega} = \nabla\times\boldsymbol{v}$. Even so, both vorticity equations have a vorticity source due to stretching and tilting, and both have a source due to the curl of friction. The key difference arises in the form of the baroclinicity vector. Namely, the Boussinesq baroclinicity does not involve the Boussinesq pressure gradient acceleration since it has zero curl. Instead, Boussinesq baroclinicity is given by[13]

$$\boldsymbol{B}_{\mathrm{bouss}} = \nabla\times\hat{\boldsymbol{z}}\,b = \nabla b\times\hat{\boldsymbol{z}}. \tag{41.147}$$

Boussinesq baroclinicity has a somewhat simpler form than baroclinicity in a compressible fluid, as given by equation (41.57)

$$\boldsymbol{B} = (\nabla\rho\times\nabla p)/\rho^2 = -\nabla\times(\rho^{-1}\,\nabla p). \tag{41.148}$$

Again, the fundamental difference arises since the Boussinesq pressure gradient acceleration is annihilated when taking the curl of the velocity equation to produce the Boussinesq vorticity

[12] As discussed in *Griffies et al.* (2020), the form (41.142) is commonly used for Boussinesq and hydrostatic ocean models.

[13] We see in Exercise 42.2 that the baroclinicity vector (41.147) also applies for the non-hydrostatic Boussinesq ocean.

equation. So rather than arise from the misalignment of pressure and density isolines, Boussinesq baroclinicity arises from the misalignment of the gravity field and density gradients.

One practical feature of the Boussinesq baroclinicity (41.147) is that we can readily deduce the presence of baroclinicity (either for the non-hydrostatic or hydrostatic Boussinesq ocean) merely by noting whether there is a slope to the buoyancy surfaces relative to the horizontal (e.g., Figure 41.10). That is, a sloping buoyancy surface provides a vorticity source for the Boussinesq ocean.

Boussinesq baroclinicity only affects a horizontal vorticity tendency

Given that the Boussinesq baroclinicity (41.147) does not involve the pressure gradient acceleration, we must modify the physical interpretation offered in Section 41.4. In particular, the curl of the non-Boussinesq pressure acceleration has components in all three directions so that the non-Boussinesq baroclinicity affects a source for each of the three vorticity components. In contrast, the Boussinesq baroclinicity is the curl of the Archimedean buoyant acceleration and this acceleration acts only in the vertical. Consequently, the Boussinesq baroclinicity has no direct affect on the vertical component to absolute vorticity

$$\hat{\boldsymbol{z}} \cdot \boldsymbol{B}_{\text{bouss}} = \hat{\boldsymbol{z}} \cdot (\nabla \times \hat{\boldsymbol{z}}\, b) = 0. \tag{41.149}$$

Rather, Boussinesq baroclinicity only acts directly as a source for horizontal vorticity. Thus, Boussinesq baroclinicity can only indirectly affect vertical vorticity through the effects of baroclinicity on vertical velocity and the corresponding vertical stretching.

FIGURE 41.10: Baroclinicity in a Boussinesq ocean is manifest by nonzero horizontal gradients in the buoyancy field. Here we depict a region of relatively strong baroclinicity above a region of weaker baroclinicity. A sloping buoyancy surface is therefore synonymous with a nontrivial baroclinic structure. We label anomalously positive ($b' > 0$) and negative buoyancy ($b' < 0$), where the prime denotes anomalies relative to a horizontal average. Furthermore, as per equation (41.149), baroclinicity in a Boussinesq ocean only acts as a source for horizontal vorticity.

Comments on shallow water vorticity

In Chapter 40, we studied vorticity in the shallow water fluid. As noted in Section 40.3.3, we are only concerned with the vertical component to vorticity in the shallow water fluid, since the horizontal components are tiny by comparison. Furthermore, equation (40.28) says that the vertical component to shallow water absolute vorticity is materially altered only through material changes to the layer thickness. There is no impact from baroclinicity on the shallow water vorticity. The absence of baroclinicity follows trivially from the absence of any horizontal

buoyancy gradients within the shallow water layer. In this manner, the shallow water layer is barotropic.

41.7.3 Vertical vorticity equation

Following the discussion in Section 41.3.4 for the unapproximated vorticity, we here examine the vertical component of the hydrostatic and Boussinesq vorticity equation (41.146)

$$\frac{\mathrm{D}\zeta_{\mathrm{a}}}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla)\, w + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}), \tag{41.150}$$

with the absence of baroclinicity noted above in Section 41.7.2. The stretching, tilting, and friction curl appearing on the right hand side provide vorticity sources that affect the left hand side's material time evolution. We see this evolution more fully by expanding the terms to render

$$\partial_t \zeta_{\mathrm{a}} + (\boldsymbol{v} \cdot \nabla)\, \zeta + \beta\, v = \hat{\boldsymbol{z}} \cdot (\partial_z \boldsymbol{u} \times \nabla_z w) + (\zeta + f)\, \partial_z w + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}). \tag{41.151}$$

Planetary geostrophic limit

The linearized, inviscid, and steady version of the vorticity equation (41.151) leads to the linear vorticity balance studied in Section 32.5.4 and Chapter 45

$$\beta\, v = f\, \partial_z w. \tag{41.152}$$

This relation comprises the inviscid vorticity equation for the planetary geostrophic equations. It represents a kinematic balance since no forces are exposed here to explicitly cause motion, though such forces do appear in the momentum equation. Reading the balance from right to left indicates that any process generating vorticity via vortex stretching must be balanced by meridional motion. That is, the fluid responds to vortex stretching by moving meridionally through the planet's vorticity field. Since the vorticity of a planetary geostrophic fluid is solely determined by planetary vorticity, meridional movement is the only means for the fluid to balance vortex sources. Conversely, reading the equality from left to right reveals that any meridional motion itself must be balanced by vortex stretching.

Vorticity flux vector

We can write the vorticity equation (41.151) in an alternative form by making use of $\nabla \cdot \boldsymbol{v} = \nabla \cdot \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = 0$ to yield

$$\partial_t \zeta_{\mathrm{a}} = -\nabla \cdot (\boldsymbol{v}\, \zeta_{\mathrm{a}} - w\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}) + \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}). \tag{41.153}$$

Furthermore, we can write the friction curl in the form

$$\begin{aligned}
\hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{F}) &= \nabla z \cdot (\nabla \times \boldsymbol{F}) && (41.154\mathrm{a})\\
&= \nabla \cdot [z\, \nabla \times \boldsymbol{F}] && (41.154\mathrm{b})\\
&= \nabla \cdot [\nabla \times (z\, \boldsymbol{F}) - \nabla z \times \boldsymbol{F}] && (41.154\mathrm{c})\\
&= -\nabla \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{F}). && (41.154\mathrm{d})
\end{aligned}$$

Hence, the vertical component of the Boussinesq vorticity evolves according to the convergence of the vorticity flux

$$\partial_t \zeta_{\mathrm{a}} = -\nabla \cdot \boldsymbol{J}_{\zeta} \qquad \text{with} \qquad \boldsymbol{J}_{\zeta} = \boldsymbol{v}\, \zeta_{\mathrm{a}} - w\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \hat{\boldsymbol{z}} \times \boldsymbol{F}, \tag{41.155}$$

which can be compared to the vorticity flux (41.45) for the compressible nonhydrostatic fluid. Again, the main difference arises from the absence of a baroclinicity contribution for the hydrostatic Boussinesq ocean.

The identity $\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{u} + \hat{\boldsymbol{z}}\, \zeta_{\mathrm{a}}$ allows us to write

$$\boldsymbol{v}\, \zeta_{\mathrm{a}} - w\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = \boldsymbol{u}\, \zeta_{\mathrm{a}} - w\, \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{u}, \tag{41.156}$$

which is a horizontal vector. Furthermore, note that $\hat{\boldsymbol{z}} \times \boldsymbol{F}$ is a horizontal vector, which then means that there is no vertical contribution to the vorticity flux vector, $\boldsymbol{J}_\zeta \cdot \hat{\boldsymbol{z}} = 0$. We previously encountered this property in Section 41.3.4 when discussing the vorticity flux for the non-Boussinesq fluid, with Figure 41.1 providing a schematic.

41.8 Evolution of depth integrated vertical vorticity

In this section we study the depth integral of the vertical vorticity equation (41.45)

$$\partial_t \zeta_{\mathrm{a}} = -\nabla \cdot \boldsymbol{J}_\zeta \quad \text{with} \quad \boldsymbol{J}_\zeta = \boldsymbol{v}\, \zeta_{\mathrm{a}} - \boldsymbol{\omega}_{\mathrm{a}}\, w - \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{z}} \times \boldsymbol{F}. \tag{41.157}$$

We perform the depth integral over the full depth of the ocean from its bottom at $z = \eta_{\mathrm{b}}(x, y)$ to the ocean surface at $z = \eta(x, y, t)$ (see Figure 36.1). Studies of the depth integrated vorticity equation allow us to focus on the two dimensional budgets with particular attention to how boundary torques alter the budget. This section anticipates analysis of the depth integrated planetary geostrophic vorticity equation in Section 45.4, with that analysis of use for understanding the role of topography in forcing the large-scale ocean circulation. We also consider the vorticity of the depth integrated flow in Section 41.9, which is commonly considered in numerical applications. Notably, the discussion in the present section does not assume pressure is approximatly hydrostatic, so that all results hold for the general case of a non-hydrostatic flow.

41.8.1 Comments on the role of baroclinicity

Results of the analysis in this section can be readily specialized to the Boussinesq and hydrostatic case given by equation (41.155). The key distinction, as noted in Section 41.7.2, is that Boussinesq baroclinicity does not directly affect changes to the vertical component of the Boussinesq vorticity (whether hydrostatic or non-hydrostatic; see Exercise 42.2). This property of the Boussinesq baroclinicity means that the boundary pressure torques discussed in Sections 41.8.3 and 41.8.4 play no direct role in the Boussinesq vorticity equation. However, these boundary pressure torques play a direct role in vertical motion next to the boundaries, especially next to the bottom, with such motion affecting a source to vorticity through stretching. We have much to say in Section 45.4 concerning how boundary pressure torques affect vertical motion for vorticity for the planetary geostrophic fluid. Additionally, as seen in Section 41.9, boundary pressure torques do play a direct role in affecting vorticity of the depth integrated flow in both the Boussinesq and non-Boussinesq fluids.

This discussion exemplifies the sometimes subtle differences between vorticity sources depending on the precise nature of the vorticity, whether it be vorticity for a fluid element as discussed in this section, vorticity of the depth integrated flow in Section 41.9, or vorticity of the depth averaged flow in Section 41.9.7. When studying flavors of vorticity, it is important to be clear on details of their evolution equations since the details color the physical interpretations.

41.8.2 Leibniz rule expressions

The necessary manipulations are typical for the analysis of depth integrated budgets, such as considered for the depth integrated momentum in Section 29.4 and depth integrated angular momentum in Section 29.5. For vorticity we are interested in manipulating following equation

$$\int_{\eta_\mathrm{b}}^{\eta} \frac{\partial \zeta_\mathrm{a}}{\partial t}\,\mathrm{d}z = -\int_{\eta_\mathrm{b}}^{\eta} \nabla\cdot\boldsymbol{J}_\zeta\,\mathrm{d}z, \tag{41.158}$$

where $\boldsymbol{J}_\zeta$ is the vorticity flux given by equation (41.157). We make use of Leibniz's rule (Section 21.2.4) to move the time and space derivatives from inside the integrals to outside[14]

$$\int_{\eta_\mathrm{b}}^{\eta} \frac{\partial \zeta_\mathrm{a}}{\partial t}\,\mathrm{d}z = -[\zeta_\mathrm{a}\,\partial_t\eta]_{z=\eta} + \frac{\partial}{\partial t}\int_{\eta_\mathrm{b}}^{\eta}\zeta_\mathrm{a}\,\mathrm{d}z \tag{41.159}$$

$$-\int_{\eta_\mathrm{b}}^{\eta}\nabla_z\cdot\boldsymbol{J}_\zeta\,\mathrm{d}z = [\nabla_z\eta\cdot\boldsymbol{J}_\zeta]_{z=\eta} - [\nabla_z\eta_\mathrm{b}\cdot\boldsymbol{J}_\zeta]_{z=\eta_\mathrm{b}} - \nabla_z\cdot\int_{\eta_\mathrm{b}}^{\eta}\boldsymbol{J}_\zeta\,\mathrm{d}z \tag{41.160}$$

$$-\int_{\eta_\mathrm{b}}^{\eta}\frac{\partial(\hat{\boldsymbol{z}}\cdot\boldsymbol{J}_\zeta)}{\partial z}\,\mathrm{d}z = -[\hat{\boldsymbol{z}}\cdot\boldsymbol{J}_\zeta]_{z=\eta} + [\hat{\boldsymbol{z}}\cdot\boldsymbol{J}_\zeta]_{z=\eta_\mathrm{b}}. \tag{41.161}$$

These results then lead to

$$\frac{\partial}{\partial t}\int_{\eta_\mathrm{b}}^{\eta}\zeta_\mathrm{a}\,\mathrm{d}z = [\zeta_\mathrm{a}\,\partial_t\eta - \nabla(z-\eta)\cdot\boldsymbol{J}_\zeta]_{z=\eta} + [\nabla(z-\eta_\mathrm{b})\cdot\boldsymbol{J}_\zeta]_{z=\eta_\mathrm{b}} - \nabla_z\cdot\int_{\eta_\mathrm{b}}^{\eta}\boldsymbol{J}_\zeta\,\mathrm{d}z. \tag{41.162}$$

The time tendency for the depth integral of the vertical component of absolute vorticity, for a fluid column at a fixed horizontal position (left hand side) is determined by a suite of boundary contributions due to baroclinicity, vortex stretching and friction, plus the convergence of the depth integrated vorticity flux (final term on right hand side). We next massage the boundary contributions to expose their associated physical processes.

41.8.3 Bottom boundary contribution

The bottom boundary contribution to the vorticity equation (41.162) takes on the form

$$\nabla(z-\eta_\mathrm{b})\cdot\boldsymbol{J}_\zeta = \nabla(z-\eta_\mathrm{b})\cdot\left[\boldsymbol{v}\,\zeta_\mathrm{a} - \boldsymbol{\omega}_\mathrm{a}\,w - \hat{\boldsymbol{z}}\times\rho^{-1}\nabla p + \hat{\boldsymbol{z}}\times\boldsymbol{F}\right]_{z=\eta_\mathrm{b}} \tag{41.163a}$$

$$= -|\nabla(z-\eta_\mathrm{b})|\,\hat{\boldsymbol{n}}\cdot\left[-\boldsymbol{\omega}_\mathrm{a}\,w - \hat{\boldsymbol{z}}\times\rho^{-1}\nabla p + \hat{\boldsymbol{z}}\times\boldsymbol{F}\right]_{z=\eta_\mathrm{b}}, \tag{41.163b}$$

where we made use of the no-normal flow bottom kinematic boundary condition, $\hat{\boldsymbol{n}}\cdot\boldsymbol{v}=0$ (Section 20.4.1), and where

$$\hat{\boldsymbol{n}} = -\left[\frac{\nabla(z-\eta_\mathrm{b})}{|\nabla(z-\eta_\mathrm{b})|}\right] = -\left[\frac{\hat{\boldsymbol{z}}-\nabla_z\eta_\mathrm{b}}{\sqrt{1+\nabla_z\eta_\mathrm{b}\cdot\nabla_z\eta_\mathrm{b}}}\right] \tag{41.164}$$

is the outward unit normal at the bottom.

Vortex stretching by vertical flow along a sloping bottom

The first term in the bottom boundary flux (41.163b) provides an inviscid vertical transport of the normal component of the absolute vorticity at the boundary. This term contributes through the action of vertical motion next to a sloping bottom, thus providing a vertical transfer of the vorticity component that is perpendicular to the bottom. This motion provides a form of vortex

[14] Recall that since $\eta(x,y,t)$ is a spatial function just of the horizontal position, there is no difference between $\nabla\eta$ and $\nabla_z\eta$. The same point holds for $\eta_\mathrm{b}(x,y)$ as well.

stretching that vanishes for a flat bottom, in which case $w(\eta_\mathrm{b}) = 0$. It also vanishes for flow that parallels the bottom, whereby $\boldsymbol{u} \cdot \nabla \eta_\mathrm{b} = 0$ so that $w(\eta_\mathrm{b}) = 0$ according to the bottom kinematic boundary condition (20.41).

Bottom pressure torques

The second term in the bottom boundary flux (41.163b) arises from baroclinicity next to the bottom, in which case we consider the following term

$$\hat{\boldsymbol{n}} \cdot [\hat{\boldsymbol{z}} \times (\rho^{-1} \nabla p)]_{z=\eta_\mathrm{b}} = [\rho^{-1} \nabla p]_{z=\eta_\mathrm{b}} \cdot (\hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}) \equiv [\rho^{-1} \nabla p]_{z=\eta_\mathrm{b}} \cdot \boldsymbol{t}, \tag{41.165}$$

where we introduced the tangent direction

$$\boldsymbol{t} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}} = \left[\frac{\nabla \eta_\mathrm{b} \times \hat{\boldsymbol{z}}}{|\nabla(z - \eta_\mathrm{b})|} \right]. \tag{41.166}$$

The vector $\boldsymbol{t}$ is horizontal and it points along isolines of constant topography in a direction with land to the left pointing in the direction of $\boldsymbol{t}$, as depicted in Figure 41.11. Since $\hat{\boldsymbol{z}}$ and $\hat{\boldsymbol{n}}$ are not orthogonal, $\boldsymbol{t}$ is not normalized so that it is not adorned with a hat.

Let us decompose the pressure gradient at the bottom according to

$$\nabla p = \hat{\boldsymbol{n}} \, (\hat{\boldsymbol{n}} \cdot \nabla p) + \hat{\boldsymbol{t}} \, (\hat{\boldsymbol{t}} \cdot \nabla p) \qquad z = \eta_\mathrm{b}, \tag{41.167}$$

where $\hat{\boldsymbol{t}} = \boldsymbol{t}/|\boldsymbol{t}|$ is the normalized horizontal tangent vector. Evidently, for the boundary condition (41.165) we only need the $\hat{\boldsymbol{t}} \, (\hat{\boldsymbol{t}} \cdot \nabla p)$ term. But that term is simply the gradient of the bottom pressure[15]

$$\hat{\boldsymbol{t}} \, (\hat{\boldsymbol{t}} \cdot \nabla p) = \nabla p_\mathrm{b}. \tag{41.168}$$

We can provide a bit more thorough derivation of this result by using the methods of generalized vertical coordinates from Section 59.12, whereby

$$\nabla p = (\hat{\boldsymbol{z}} - \nabla_\sigma z) \, \partial_z p + \nabla_\sigma p, \tag{41.169}$$

where σ is an arbitrary generalized vertical coordinate. Evaluating the pressure gradient (41.169) at the ocean bottom ($z = \eta_\mathrm{b}$), and letting σ align with the bottom, leads to

$$[\nabla p]_{z=\eta_\mathrm{b}} = (\hat{\boldsymbol{z}} - \nabla \eta_\mathrm{b}) \, \partial_z p + \nabla p_\mathrm{b}. \tag{41.170}$$

As before, we conclude that ∇p_b is the horizontal component of $[\nabla p]_{z=\eta_\mathrm{b}}$ in the direction tangent to the bottom.

We thus find the contribution from baroclinicity at the ocean bottom takes the form

$$\nabla(z - \eta_\mathrm{b}) \cdot \boldsymbol{J}_\zeta^{\mathrm{baroclinicity}} = \rho^{-1} \nabla p_\mathrm{b} \cdot (\nabla \eta_\mathrm{b} \times \hat{\boldsymbol{z}}) = \rho^{-1} \hat{\boldsymbol{z}} \cdot [\nabla p_\mathrm{b} \times \nabla \eta_\mathrm{b}] = \rho^{-1} \hat{\boldsymbol{z}} \cdot [\nabla \times (p_\mathrm{b} \nabla \eta_\mathrm{b})]. \tag{41.171}$$

Evidently, the contribution from baroclinicity next to the bottom arises from the bottom pressure torque due to bottom pressure isolines that are not parallel to bottom topography isolines. We have more to say concerning boundary pressure torques in Section 41.9.3 as they also affect vorticity of the depth integrated flow.

[15] The result (41.168) accords with our discussion of approximate hydrostatic pressure in Section 28.3.3.

FIGURE 41.11: Orientation of the unit vectors next to the bottom of the fluid. The vertical unit vector, $\hat{\boldsymbol{z}}$, points vertically upward and the outward unit vector, $\hat{\boldsymbol{n}}$, points downward into the rock (shaded gray). The along-topography horizontal vector, $\boldsymbol{t} = \hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}$, points along lines of constant topography with land to the left when facing in the direction of $\boldsymbol{t}$; in this figure it points out from the page. The vector $\boldsymbol{t}$ is not necessarily a unit vector since it is not orthogonal to $\hat{\boldsymbol{n}}$.

Torques from bottom friction

The third term in the boundary flux (41.163b) is the contribution from friction along the bottom

$$-\hat{\boldsymbol{n}} \cdot (\hat{\boldsymbol{z}} \times \boldsymbol{F}) = -\boldsymbol{F} \cdot (\hat{\boldsymbol{n}} \times \hat{\boldsymbol{z}}) \equiv -\boldsymbol{F} \cdot \boldsymbol{t}. \tag{41.172}$$

Hence, contributions to the vertical vorticity evolution arise from the component of friction that projects onto the direction that parallels isobaths. To further our understanding of this result, consider a bottom friction written as a Rayleigh drag (e.g., Section 34.2.3) so that $\boldsymbol{F} = -\gamma\, \boldsymbol{u}$ and

$$-\boldsymbol{F} \cdot \boldsymbol{t} = \gamma\, \boldsymbol{u} \cdot \boldsymbol{t}, \tag{41.173}$$

with γ an inverse time scale. If the flow is oriented with shallow water to the right; e.g., into the page in Figure 41.11, then $-\boldsymbol{F} \cdot \boldsymbol{t} < 0$, thus contributing a negative vorticity tendency. In general, the bottom friction acts to damp the depth integrated vorticity, which is expected since bottom friction does not spontaneously spin-up the flow.

41.8.4 Surface boundary contribution

The surface boundary contribution to the vorticity equation (41.162) takes on a similar form to the bottom, with the new feature that the free surface is both moving and permeable (Section 20.4.3). This boundary term is given by

$$\zeta_{\mathrm{a}}\, \partial_t \eta - \nabla(z-\eta) \cdot \boldsymbol{J}_\zeta = \zeta_{\mathrm{a}}\, \partial_t \eta - \nabla(z-\eta) \cdot \left[\boldsymbol{v}\, \zeta_{\mathrm{a}} - w\, \boldsymbol{\omega}_{\mathrm{a}} - \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p + \hat{\boldsymbol{z}} \times \boldsymbol{F}\right]_{z=\eta} \tag{41.174a}$$

$$= \zeta_{\mathrm{a}} \left[\partial_t \eta + \boldsymbol{u} \cdot \nabla_z \eta - w\right]_{z=\eta} + \nabla(z-\eta) \cdot \left[w\, \boldsymbol{\omega}_{\mathrm{a}} + \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p - \hat{\boldsymbol{z}} \times \boldsymbol{F}\right]_{z=\eta} \tag{41.174b}$$

$$= \zeta_{\mathrm{a}}\, Q_{\mathrm{m}}/\rho + |\nabla(z-\eta)|\, \hat{\boldsymbol{n}} \cdot \left[w\, \boldsymbol{\omega}_{\mathrm{a}} + \hat{\boldsymbol{z}} \times \rho^{-1}\, \nabla p - \hat{\boldsymbol{z}} \times \boldsymbol{F}\right]_{z=\eta}, \tag{41.174c}$$

where we made use of the surface kinematic boundary condition (20.79) to introduce the surface mass flux Q_{m}, and where

$$\hat{\boldsymbol{n}} = \frac{\nabla(z-\eta)}{|\nabla(z-\eta)|} = \frac{\nabla_z \eta + \hat{\boldsymbol{z}}}{\sqrt{1 + \nabla_z \eta \cdot \nabla_z \eta}} \tag{41.175}$$

is the outward unit normal at the surface. The first term in the surface boundary flux (41.174c) provides transport of boundary vorticity due to the transfer of mass across the boundary. The second term provides an inviscid vertical transport of absolute vorticity at the surface bound-

ary, thus acting as a vortex stretching contribution. The third term provides a torque due to misalignments between the applied pressure isobars and the free surface isolines

$$|\nabla(z-\eta)|\,\hat{\boldsymbol{n}}\cdot(\hat{\boldsymbol{z}}\times\rho^{-1}\,\nabla p_{\mathrm{a}}) = \rho^{-1}\,\nabla p_{\mathrm{a}}\cdot(\nabla\eta\times\hat{\boldsymbol{z}}) = \rho^{-1}\,\hat{\boldsymbol{z}}\cdot(\nabla p_{\mathrm{a}}\times\nabla\eta) = \rho^{-1}\,\hat{\boldsymbol{z}}\cdot[\nabla\times(p_{\mathrm{a}}\nabla\eta)], \quad (41.176)$$

where the density, ρ, is evaluated at the ocean surface. Note that we made use of the same kinematics as for the bottom, thus allowing us to write

$$\hat{\boldsymbol{n}}\cdot[\hat{\boldsymbol{z}}\times\rho^{-1}\,\nabla p]_{z=\eta} = \hat{\boldsymbol{n}}\cdot(\hat{\boldsymbol{z}}\times\rho^{-1}\,\nabla p_{\mathrm{a}}), \quad (41.177)$$

which is directly analogous to the bottom pressure equation (41.169). The fourth term in equation (41.174c) provides the corresponding contribution from the friction along the upper surface, with friction acting to reduce the magnitude of the surface boundary vorticity. For a rigid lid surface, $w(0) = 0$, $\eta = 0$, and $Q_{\mathrm{m}} = 0$ so that the only surface boundary contribution arises from friction.

41.8.5 Comments

The depth integrated vorticity budget as derived in this section is perhaps the most physically straightforward of the suite of depth integrated vorticity budgets. However, in the practice of ocean modeling, this budget is generally not used since it requires an online coding of the vorticity equation and then its depth integral. As ocean models generally time step the velocity rather than the vorticity, it is common to form a vorticity budget based on the depth integrated flow or the depth averaged flow. We develop these budgets in the following section.

41.9 Vorticity for depth integrated hydrostatic flow

In this section we develop dynamical equations for vorticity of the depth integrated flow in a hydrostatic primitive equation fluid. A compelling application of these ideas comes from the study of large-scale ocean circulation. The leading order impacts from bottom pressure torques has emerged from research during recent decades, thus pointing to the fundamental role of bottom topography and flows next to sloping bottom (rather than vertical sidewalls) in affecting the ocean circulation. This recognition contrasts to traditional theories whereby the wind stress curl balances meridional motion through the beta effect. In particular, numerical model studies reveal that wind stress curl is sub-dominant in any region with nontrivial bottom velocities.[16] In this section we introduce the basics and provide more discussion in Sections 45.6 and 45.7 when studying vorticity dynamics for the planetary geostrophic system.

41.9.1 Comparing the two vorticities

In Section 41.8 we derived the evolution equation for the depth integral of the vertical component to the absolute vorticity,

$$\int_{\eta_{\mathrm{b}}}^{\eta} \zeta_{\mathrm{a}}\,\mathrm{d}z = \int_{\eta_{\mathrm{b}}}^{\eta} (f + \hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{u})\,\mathrm{d}z. \quad (41.178)$$

[16]The natural ocean has no distinction between side and bottom. Rather, as discussed in Figure 29.6, the ocean has a sloping bottom that reaches to the surface along its boundary at the "beach." *Hallberg and Rhines* (1996), *Hughes and de Cueves* (2001), and many subsequent studies emphasize that theoretical and numerical models using vertical sides and a flat bottom exhibit somewhat unnatural dynamical balances, whereas models with sloping bottoms better capture effects from topography consistent with the theory presented in this chapter.

In this section we study the evolution equation for the relative vorticity in the depth integrated horizontal flow

$$\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{U}^{\rho} = \hat{\boldsymbol{z}} \cdot \nabla \times \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u}\, \rho \, \mathrm{d}z, \tag{41.179}$$

where we introduced the depth integrated horizontal mass flux

$$\boldsymbol{U}^{\rho} = \int_{\eta_{\mathrm{b}}}^{\eta} \rho\, \boldsymbol{u}\, \mathrm{d}z. \tag{41.180}$$

For a Boussinesq ocean we set the density to a constant, in which case the difference between the two relative vorticities is[17]

$$\hat{\boldsymbol{z}} \cdot \nabla \times \left[\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u}\, \mathrm{d}z \right] - \int_{\eta_{\mathrm{b}}}^{\eta} \hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{u}\, \mathrm{d}z = \hat{\boldsymbol{z}} \cdot \left[\nabla \eta \times \boldsymbol{u}(\eta) - \nabla \eta_{\mathrm{b}} \times \boldsymbol{u}(\eta_{\mathrm{b}}) \right]. \tag{41.181}$$

Flows along boundaries generally have a nontrivial projection in the direction parallel to boundary isosurfaces, in which case the cross products are nonzero thus leading to differences in the two relative vorticities.

41.9.2 Evolution of vorticity for the depth integrated horizontal flow

In Section 29.4 we developed the horizontal momentum equation for a hydrostatic fluid, as given by equation (29.50)

$$(\partial_t + f\, \hat{\boldsymbol{z}} \times)\, \boldsymbol{U}^{\rho} = \boldsymbol{u}(\eta)\, Q_{\mathrm{m}} - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} - \nabla_z \mathscr{P} + \boldsymbol{D} + \nabla_z \cdot \left[\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}^{\mathrm{kinetic}}_{\mathrm{hor}}\, \mathrm{d}z \right]. \tag{41.182}$$

We here introduced the potential energy per horizontal area of the fluid column (equation (29.41)), the depth integrated horizontal friction (equation (29.51)), and the divergence of the horizontal kinetic stress tensor (equation (29.33))

$$\mathscr{P} = \int_{\eta_{\mathrm{b}}}^{\eta} g\, \rho\, z\, \mathrm{d}z \quad \text{and} \quad \boldsymbol{D} = \int_{\eta_{\mathrm{b}}}^{\eta} \rho\, \boldsymbol{F}_{\mathrm{horz}}\, \mathrm{d}z \quad \text{and} \quad \mathbb{T}^{\mathrm{kinetic}}_{\mathrm{hor}} = -\rho\, \boldsymbol{u} \otimes \boldsymbol{u}. \tag{41.183}$$

All terms on the right hand side of equation (41.182) provide a stress that drives changes in $\boldsymbol{U}^{\rho}$. Hence, the curl of these terms provides a torque, in which case we have

$$\begin{aligned} \hat{\boldsymbol{z}} \cdot \partial_t (\nabla \times \boldsymbol{U}^{\rho}) &= -\nabla \cdot (f\, \boldsymbol{U}^{\rho}) \\ &\quad + \hat{\boldsymbol{z}} \cdot \nabla \times \left[\boldsymbol{u}(\eta)\, Q_{\mathrm{m}} - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \Delta \boldsymbol{\tau} + \boldsymbol{D} + \nabla_z \cdot \left(\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}^{\mathrm{kinetic}}_{\mathrm{hor}}\, \mathrm{d}z \right) \right], \end{aligned} \tag{41.184}$$

where we used the vector identity

$$\hat{\boldsymbol{z}} \cdot \nabla \times (f\, \hat{\boldsymbol{z}} \times \boldsymbol{U}^{\rho}) = \nabla \cdot (f\, \boldsymbol{U}^{\rho}), \tag{41.185}$$

as well as $\nabla \times \nabla_z \mathscr{P} = 0$. We now discuss the various physical processes appearing in the vorticity equation (41.184).

[17] As noted in footnote 14, we can reduce notational clutter by writing ∇ rather than ∇_z when operating on functions that are independent of z, such as η, p_{a}, η_{b} and p_{b}. Since these fields are independent of z, then $\nabla_z \eta = \nabla \eta$, and likewise for p_{a}, η_{b} and p_{b}. We sometimes make use of this notation, though write ∇_z where it can help to reduce ambiguity.

Beta effect

The first term on the right hand side of the vorticity equation (41.184) arises from the convergence of mass within a fluid column due to depth integrated horizontal flow. We can further decompose the effects from this term by performing the product rule

$$-\nabla \cdot (f\, \boldsymbol{U}^{\rho}) = -f\, \nabla \cdot \boldsymbol{U}^{\rho} - \beta\, V^{\rho}. \tag{41.186}$$

The contribution from $\beta\, V^{\rho}$ arises from the beta effect as discussed in Section 41.6.2. For the first term, the weighting by the Coriolis parameter means that mass convergence at higher latitudes has more impact on vorticity changes than at lower latitudes. We can understand this weighting by noting that vertical fluid columns are more aligned with the planetary rotation at the high latitudes. Hence, when the mass of vertical columns converges at the higher latitudes, there is more impact on changes to the vorticity of the depth integrated flow.

Mass transfer, turbulent momentum transfer, and nonlinear effects

The term $\nabla \times [\boldsymbol{u}(\eta)\, Q_{\mathrm{m}}]$ appearing in in equation (41.187) accounts for vorticity crossing the ocean surface as affected by the mass flux. The term $\nabla \times \Delta \boldsymbol{\tau}$ is the torque from turbulent stresses at the ocean surface and bottom, and $\hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{D}$ is the torque from horizontal frictional stresses in the fluid interior. The final term arises from the nonlinear kinetic stresses, $\mathbb{T}^{\text{kinetic}}_{\text{hor}}$, that account for curls in the self-advection operator.

41.9.3 Boundary pressure torques

The pressure terms in equation (41.184)

$$\hat{\boldsymbol{z}} \cdot \nabla \times (-\eta \nabla p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla p_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot \nabla \times (p_{\mathrm{a}} \nabla \eta - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) \tag{41.187}$$

arise from curls of the pressure form stresses (see Chapter 29) at the ocean surface and bottom, and these contributions are referred to as *pressure torques*. When the fluid is a column of ocean water, then the surface pressure contribution is the *atmospheric pressure torque* and the bottom pressure term is the *bottom pressure torque*.

Geometry of boundary pressure torques

Geometrically, there is a nonzero atmospheric pressure torque when the applied pressure, p_{a}, has a gradient when moving along contours of constant free surface. Likewise, there is a nonzero bottom pressure torque when bottom pressure, p_{b}, changes along contours of constant bottom topography. Mathematically, we reveal these properties through use of either Exercise 7.1 or 41.12. For example, the bottom pressure torque along an isobath (contour of constant η_{b}) can be written

$$\hat{\boldsymbol{z}} \cdot \nabla \eta_{\mathrm{b}} \times \nabla p_{\mathrm{b}} = -(\hat{\boldsymbol{n}} \cdot \nabla \eta_{\mathrm{b}})\, (\hat{\boldsymbol{t}} \cdot \nabla p_{\mathrm{b}}), \tag{41.188}$$

where $\hat{\boldsymbol{t}}$ is a unit tangent vector directed along the isobath, and $\hat{\boldsymbol{n}}$ is a unit vector that points to the left of $\hat{\boldsymbol{t}}$ (see Figure 41.12). Both $\hat{\boldsymbol{t}}$ and $\hat{\boldsymbol{n}}$ are horizontal vectors.[18] Hence, $\hat{\boldsymbol{n}} \cdot \nabla \eta_{\mathrm{b}}$ measures the slope of the bottom topography in the direction normal to an isobath, and $\hat{\boldsymbol{t}} \cdot \nabla p_{\mathrm{b}}$ measures the change of the bottom pressure along the isobath. There is a nonzero bottom pressure torque

[18] It is important to note that $\hat{\boldsymbol{n}}$ is not the outward normal direction to the bottom, contrary to its usage in Section 41.8. Here, $\hat{\boldsymbol{n}}$ it is the horizontal direction within the bottom surface that is normal to contours of constant topography.

along an isobath so long as there is a slope to the bottom pressure along the isobath, and there is a change in bottom pressure moving along the isobath.

FIGURE 41.12: Geometry depicting a contour along a particular line of constant topography (i.e., an isobath), $\eta_{\rm b}(x, y)$. The along-contour direction is $\hat{\boldsymbol{t}} = {\rm d}\boldsymbol{x}/{\rm d}s$, with s the arc length along the contour. The unit direction pointing to the left of $\hat{\boldsymbol{t}}$ is written $\hat{\boldsymbol{n}}$, with $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0$ and $\hat{\boldsymbol{t}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$. Both $\hat{\boldsymbol{n}}$ and $\hat{\boldsymbol{t}}$ are horizontal unit vectors. There is a nonzero bottom pressure torque if bottom pressure changes when following an isobath.

Geostrophic velocity associated with the bottom pressure torque

To further our understanding of the pressure torques in equation (41.187), focus on the bottom pressure and introduce a geostrophic velocity[19]

$$\rho_0 \, f \, \boldsymbol{u}_{\rm g} = \hat{\boldsymbol{z}} \times (\nabla_z p)_{z=\eta_{\rm b}} = \hat{\boldsymbol{z}} \times [\nabla p_{\rm b} + g \, \rho(\eta_{\rm b}) \, \nabla \eta_{\rm b}], \tag{41.189}$$

where the second equality made use of equation (28.60b) to express the horizontal pressure gradient at the bottom, $(\nabla_z p)_{z=\eta_{\rm b}}$, in terms of the gradient of bottom pressure and gradient of bottom topography. Hence,

$$\nabla p_{\rm b} = -\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm g} - g \, \rho(\eta_{\rm b}) \, \nabla \eta_{\rm b}, \tag{41.190}$$

so that the bottom pressure torque takes the form

$$\hat{\boldsymbol{z}} \cdot \nabla \times (\eta_{\rm b} \nabla p_{\rm b}) = \hat{\boldsymbol{z}} \cdot (\nabla \eta_{\rm b} \times \nabla p_{\rm b}) = -\rho_0 \, f \, \boldsymbol{u}_{\rm g} \cdot \nabla \eta_{\rm b}. \tag{41.191}$$

This equation is merely a replacement of the bottom pressure gradient with a corresponding geostrophic velocity. However, if this geostrophic velocity is assumed to satisfy the kinematic boundary condition (20.41), then we reach the equality[20]

$$\hat{\boldsymbol{z}} \cdot \nabla \eta_{\rm b} \times \nabla p_{\rm b} = -\rho_0 \, f \, w_{\rm g}, \tag{41.192}$$

which links the bottom pressure torque to vertical vortex stretching by the vertical component to the geostrophic velocity. Evidently, if the bottom geostrophic velocity is negative ($w_{\rm g} < 0$), then

[19]The geostrophic velocity is a balance between the Coriolis acceleration and the *horizontal* pressure gradient. We thus need to decompose the horizontal pressure gradient into the bottom pressure gradient and the gradient of the botom slope, as per equation (28.60b).

[20]The velocity, $\boldsymbol{v}$, satisfies the kinematic boundary condition (20.41), in which $\boldsymbol{v}(\eta_{\rm b}) \cdot \hat{\boldsymbol{n}} = 0$. Decomposing the velocity into its geostrophic and ageostrophic components, $\boldsymbol{v} = \boldsymbol{v}_{\rm g} + \boldsymbol{v}_{\rm a}$, does not generally imply that $\boldsymbol{v}_{\rm g}$ and $\boldsymbol{v}_{\rm a}$ separately satisfy the kinematic boundary condition. Rather, we must make that assumption in order to reach the equality (41.192).

that induces vortex stretching and a corresponding positive tendency for vorticity of the depth integrated flow. The opposite holds with $w_{\mathrm{g}} > 0$, in which vortex squashing induces a negative tendency for vorticity of the depth integrated flow.

The equality (41.192) is sometimes used to infer the bottom pressure torque by diagnosing the bottom vertical velocity, $w(\eta_{\mathrm{b}})$ (*Spence et al.*, 2012). Although this diagnostic is suitable for some studies, there are important caveats. Namely, the bottom vertical velocity is generally affected by bottom frictional effects and thus can have a nontrivial Ekman component.[21] Nonlinear effects can also be important especially when considering motions with sizable Rossby numbers. Neither the Ekman component nor nonlinear terms are directly related to the bottom pressure torque. We thus expect $\rho_0 f w(\eta_{\mathrm{b}})$ to be distinct from $\hat{\boldsymbol{z}} \cdot \nabla \eta_{\mathrm{b}} \times \nabla p_{\mathrm{b}}$ in regions of sizable deep flows where bottom friction and/or nonlinear effects are of leading order importance.[22] The studies from *Gula et al.* (2015) and *LeCorre et al.* (2020) illustrate these points from numerical simulations of the subpolar North Atlantic circulation.

41.9.4 Steady state vorticity budget

The steady state form of the vorticity budget (41.184) leads to the balance

$$\begin{aligned} \beta V^{\rho} &= -f \nabla \cdot \boldsymbol{U}^{\rho} \\ &\quad + \hat{\boldsymbol{z}} \cdot \nabla \times \left[\boldsymbol{u}(\eta) Q_{\mathrm{m}} - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \Delta \boldsymbol{\tau} + \boldsymbol{D} + \nabla_z \cdot \left(\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}_{\mathrm{hor}}^{\mathrm{kinetic}} \, \mathrm{d}z \right) \right]. \end{aligned} \tag{41.193}$$

Writing the balance in this manner reveals how the beta affect affords a steady meridional mass transport as a balance with the variety of terms on the right hand side.

Specializing the budget to expose a variety of balanced flow regimes

Let us further specialize to the case appropriate for many studies of the large-scale circulation, whereby we make the following assumptions.

- Uniform mass atmosphere so that p_{a} is a constant.
- The frictional stresses from horizontal strains within the fluid interior, $\boldsymbol{D}$, can be neglected.
- Zero boundary mass transport so that $Q_{\mathrm{m}} = 0$ and, correspondingly, the steady depth integrated mass budget (20.88) means that $\nabla \cdot \boldsymbol{U}^{\rho} = 0$ when $Q_{\mathrm{m}} = 0$.

These simplifications bring the balance (41.193) to the form

$$\beta V^{\rho} = \hat{\boldsymbol{z}} \cdot \nabla \times \left[\eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \Delta \boldsymbol{\tau} + \nabla_z \cdot \left(\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}_{\mathrm{hor}}^{\mathrm{kinetic}} \, \mathrm{d}z \right) \right] \tag{41.194a}$$

$$\text{MERIDIONAL TRANSPORT} = \text{BOTTOM PRESS TORQUE} + \text{BOUNDARY STRESS} + \text{NONLINEAR}. \tag{41.194b}$$

This steady balance reveals distinct flow regimes depending on which of the terms dominate, and as such it serves as a useful framework for analysis.

[21] Recall our discussion of Ekman boundary layers in Chapter 34.

[22] In addition to the Ekman and nonlinear effects noted here, diagnosing $w(\eta_{\mathrm{b}})$ in a numerical model can be frought with difficulties related to the discrete grid stencil given that grids can be quite coarse in the deep ocean with many ocean model configurations.

Topographic nonlinear balance

Jackson et al. (2006), *Patmore et al.* (2019), and *LeCorre et al.* (2020) emphasize the importance of the nonlinear term in equation (41.194b) when flows are especially strong. The bottom pressure torque contribution is particularly strong where flows are strong near the bottom. Such nonlinear flow regimes generally have variations over length scales much smaller than that of the wind stress. Hence, if the horizontal friction is small, as it is even for strong flows not directly adjacent to solid boundaries, and the bottom frictional drag is small, then the vorticity balance (41.194a) in the nonlinear inviscid regime takes on the form

$$\beta V^\rho = \hat{\boldsymbol{z}} \cdot \nabla \times \left[\eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \nabla_z \cdot \left(\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}_{\mathrm{hor}}^{\mathrm{kinetic}} \, \mathrm{d}z \right) \right] \qquad \text{topographic nonlinear balance.} \tag{41.195}$$

Observe that the nonlinear term and bottom pressure torque have derivatives wherease there are none on the βV^ρ term. These derivatives make the right hand side terms have variations at smaller scales than βV^ρ. We infer that the smaller scales present in the bottom pressure torque and the nonlinear term nearly balance, and with any residual leading to the broader scale meridional transport. Figure 6 in *LeCorre et al.* (2020) provides a striking example of this balance in a numerical simulation of the North Atlantic subpolar gyre.

Linear regime of planetary geostrophy

For the linear regime of planetary geostrophic flow (Chapter 45), the nonlinear term from the kinetic stress is small, so that the balance is between meridional transport, bottom pressure torque, and curl of turbulent boundary stresses. The *Sverdrup balance* is one particular example of a planetary geostrophic balance, with Sverdrup balance ignoring the bottom pressure torque and bottom turbulent stresses, and thus focuses just on the balance between meridional transport with the turbulent surface stresses largely arising from winds

$$\beta V^\rho = \hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{\tau}^\eta \qquad \text{Sverdrup balance.} \tag{41.196}$$

However, as emphasized by *Hallberg and Rhines* (1996) and *Hughes and de Cueves* (2001), as well as more recent studies, contributions from bottom pressure torques are of leading order importance in the presence of flow next to sloping side boundaries, thus making the traditional Sverdrup balance mostly relevant in the open ocean away from boundaries. A more general balance is known as *topographic Sverdrup balance*

$$\beta V^\rho = \hat{\boldsymbol{z}} \cdot \nabla \times (\eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \boldsymbol{\tau}^\eta) \qquad \text{topographic Sverdrup balance.} \tag{41.197}$$

We further study these balances of planetary geostrophy in Sections 45.4, 45.6, and 45.7.

41.9.5 Integral balances satisfied by steady flows

Reconsider the steady vorticity balance (41.193), here written in the form

$$\nabla \cdot (f \boldsymbol{U}^\rho) = \hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{M} \tag{41.198}$$

where we introduced the stress vector

$$\boldsymbol{M} = \boldsymbol{u}(\eta) \, Q_{\mathrm{m}} - \eta \nabla_z p_{\mathrm{a}} + \eta_{\mathrm{b}} \nabla_z p_{\mathrm{b}} + \Delta \boldsymbol{\tau} + \boldsymbol{D} + \nabla_z \cdot \left(\int_{\eta_{\mathrm{b}}}^{\eta} \mathbb{T}_{\mathrm{hor}}^{\mathrm{kinetic}} \, \mathrm{d}z \right). \tag{41.199}$$

Now integrate equation (41.198) over an area, $\mathcal{S}$, with Gauss's divergence theorem on the left hand side leading to

$$\int_{\mathcal{S}} \nabla \cdot (f\, \boldsymbol{U}^{\rho})\, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{S}} f\, \boldsymbol{U}^{\rho} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}s, \tag{41.200}$$

where $\hat{\boldsymbol{n}}$ is the horizontal outward unit normal on the boundary, $\partial \mathcal{S}$, and $\mathrm{d}s$ is the arc-length increment along the boundary. This term is the mass transport crossing the boundary as weighted by the Coriolis parameter.

Use of Stokes' curl theorem on the right hand side of equation (41.198) leads to

$$\int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot \nabla \times \boldsymbol{M}\, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{S}} \boldsymbol{M} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s, \tag{41.201}$$

where $\hat{\boldsymbol{t}}$ is the horizontal unit tangent vector along the boundary, and the integral is oriented in the counter-clockwise direction. To help interpret the closed loop integral in equation (41.201), consider just the contribution from bottom pressure

$$\oint_{\partial \mathcal{S}} \boldsymbol{M}_{\text{bottom press}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s = \oint_{\partial \mathcal{S}} \eta_{\mathrm{b}}\, \nabla p_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s = -\oint_{\partial \mathcal{S}} p_{\mathrm{b}}\, \nabla \eta_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s, \tag{41.202}$$

which is the work done by bottom topographic form stress around the closed contour. The other terms in equation (41.198) have interpretations as the work arising from integrating stresses from mass transport through the surface, atmospheric form stress, turbulent boundary stresses, interior frictional stresses, and nonlinear kinetic stress. Observe that the integral of bottom pressure torque in equation (41.202) vanishes if the closed contour follows either an isobath or a bottom pressure isobar. The vanishing of this integral means that bottom pressure torques have zero net circulation around isobaths or bottom isobars. An analogous property is satisfied by the atmospheric pressure torque when integrated around closed contours of constant atmospheric pressure, p_{a}, or constant surface height, η.

Bringing the above results together renders the general balance around the boundray of an arbitrary closed region

$$\oint_{\partial \mathcal{S}} f\, \boldsymbol{U}^{\rho} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}s = \oint_{\partial \mathcal{S}} \boldsymbol{M} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s. \tag{41.203}$$

We thus see that transport across the closed boundary, as weighted by the Coriolis parameter, arises from a nonzero net work around the boundary by the variety of stresses comprising $\boldsymbol{M}$. We are afforded a key simplification if $\boldsymbol{U}^{\rho} \cdot \hat{\boldsymbol{n}} = 0$ at each point along the boundary. For example, if $\nabla \cdot \boldsymbol{U}^{\rho} = 0$, which generally also requires $Q_{\mathrm{m}} = 0$, then contours along which $\boldsymbol{U}^{\rho} \cdot \hat{\boldsymbol{n}} = 0$ correspond to closed streamlines of the steady $\boldsymbol{U}^{\rho}$. Hence, we find the following balance holds around any closed streamline

$$\oint_{\partial \mathcal{S}} \boldsymbol{M} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s = 0. \quad \text{for } \partial \mathcal{S} \text{ a closed streamline of } \boldsymbol{U}^{\rho}. \tag{41.204}$$

Closed streamlines do not always exist. But when they do, such as for steady ocean gyre circulations, this balance holds. In Section 45.6.3, we consider the planetary geostrophic version of this balance.

41.9.6 Formulation based on the vector-invariant velocity equation

In formulating the budget equation (41.184) for vorticity of the depth integrated flow, we started with the depth integrated momentum in Section 29.4.5. However, many numerical models are formulated using the vector invariant form of the horizontal velocity equation (41.142), here

written in the equivalent form for a Boussinesq ocean

$$\underbrace{\partial_t \boldsymbol{u} + f\,\hat{\boldsymbol{z}}\,\times \boldsymbol{u} + \nabla_z p/\rho_0 - \boldsymbol{F}}_{\text{linear terms plus friction}} = \underbrace{-\zeta\,\hat{\boldsymbol{z}}\times\boldsymbol{u} - w\,\partial_z\boldsymbol{u} - \nabla_z \boldsymbol{u}^2/2.}_{\text{Magnus + vertical advection + kinetic energy}} \tag{41.205}$$

The three nonlinear terms on the right hand side arise from expanding the nonlinear self-advection term, $(\boldsymbol{v}\cdot\nabla)\,\boldsymbol{u}$, following the manipulations in Section 41.7.1. Much of the formulation to follow emulates that considered thus far, with the exception of the nonlinear terms and elements of the boundary contributions.

We take the vertical integral of equation (41.205)

$$\int_{\eta_\mathrm{b}}^{\eta} [\partial_t \boldsymbol{u} + f\,\hat{\boldsymbol{z}}\,\times \boldsymbol{u} + \nabla_z p/\rho_0 - \boldsymbol{F}]\,\mathrm{d}z = -\int_{\eta_\mathrm{b}}^{\eta} \big(\zeta\,\hat{\boldsymbol{z}}\times\boldsymbol{u} + w\,\partial_z\boldsymbol{u} + \nabla_z\boldsymbol{u}^2/2\big)\,\mathrm{d}z, \tag{41.206}$$

and then the curl

$$\nabla\times\int_{\eta_\mathrm{b}}^{\eta} (\partial_t \boldsymbol{u} + f\,\hat{\boldsymbol{z}}\,\times \boldsymbol{u} + \nabla_z p/\rho_0 - \boldsymbol{F})\,\mathrm{d}z = -\nabla\times\int_{\eta_\mathrm{b}}^{\eta} (\zeta\,\hat{\boldsymbol{z}}\times\boldsymbol{u} + w\,\partial_z\boldsymbol{u} + \nabla_z\boldsymbol{u}^2/2)\,\mathrm{d}z. \tag{41.207}$$

Making use of the following identities

$$\hat{\boldsymbol{z}}\cdot\left[\nabla\times\int_{\eta_\mathrm{b}}^{\eta}\partial_t\boldsymbol{u}\,\mathrm{d}z\right] = \hat{\boldsymbol{z}}\cdot\partial_t(\nabla\times\boldsymbol{U}) - \hat{\boldsymbol{z}}\cdot\nabla\times[\boldsymbol{u}(\eta)\,\partial_t\eta] \tag{41.208a}$$

$$\hat{\boldsymbol{z}}\cdot\left[\nabla\times\int_{\eta_\mathrm{b}}^{\eta} f\,\hat{\boldsymbol{z}}\,\times\boldsymbol{u}\,\mathrm{d}z\right] = \nabla\cdot(f\,\boldsymbol{U}) \tag{41.208b}$$

$$\hat{\boldsymbol{z}}\cdot\left[\nabla\times\int_{\eta_\mathrm{b}}^{\eta}\nabla_z p\,\mathrm{d}z\right] = \hat{\boldsymbol{z}}\cdot\nabla\times(\eta\nabla p_\mathrm{a} - \eta_\mathrm{b}\nabla p_\mathrm{b}) \tag{41.208c}$$

$$\hat{\boldsymbol{z}}\cdot\left[\nabla\times\int_{\eta_\mathrm{b}}^{\eta}\zeta\,\hat{\boldsymbol{z}}\times\boldsymbol{u}\,\mathrm{d}z\right] = \nabla\cdot\left[\int_{\eta_\mathrm{b}}^{\eta}\zeta\,\boldsymbol{u}\,\mathrm{d}z\right] \tag{41.208d}$$

$$\hat{\boldsymbol{z}}\cdot\left[\nabla\times\int_{\eta_\mathrm{b}}^{\eta}\rho_0\,\boldsymbol{F}\,\mathrm{d}z\right] = \hat{\boldsymbol{z}}\cdot\nabla\times(\Delta\boldsymbol{\tau} + \boldsymbol{D}), \tag{41.208e}$$

leads to

$$\begin{aligned}\hat{\boldsymbol{z}}\cdot\partial_t(\nabla\times\boldsymbol{U}) &= -\nabla\cdot\left[f\,\boldsymbol{U} + \int_{\eta_\mathrm{b}}^{\eta}\zeta\,\boldsymbol{u}\,\mathrm{d}z\right]\\ &+ \hat{\boldsymbol{z}}\cdot\nabla\times\left[\boldsymbol{u}(\eta)\,\partial_t\eta - \eta\nabla p_\mathrm{a} + \eta_\mathrm{b}\nabla p_\mathrm{b} + (\Delta\boldsymbol{\tau}+\boldsymbol{D})/\rho_0 - \int_{\eta_\mathrm{b}}^{\eta}(w\,\partial_z\boldsymbol{u} + \nabla_z\boldsymbol{u}^2/2)\,\mathrm{d}z\right].\end{aligned} \tag{41.209}$$

The left hand side is the time tendency of the vorticity of the depth integrated horizontal flow, with this time tendency driven by the various linear and nonlinear terms on the right hand side. This evolution equation should be compared to equation (41.184) as derived from the advective form of the momentum equation. Likewise, we derive a steady state balance by setting the time tendencies to zero to yield

$$\begin{aligned}\beta\,V &= -f\,\nabla\cdot\boldsymbol{U} - \nabla\cdot\left[\int_{\eta_\mathrm{b}}^{\eta}\zeta\,\boldsymbol{u}\,\mathrm{d}z\right]\\ &+ \hat{\boldsymbol{z}}\cdot\nabla\times\left[\boldsymbol{u}(\eta)\,\partial_t\eta - \eta\nabla p_\mathrm{a} + \eta_\mathrm{b}\nabla p_\mathrm{b} + (\Delta\boldsymbol{\tau}+\boldsymbol{D})/\rho_0 - \int_{\eta_\mathrm{b}}^{\eta}(w\,\partial_z\boldsymbol{u} + \nabla_z\boldsymbol{u}^2/2)\,\mathrm{d}z\right],\end{aligned} \tag{41.210}$$

which should be compared to equation (41.193).

41.9.7 Vorticity of the depth averaged flow

The vorticity of the depth averaged flow is given by $\hat{\boldsymbol{z}} \cdot \nabla \times \overline{\boldsymbol{u}}$, where $\overline{\boldsymbol{u}}$ is given by equation (29.34) for a compressible non-Boussinesq fluid, and which takes on the following form for a Boussinesq ocean

$$\overline{\boldsymbol{u}} = \frac{\int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z}{\eta - \eta_{\mathrm{b}}} = \frac{\boldsymbol{U}}{\eta - \eta_{\mathrm{b}}}. \tag{41.211}$$

The difference is given by

$$\nabla \times \boldsymbol{U} - (\eta - \eta_{\mathrm{b}}) \, \nabla \times \overline{\boldsymbol{u}} = \nabla(\eta - \eta_{\mathrm{b}}) \times \overline{\boldsymbol{u}}, \tag{41.212}$$

so that the two vorticities are the same in the special case of a depth averaged flow that is parallel to $\nabla(\eta - \eta_{\mathrm{b}})$. Quite trivially, $\nabla(\eta - \eta_{\mathrm{b}}) \times \overline{\boldsymbol{u}} = 0$ occurs for a rigid lid and flat bottom ocean, in which $\nabla \eta = \nabla \eta_{\mathrm{b}} = 0$. More generally, $\nabla(\eta - \eta_{\mathrm{b}}) \times \overline{\boldsymbol{u}} \neq 0$, particularly in the presence of topography. We further study the budgets for these two vorticities, for planetary geostrophic flow, in Sections 45.6 and 45.7.

41.9.8 Comments and further study

The diagnostic budgets derived in this section have appeared in many studies of ocean vorticity. When diagnosing the budget terms in a numerical model, the choice for how to mathematically formulate the diagnostic balances is largely driven by physical transparency as well as by numerical precision. Concerning numerical precision, it is useful to note that vorticity, as the derivative of velocity, has more power at the high spatial wave numbers than does velocity. In a numerical model, such power can manifest as grid scale noise. It is thus of use to perform much of the calculation online to enable the most accurate available diagnostic. Even so, further spatial smoothing is generally required, especially in realistic models, to extract physically interpretable signals.

41.10 Exercises

EXERCISE 41.1: RELATING THE INTEGRAL OF DIVERGENCE AND VORTICITY

For some purposes, it is useful to consider the evolution of the flow divergence as well as the vorticity. In this chapter we focused on the vorticity. Here are to prove, using Cartesian tensors, that

$$\int_{\mathcal{R}} (\boldsymbol{v} \, \nabla \cdot \boldsymbol{v} + \boldsymbol{\omega} \times \boldsymbol{v}) \, \mathrm{d}V = \oint_{\partial \mathcal{R}} [\boldsymbol{v} \, (\boldsymbol{v} \cdot \hat{\boldsymbol{n}}) - \hat{\boldsymbol{n}} \, \mathcal{K}] \, \mathrm{d}\mathcal{S}, \tag{41.213}$$

where $\mathcal{K} = \boldsymbol{v} \cdot \boldsymbol{v}/2$ is the kinetic energy per mass. Hint: make use of the vector identity (41.32) as well as the scalar form of Gauss's divergence theorem given by equation (2.73).

EXERCISE 41.2: STRAIN AND ROTATION FOR STRETCHING AND TILTING

In this exercise we write the 3×3 strain rate tensor, $\mathbb{S}$, and rotation tensor, $\mathbb{R}$, for the examples of vortex stretching and vortex tilting considered in Section 41.5.3. Recall that elements of $\mathbb{S}$ are given by equation (19.43a) and $\mathbb{R}$ have elements given by equation (19.43b). Hint: there is no unique answer for the strain rate tensors, so offer a simple example that renders the desired behavior of a vortex line.

(a) Write a strain rate tensor corresponding to vortex stretching as per equation (41.76) along with $\omega^x = \omega^y = 0$, and write the corresponding vorticity source term $\boldsymbol{\omega} \cdot \mathbb{S}$.

(b) Write the rotation tensor for vortex stretching as per equation (41.76) and verify that $\omega_m \cdot \mathbb{R}_{mn} = 0$.

(c) Write a strain rate tensor corresponding to vortex tilting as per equation (41.82) along with $\omega^y = \omega^z = 0$.

(d) Write the rotation tensor for vortex tilting as per equation (41.82) and verify that $\omega_m \, \mathbb{R}_{mn} = 0$.

EXERCISE 41.3: BAROCLINICITY WITH $\rho_0(z)$

Recall the discussion of the Boussinesq momentum equation in Section 30.1.2. The form given by equation (30.8) is written with the reference density, $\rho_0 = \rho_0(z)$. We then stated that the form of the baroclinicity vector appearing in the Boussinesq vorticity equation is greatly simplified by setting ρ_0 to a global constant, and thus dropping the z dependence. Derive the second term in the baroclinicity

$$\boldsymbol{B} = \nabla \left[b - \frac{\delta p}{\rho_0^2} \frac{\mathrm{d}\rho_0}{\mathrm{d}z} \right] \times \hat{\boldsymbol{z}}, \tag{41.214}$$

so that $\boldsymbol{B} = \nabla b \times \hat{\boldsymbol{z}}$ when ρ_0 is assumed to be a global constant. Hint: write the vector-invariant form of equation (30.8) with $\rho_0(z)$. Then take the curl.

EXERCISE 41.4: FRICTION IN THE VORTICITY EQUATION

Assume a viscous friction operator of the form

$$\boldsymbol{F} = \nu \nabla^2 \boldsymbol{v}, \tag{41.215}$$

with ν a constant molecular kinematic viscosity. Assuming Cartesian coordinates, write the vorticity equation (41.42) with this term included.

EXERCISE 41.5: FRICTION FOR NON-DIVERGENT FLOWS

Consider a non-divergent flow with a Laplacian frictional acceleration

$$\boldsymbol{F} = \nu \nabla^2 \boldsymbol{v} \quad \text{with} \quad \nabla \cdot \boldsymbol{v} = 0, \tag{41.216}$$

with ν a constant molecular kinematic viscosity. Write this expression in terms of the vorticity. Hint: check that $\nabla \times \boldsymbol{F}$ equals to the friction appearing in the vorticity equation derived in exercise 41.4. Further hint: the derivation is given in Section 26.8.8.

EXERCISE 41.6: GENERATION OF VORTICITY BY BAROCLINICITY

Consider a body of water with a flat bottom and rigid sides. Let the top surface be at $z = 0$ and bottom at $z = -H$, and assume zero pressure applied at the top surface. Let the density have a horizontal structure given by

$$\rho(x) = \rho_0 \, (1 - \gamma \, x) \tag{41.217}$$

where ρ_0 and γ are positive constants (with dimensions of density and inverse length, respectively). We furthermore assume that $\gamma |x| \ll 1$ so that the density is XFstrictly positive. Note that a study of Figure 41.3 helps with this exercise.

As posed, the fluid is not in mechanical equilibrium since there is a horizontal density gradient. Hence, the fluid will adjust as a result of the nonzero horizontal pressure gradient force. Our aim here is to compute the baroclinicity contained in the fluid to garner a sense for the initial adjustment of vorticity.

(a) Compute the density gradient $\nabla\rho$ and draw a schematic.

(b) Compute the pressure gradient, ∇p, assuming approximate hydrostatic balance so that $\partial p/\partial z = -\rho\, g$. Draw a schematic at $x = 0$.

(c) Compute the baroclinicity/solenoidal vector $\boldsymbol{B} = \rho^{-2}\,(\nabla\rho \times \nabla p)$. Draw a schematic.

(d) Describe the vorticity induced by the baroclinicity vector.

EXERCISE 41.7: GENERATION OF CIRCULATION BY BAROCLINICITY IN AN IDEAL GAS

In this exercise we examine the baroclinicity vector for a simple ideal gas, which is described by the equation of state (24.48)

$$\rho = \frac{p\, M_{\text{mole}}}{T\, R^{\text{g}}} \equiv \frac{p}{T\, R^{\text{M}}}, \tag{41.218}$$

where R^{g} is the universal gas constant and R^{M} is the specific gas constant. We also assume the atmosphere is in approximate hydrostatic balance (Section 28.2), and we ignore rotation (relatively small lateral region of the atmosphere). For further hints to this exercise, see Section 4.1 of *Holton* (1992) or Section 2.4.3 of *Markowski and Richardson* (2010), where they discuss circulation generated by differences in land-sea temperatures, thus leading to a sea breeze.

(a) Express the baroclinicity vector, $\boldsymbol{B}$, in terms of pressure and temperature gradients.

(b) Express the baroclinicity vector in terms of pressure and potential temperature gradients. Hint: see Section 24.4.11 for potential temperature in an ideal gas.

(c) Consider an ideal gas atmosphere straddling the ocean and flat land as in Figure 41.13. Let the daytime air be relatively cool over the ocean and relatively warm over the land. Furthermore, assume the sea level pressure is the same value over land and ocean. Ignoring rotation, draw isolines of constant temperature and constant pressure. Assume the horizontal temperature gradient is constant with height. Here are some hints.

- Temperature decreases from land to ocean and decreases when ascending into the atmosphere.
- Pressure is assumed to be horizontally constant at sea level and it decreases upward. Use the ideal gas law to determine the sense for the horizontal pressure gradient as one ascends. Consult the discussion in Section 24.4.10 for geopotentials in an ideal gas atmosphere.
- We are only concerned with a qualitative sense for the isolines in the lower atmosphere and over a horizontal region small enough that rotation can be ignored.

(d) Describe the sense for the circulation induced by the baroclinicity. Does circulation correspond to your experience at a sunny beach day as the air warms over the land faster than over the adjacent ocean? What force causes air to rise and to fall?

EXERCISE 41.8: CIRCULATION WITH ISLANDS

Our discussion of Stokes' theorem has been thus far restricted to a simply connected domain, in which

$$\oint_{\partial\mathcal{S}} \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{x} = \int_{\mathcal{S}} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{41.219}$$

For a simply connected domain, the closed contour can be shrunk to a point without leaving the domain.

FIGURE 41.13: Setup for the sea breeze Exercise 41.7. We here depict a vertical-zonal crossection of the atmosphere where the lower boundary straddles the ocean and land. The atmosphere over the ocean is assumed to be cooler than the atmosphere over the land, as typically occurs on a sunny afternoon with solar radiation warming land faster than the ocean.

A more general topology consists of a region with holes, whereby closed contours cannot in general be shrunk to a point without leaving the region. In an oceanographic context, the "holes" are islands or continents and the circulation is that for the depth integrated flow. Figure 41.14 shows a region of the ocean containing three arbitrarily shaped impenetrable islands, with the three islands surrounded by a contour. The contour cannot be shrunk to a point without crossing over the islands, thus making this region of the ocean multiply-connected. The presence of islands thus adds a level of complexity to the World Ocean that is absent an AquaPlanet or the global atmosphere.

Derive the following expression for the circulation in multiply-connected regions

$$\oint_{\partial\mathcal{S}} \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{x} = \sum_{n=1}^{N}\left(\oint_{\partial\mathcal{S}_n} \boldsymbol{v}\cdot \mathrm{d}\boldsymbol{x}\right) + \int_{\mathcal{S}} \boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}, \tag{41.220}$$

where N is the number of islands, $\mathcal{S}_n$ is the contour surrounding each island, and $\mathcal{S}$ is the region of water that excludes the islands. In words, this result says that the circulation around a region equals to the circulation around the islands within the region, plus the normal component of the vorticity integrated over the area within the fluid region. Removing the islands allows the island contours to be shrunk to zero size, in which case we recover the simply connected result (41.219). As part of your solution, make use of the contour integral method detailed in Figure 40.9.

EXERCISE 41.9: EVOLUTION OF CIRCULATION AROUND ISLANDS

The momentum equation for a homogeneous layer of inviscid shallow water on a tangent plane is given by

$$\partial_t \boldsymbol{u} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} + f\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -g\,\nabla\eta. \tag{41.221}$$

In this equation, $\boldsymbol{u} = (u, v)$ is the horizontal velocity, f is the Coriolis parameter (need not be constant), g is the effective gravitational acceleration, and η is the deviation of the free surface from its horizontal resting position. All spatial derivatives are horizontal, so that

$$\boldsymbol{u}\cdot\nabla = u\,\partial_x + v\,\partial_y. \tag{41.222}$$

Use of a vector identity allows us to write

$$\partial_t \boldsymbol{u} + (f+\zeta)\,\hat{\boldsymbol{z}}\times\boldsymbol{u} = -\nabla\left(\boldsymbol{u}^2/2 + g\,\eta\right), \tag{41.223}$$

FIGURE 41.14: A region of the ocean consisting of three islands, $\mathcal{S}_1$, $\mathcal{S}_2$, and $\mathcal{S}_3$, each with boundaries $\partial\mathcal{S}_n$ and with the closed contour, $\partial\mathcal{S}$, drawn around the three islands. The contour $\partial\mathcal{S}$ cannot be shrunk to a point without crossing over the islands, thus indicating that the domain is multiply connected. Exercise 41.8 is concerned with deriving an expression for the circulation of the depth-integrated flow as defined along the closed contour, $\partial\mathcal{S}$. In that derivation we can make use of the contour initegral method detailed in Figure 40.9.

where

$$\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) \tag{41.224}$$

is the vorticity of the shallow water fluid.

Consider an island, such as one shown in Figure 41.14. Each island is static and impenetrable to fluid flow, which means that

$$\boldsymbol{u} \cdot \hat{\boldsymbol{n}} = 0 \tag{41.225}$$

where $\hat{\boldsymbol{n}}$ is the outward normal on an island boundary. This no-normal flow constraint means that the velocity just next to an island is parallel to the island[23]

$$\boldsymbol{u} \times \mathrm{d}\boldsymbol{x} = 0. \tag{41.226}$$

Equivalently, the island represents a solid material boundary across which no flow passes. Show that the inviscid shallow-water circulation around an island remains constant in time

$$\frac{\mathrm{d}}{\mathrm{d}t} \oint_I \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{x} = 0. \tag{41.227}$$

Recall that Kelvin's circulation theorem is formulated for a material circuit in an inviscid fluid, with the circuit moving with the flow. This exercise shows that the circulation theorem also holds for a material circuit enclosing a static solid boundary.

EXERCISE 41.10: HELICITY FOR A PERFECT BAROTROPIC FLUID IN A GRAVITY FIELD AND NON-ROTATING REFERENCE FRAME

Consider a closed material volume, $\mathcal{R}$, of a perfect single-constituent barotropic fluid ($\rho = \rho(p)$) in a gravity field ($\boldsymbol{g} = -\nabla\Phi$) and in a non-rotating reference frame ($\boldsymbol{\Omega} = 0$). Let this material volume have a boundary that is always tangent to the fluid vorticity, $\boldsymbol{\omega}$. Hence, the outward

[23]This boundary condition is valid only for inviscid fluids such as that considered here. For a real fluid with nonzero viscosity, all components of the velocity vector vanish at solid boundaries due to the no-slip condition.

normal to the region boundary is orthogonal to the vorticity,

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{\omega} = 0. \tag{41.228}$$

Such volumes define closed vortex tubes, such as a smoke ring or linked smoke rings. The *helicity* of the fluid within the vortex tube volume is defined as the integration of the helicity density, $\boldsymbol{v} \cdot \boldsymbol{\omega}$, over the closed volume

$$\mathbb{H} = \int_{\mathcal{R}(\boldsymbol{v})} \boldsymbol{v} \cdot \boldsymbol{\omega} \, \mathrm{d}V, \tag{41.229}$$

where the volume $\mathcal{R}(\boldsymbol{v})$ is material. In Cartesian coordinates, the helicity density takes the form

$$\boldsymbol{v} \cdot \boldsymbol{\omega} = u\,(\partial_y w - \partial_z v) + v\,(\partial_z u - \partial_x w) + w\,(\partial_x v - \partial_y u). \tag{41.230}$$

Although the helicity density vanishes for some common examples, such as for a fluid in rigid-body rotation, it need not vanish in general.

(a) Show that helicity is materially constant following the material volume

$$\frac{\mathrm{d}\mathbb{H}}{\mathrm{d}t} = 0. \tag{41.231}$$

(b) Discuss why helicity is not defined for a shallow water fluid.

Use the following hints.

- Make use of Φ_{p} that satisfies equation (41.13).
- The shallow water fluid model is based on the small aspect ratio limit, in which the fluid depth is much smaller than its lateral extent. In this limit, the vertical component of vorticity dominates over the horizontal. See further discussion in Section 41.5.4.

EXERCISE 41.11: DISCRETE CALCULATION OF BOTTOM PRESSURE TORQUE

In many diagnostic studies with numerical models it is of interest to compute pressure torques affecting vorticity. One particularly common diagnostic concers the bottom pressure torque arising in equation (41.187). Derive a discrete expression for the area averaged bottom pressure torque

$$\overline{\mathrm{BPT}} = A^{-1} \int_{\mathcal{S}} \hat{\boldsymbol{z}} \cdot \nabla \times (\eta_{\mathrm{b}} \nabla p_{\mathrm{b}}) \, \mathrm{d}\mathcal{S} = A^{-1} \oint_{\partial \mathcal{S}} \eta_{\mathrm{b}} \nabla p_{\mathrm{b}} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell, = -A^{-1} \oint_{\partial \mathcal{S}} p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} \cdot \hat{\boldsymbol{t}} \, \mathrm{d}\ell, \tag{41.232}$$

over the shaded region depicted in Figure 41.15, with $A = \int_{\mathcal{S}} \mathrm{d}\mathcal{S}$ the horizontal area of this region. Hint: this exercise shares much with the area averaged vorticity in Exercise 38.7, although the final result is distinct. Note: given that the bottom pressure torque is generally the small difference between large numbers, it is very useful to perform the diagnostic calculation online so that full computational precision can be maintained.

EXERCISE 41.12: DYNAMICAL PORTION OF THE TOPOGRAPHIC FORM STRESS

We discussed bottom topographic form stress in Chapter 29, with its curl leading to the bottom pressure torque in equation (41.187). As noted in Section 29.1.3, the dominant portion of the bottom topographic form stress acting on the ocean has little to do with fluid motion. Rather, it merely holds the ocean fluid within the basin, much as water is held within a drinking container through pressure imparted by the container sides.

FIGURE 41.15: Discrete grid layout for variables needed to compute the bottom pressure torque as averaged over the shaded vorticity region. The bottom topography and bottom pressure are both known at the tracer points.

(a) To help isolate the dynamically relevant portion of the bottom bottom pressure, show that we can write the horizontal gradient of the bottom pressure for a hydrostatic fluid according to

$$\nabla_z p_{\mathrm{b}} = g\,[\rho(\eta)\,\nabla_z \eta - \rho(\eta_{\mathrm{b}})\,\nabla_z \eta_{\mathrm{b}}] + g \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z \rho \,\mathrm{d}z. \tag{41.233}$$

where we ignore the applied surface pressure, p_{a}, for simplicity.

(b) Hence, show that the bottom pressure torque takes the form

$$\hat{\boldsymbol{z}} \cdot \nabla_z \eta_{\mathrm{b}} \times \nabla_z p_{\mathrm{b}} = g\,\hat{\boldsymbol{z}} \cdot \nabla_z \eta_{\mathrm{b}} \times \left[\rho(\eta) \nabla_z \eta + \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z \rho \,\mathrm{d}z\right] \equiv \hat{\boldsymbol{z}} \cdot \nabla \eta_{\mathrm{b}} \times \nabla p_{\mathrm{b}}^{*}, \tag{41.234}$$

where

$$\nabla_z p_{\mathrm{b}}^{*} = g\,\rho(\eta)\,\nabla_z \eta + g \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z \rho \,\mathrm{d}z. \tag{41.235}$$

Note how $\nabla_z p_{\mathrm{b}}^{*}$ has no contribution from the potentially very large term, $-g\,\rho(\eta_{\mathrm{b}})\,\nabla_z \eta_{\mathrm{b}}$, arising from gradients in the bottom topography.

(c) *Molemaker et al.* (2015) and *Gula et al.* (2015) assume knowledge of the bottom pressure torque along contours of constant topography. Given that knowledge they then make use of the following diagnostic expression for p_{b}^{*}

$$p_{\mathrm{b}}^{*}(s) - p_{\mathrm{b}}^{*}(s_0) = -\int_{s_0}^{s} \frac{\hat{\boldsymbol{z}} \cdot (\nabla \eta_{\mathrm{b}} \times \nabla p_{\mathrm{b}})}{\hat{\boldsymbol{n}} \cdot \nabla \eta_{\mathrm{b}}} \,\mathrm{d}s, \tag{41.236}$$

with $p_{\mathrm{b}}^{*}(s_0)$ the value at the arbitrary starting point for the contour. Derive equation (41.236), with the following information of possible use.

- As depicted in Figure 41.12, s is the arc length along the chosen contour of constant η_{b}, with s increasing in the tangent direction, $\hat{\boldsymbol{t}}$. Likewise, $\hat{\boldsymbol{n}}$ is a unit vector pointing to the left of the contour so that $\hat{\boldsymbol{n}} \cdot \hat{\boldsymbol{t}} = 0$ and $\hat{\boldsymbol{t}} \times \hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$.

- Along any contour of constant $\eta_{\mathrm{b}}(x, y)$ we have

$$0 = \mathrm{d}\eta_{\mathrm{b}} = \nabla \eta_{\mathrm{b}} \cdot \mathrm{d}\boldsymbol{x} = \nabla \eta_{\mathrm{b}} \cdot \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}s}\,\mathrm{d}s = \nabla \eta_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\,\mathrm{d}s. \tag{41.237}$$

- The main mathematics of this exercise are contained in Exercise 7.1.

Equation (41.236) provides a means to compute the anomalous p_{b}^* [anomalous relative to $p_{\mathrm{b}}^*(s_0)$] along a constant topography contour. Mapping $p_{\mathrm{b}}^*(s) - p_{\mathrm{b}}^*(s_0)$ for a suite of contours then provides the means to determine the dynamically relevant portion of the bottom pressure and then, when multiplying by the bottom slope, compute the dynamically relevant portion of the form stress.

Chapter 42

Potential vorticity mechanics

Potential vorticity (PV) is a dynamical tracer of immense importance to the study of geophysical fluid mechanics. One application of potential vorticity concerns its direct connection to the flow field in certain balanced models (e.g., geostrophically balanced models), with *Hoskins* (1991) providing an insightful starting point for this perspective. Potential vorticity is also useful as a tracer whose structure signals a variety of dynamical interactions, particularly with boundaries, and that can be directly tied to flow stability properties. In this chapter we establish fundamental properties of potential vorticity and its time evolution. The potential vorticity we consider here is sometimes referred to as *Ertel* potential vorticity (*Ertel*, 1942), which is the most basic of the many potential vorticities encountered in geophysical fluids mechanics.

The barotropic fluid forms a pedagogically useful starting point for our study. However, realistic geophysical flows are baroclinic, and it is the baroclinic fluid where "PV thinking" is arguably the most useful and powerful. The general method exploited for the construction of potential vorticity is to choose a scalar field to strategically orient the absolute vorticity. If the scalar is a material invariant, and it annihilates the baroclinicity vector, then the corresponding potential vorticity is a material invariant in the absence of irreversible processes. For a barotropic fluid, the choice of scalar field is rather arbitrary, with preference given to one that is materially invariant. For a baroclinic fluid we are more restricted since the scalar must orient vorticity in a direction that annihilates the torque from baroclinicity and, ideally, be itself materially invariant in the absence of irreversible processes. Even in the presence of irreversible processes, potential vorticity remains an important flow property that constrains the motion and provides insights into the mechanics of that motion.

CHAPTER GUIDE

This chapter requires an understanding of vorticity from Chapter 41 as well as skills with vector calculus identities for Cartesian coordinates as detailed in Chapter 2. The concepts and methods developed in this chapter are fundamental to the notions of potential vorticity, and are essential for the budget equations developed in Chapter 43. We also encounter potential vorticity when studying balanced models in Part VIII of this book.

42.1 Potential vorticity in perfect fluids

In this section we derive the material invariance of potential vorticity (PV) for a perfect homogeneous fluid.[1] We make use of Kelvin's circulation theorem for an infinitesimal closed loop, in which case the primary object of interest is a particular component of the absolute vorticity.

42.1.1 Perfect barotropic fluid

Consider a perfect barotropic fluid. As for the shallow water discussion in Section 40.3.3, we can apply Kelvin's circulation theorem (Section 41.2.3) to an infinitesimal material circuit within the fluid (Figure 42.1) to render the material invariance

$$\frac{\mathrm{D}}{\mathrm{D}t}(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \delta\mathcal{S}) = 0, \tag{42.1}$$

with $\delta\mathcal{S}$ the area enclosed by the circuit. The conservation of potential vorticity is built from specializing this result. For that purpose, introduce a materially invariant field

$$\frac{\mathrm{D}\chi}{\mathrm{D}t} = 0. \tag{42.2}$$

In most applications, χ is a scalar field such as tracer concentration, globally referenced Archimedean buoyancy, Conservative Temperature, or specific entropy. However, in equation (42.21) we consider the non-standard case of $\chi = z$, which is relevant for two-dimensional non-divergent barotropic fluids. The one key assumption we make is that χ is a smooth field that is not a spatial constant, so that $|\nabla\chi| \neq 0$.

42.1.2 Cylinder between two constant χ surfaces

We make use of isosurfaces of χ to orient a material circuit used to compute circulation and hence to orient the vorticity. In particular, referring to Figure 42.2, let the circuit bound a small cylinder

[1] A perfect homogeneous fluid has zero viscosity (inviscid) and a single material component. There can be no mixing of matter in this fluid since every fluid element has the same homogeneous concentration. So without viscosity, the homogeneous fluid is perfect.

FIGURE 42.1: The projection of the absolute vorticity, $\boldsymbol{\omega}_{\mathrm{a}}$, onto the normal direction of an infinitesimal moving surface, $\hat{\boldsymbol{n}}\,\delta\mathcal{S}$.

whose ends sit on isosurfaces with concentrations $\chi - \delta\chi/2$ and $\chi + \delta\chi/2$. We can consider this cylinder to be a portion of a vortex tube that is bounded by the two χ isosurfaces. The cylinder's volume is given by

$$\delta V = \delta\mathcal{S}\,\delta h, \tag{42.3}$$

where δh is the distance between the χ isosurfaces. The unit normal direction orienting the area, $\delta\mathcal{S}$, is given by

$$\hat{\boldsymbol{n}} = \nabla\chi/|\nabla\chi|. \tag{42.4}$$

It is the need to define $\hat{\boldsymbol{n}}$ that requires us to assume $|\nabla\chi| \neq 0$. The distance, δh, between the two isosurfaces is related to the χ increment, $\delta\chi$, through

$$\delta\chi = \nabla\chi\cdot\delta\boldsymbol{x} = |\nabla\chi|\,\hat{\boldsymbol{n}}\cdot\delta\boldsymbol{x} = |\nabla\chi|\,\delta h. \tag{42.5}$$

This result takes on the equivalent form

$$\delta\chi = |\nabla\chi|\,\delta h = (\hat{\boldsymbol{n}}\cdot\nabla\chi)\,\delta h, \tag{42.6}$$

so that the distance (or thickness) between the two isosurfaces is

$$\delta h = \delta\chi/|\nabla\chi|. \tag{42.7}$$

As seen in Figure 42.2, the spatial separation between the two isosurfaces is relatively small in regions of strong scalar gradients (large $|\nabla\chi|$), whereas the separation is relatively large in regions of small $|\nabla\chi|$.

42.1.3 Material invariance

We now have the necessary pieces to write the normal projection of the absolute vorticity according to the following

$$\boldsymbol{\omega}_{\mathrm{a}}\cdot\hat{\boldsymbol{n}}\,\delta\mathcal{S} = \frac{\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi}{|\nabla\chi|}\,\delta\mathcal{S} \qquad \text{equation (42.4)} \tag{42.8a}$$

$$= \frac{\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi}{|\nabla\chi|}\,\frac{\delta V}{\delta h} \qquad \text{equation (42.3)} \tag{42.8b}$$

$$= (\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi)\,\frac{\delta V}{\delta\chi} \qquad \text{equation (42.7)} \tag{42.8c}$$

$$= \frac{\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi}{\rho}\,\frac{\rho\,\delta V}{\delta\chi} \qquad \text{multiply by } \rho/\rho. \tag{42.8d}$$

FIGURE 42.2: Illustrating the geometry of a cylindrical region of fluid between two iso-surfaces of a field χ, separated by the infinitesimal amount $\delta\chi$. We can conceive of this cylinder as a portion of a vortex tube that is bounded by the two χ isosurfaces. The volume of the cylinder is $\delta V = \delta\mathcal{S}\,\delta h$, with δh the thickness and $\delta\mathcal{S}$ the area. By convention, the unit normal vector, $\hat{\boldsymbol{n}} = \nabla\chi/|\nabla\chi|$, points towards larger values of χ. It is here depicted at the center of the cylinder, which differs by an infinitesimal amount from the normal computed on either $\chi + \delta\chi/2$ or $\chi - \delta\chi/2$. If χ is a material invariant so that $\mathrm{D}\chi/\mathrm{D}t = 0$, then so too is its infinitesimal increment, $\mathrm{D}(\delta\chi)/\mathrm{D}t = 0$. As per equation (42.7), the geometric thickness between the isosurfaces is related to the field increment by $\delta h = \delta\chi/|\nabla\chi|$, so that the larger the magnitude of the gradient in the scalar field, the smaller the layer thickness. For a baroclinic fluid, material invariance of potential vorticity in a perfect fluid holds if we can find a field such that $\hat{\boldsymbol{n}} \cdot \boldsymbol{B} = 0$, with baroclinicity $\boldsymbol{B} = (\nabla\rho \times \nabla p)/\rho^2$.

Mass is materially invariant so that

$$\frac{\mathrm{D}\,(\rho\,\delta V)}{\mathrm{D}t} = 0. \tag{42.9}$$

Likewise, by assumption χ is materially invariant so that the increment between two χ isosurfaces is materially invariant

$$\frac{\mathrm{D}(\delta\chi)}{\mathrm{D}t} = 0. \tag{42.10}$$

Bringing these elements into Kelvin's circulation theorem (42.1) leads us to conclude that the potential vorticity, Q, is also materially invariant

$$Q \equiv \frac{\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi}{\rho} = \frac{\nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\chi)}{\rho} \quad \text{with} \quad \frac{\mathrm{D}Q}{\mathrm{D}t} = 0. \tag{42.11}$$

This expression for the potential vorticity is the most general form and it is often referred to as the *Ertel potential vorticity* (*Ertel*, 1942). The first expression shows the numerator as the projection of the absolute vorticity into the direction normal to χ isosurfaces. Conversely, it is a measure of the χ stratification in the direction of the absolute vorticity vector. The second expression follows since the absolute vorticity has zero divergence so that the numerator is a total divergence. This divergence form of the potential vorticity numerator has important implications for the potential vorticity budgets studied in Section 42.4 and throughout Chapter 43.

42.1.4 Perfect baroclinic fluid

Consider the case of a perfect baroclinic fluid, in which Kelvin's circulation theorem for an infinitesimal circuit takes the form

$$\frac{\mathrm{D}}{\mathrm{D}t}(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\,\delta\mathcal{S}) = \boldsymbol{B} \cdot \hat{\boldsymbol{n}}\,\delta\mathcal{S}. \tag{42.12}$$

The source on the right hand side involves the baroclinicity vector, $\boldsymbol{B}$, discussed in Sections 41.2 and 41.4, which is the curl of the pressure gradient acceleration

$$\boldsymbol{B} = \nabla \times (-\rho^{-1}\,\nabla p) = \rho^{-2}\,\nabla\rho \times \nabla p. \tag{42.13}$$

Now assume there exists a materially invariant field, $\mathrm{D}\chi/\mathrm{D}t = 0$, that also annihilates the baroclinicity vector as in Figure 42.3, so that

$$\boldsymbol{B} \cdot \hat{\boldsymbol{n}} = \frac{\boldsymbol{B} \cdot \nabla\chi}{|\nabla\chi|} = 0. \tag{42.14}$$

In that case, the derivation detailed earlier for the barotropic fluid follows directly for the baroclinic case, in which case we conclude that potential vorticity remains materially invariant

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = 0 \qquad \text{where} \qquad Q = \frac{\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi}{\rho}. \tag{42.15}$$

FIGURE 42.3: Material invariance of potential vorticity is ensured for perfect fluids that admit a materially invariant field that also annihilates the baroclinicity vector. Mathematically, this property means that $\hat{\boldsymbol{n}} \cdot \boldsymbol{B} = 0$ where $\hat{\boldsymbol{n}} = \nabla\chi/|\nabla\chi|$ is the unit normal direction for the surface. In this figure we depict the baroclinicity vector, $\boldsymbol{B}$, that is aligned with χ isosurfaces.

The existence of a materially invariant potential vorticity for perfect baroclinic fluids depends on the existence of a materially invariant scalar field that annihilates the baroclinicity vector. Buoyancy is the most common choice for this field in geophysical fluid applications, with buoyancy typically measured by specific entropy or potential temperature in the atmosphere and potential density in the ocean. We have more to say on the chosen field in the remainder of this chapter as well as in Section 43.3.

42.1.5 A variety of materially invariant potential vorticities

The material invariant statement

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = \frac{\mathrm{D}(\rho^{-1}\,\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi)}{\mathrm{D}t} = 0 \tag{42.16}$$

generates a number of further materially invariant fields. First, consider any function of Q, whereby

$$\frac{\mathrm{D}\mathcal{F}(Q)}{\mathrm{D}t} = \frac{\mathrm{d}\mathcal{F}}{\mathrm{d}Q}\,\frac{\mathrm{D}Q}{\mathrm{D}t} = 0, \tag{42.17}$$

which follows since $\mathrm{D}Q/\mathrm{D}t = 0$. Among the infinite number of possible functions, $\mathcal{F}(Q)$, the most commonly considered is $\mathcal{F}(Q) = Q^2$, whose global integral is referred to as the *potential enstrophy*.

Second, consider the *iterated potential vorticity* defined according to

$$Q^{(1)} = \rho^{-1}\,\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi \quad \text{and} \quad Q^{(n)} = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla Q^{(n-1)} \quad \text{for } n = 2, 3, 4... \tag{42.18}$$

As defined, $Q^{(1)}$ is the familiar Ertel potential vorticity, whereas higher iterations replace the field, χ, with $Q^{(n-1)}$. Since $Q^{(n-1)}$ is materially invariant, so too is $Q^{(n)}$. Consider the example

$$Q^{(2)} = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla Q^{(1)} = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla(\rho^{-1}\,\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi) = \nabla \cdot [\boldsymbol{\omega}_{\mathrm{a}}\,\rho^{-1}\,(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi)], \tag{42.19}$$

which reveals that there are n powers of absolute vorticity for $Q^{(n)}$.

42.1.6 Some remarks about potential vorticity

Perfect fluid PV material invariance ↔ Kelvin's circulation theorem

Kelvin's circulation theorem from Section 41.2.3 is at the heart of the derivations presented in this section, with the theorem applied to a strategically chosen infinitesimal loop. Because the loop is tiny, we use Stokes' theorem to convert the line integral expression of Kelvin's theorem into a statement about the material evolution of absolute vorticity projected onto the normal direction of the loop, and multiplied by the loop area. We further specialize the theorem to a cylindrical region between two isosurfaces of a materially invariant field. For the perfect barotropic fluid, we merely require that both the mass of the cylinider and the field to be materially invariant in order to realize a potential vorticity that is also materially invariant. For a baroclinic fluid, material invariance of potential vorticity requires a field that is both materially invariant *and* that annihilates the baroclinicity vector. We have more to say in regards to the availability of such fields in the remainder of this chapter.

There are numerous forms for potential vorticity

The expression (42.11) is, on first glance, quite distinct from the shallow water potential vorticity, $Q = (\zeta + f)/h$, studied in Chapter 40 (see equation (40.30)). However, as shown in Section 62.3, they are closely related for the special case of entropic potential vorticity in a Boussinesq ocean when formulated using isopycnal/isentropic coordinates. Even so, there are a variety of other forms for potential vorticity, with the forms (and physical dimensions) depending on the dynamical and thermodynamical properties. We encounter some further forms of potential vorticity in the remainder of this chapter, as well as in the oceanic potential vorticity discussions of Chapter 62 and in our study of balanced models in Part VIII. The review paper by *Müller* (1995) offers a lucid presentation of potential vorticity and its many forms encountered in physical oceanography.

Motivating the adjective "potential"

In Section 40.3.2 we motivated the advective "potential" for the shallow water potential vorticity. We do so here for Ertel's potential vorticity. For that purpose, write potential vorticity in the form

$$Q = \frac{\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}}{\rho}\,|\nabla\chi| \qquad \text{with} \qquad \hat{\boldsymbol{n}} = \frac{\nabla\chi}{|\nabla\chi|}. \tag{42.20}$$

In cases where ρ is roughly a constant, and when Q is materially invariant, the component of the absolute vorticity in the direction parallel to $\nabla\chi$ increases when the fluid parcel moves into a region where $|\nabla\chi|$ decreases. There is hence a "release" of absolute vorticity aligned with $\nabla\chi$ in regions where χ isosurfaces are spread. We conceive of this increased vorticity as through the stretching of the cylindrical vortex tube extending between χ isosurfaces along the $\hat{\boldsymbol{n}}$ direction. In

contrast, when the χ isosurfaces are tightly packed, then the vortex tube is squashed and so too is the vorticity. We thus conceive of potential vorticity as the "potential" for releasing absolute vorticity that is oriented in the direction parallel to $\nabla\chi$.

Potential vorticity as a dynamical tracer

We refer to potential vorticity as a *dynamical tracer* since it depends directly on the velocity field through the vorticity. It also depends on the scalar field, χ, which is commonly taken as a thermodynamic tracer such as the potential temperature, θ. In these cases, potential vorticity embodies both dynamical and thermodynamical information; i.e., it measures properties of both the flow and the fluid. In contrast, material tracers such as salinity, and thermodynamic tracers such as θ, are properties of the fluid whose distribution is affected by the velocity but whose local measurement does not require knowledge of the flow.

Entropic potential vorticity as the grand unifier

Entropic potential vorticity provides a connection between vorticity (mechanics) and stratification (thermodynamics). By connecting these two basic facets of geophysical fluid flows, the study of potential vorticity and its conservation properties provides a powerful and unique lens to help rationalize the huge variety of geophysical flow regimes, and to predict their response to changes in forcing. It is for this reason that potential vorticity is sometimes considered the grand unifying concept in geophysical fluid mechanics.

Potential vorticity as a diagnostic tracer

Suppose we have an initial flow field in which $\rho\, Q = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi = 0$, which means that the absolute vorticity is aligned with surfaces of constant χ. In an inviscid and adiabatic fluid, material conservation of Q means that $\boldsymbol{\omega}_{\mathrm{a}}$ remains within constant χ surfaces for all time. We infer from this particular example that if we know the evolution of χ, then we know the evolution of vortex lines defined by $\boldsymbol{\omega}_{\mathrm{a}}$, which in turn allows for the inference of a number of further flow properties. This particular example offers a hint at the multiple applications of "PV thinking" to understand and predict fluid motion, with *Hoskins* (1991) providing an elegant survey of such thinking.

Potential vorticity versus momentum

Momentum is affected by pressure, and pressure fluctuations propagate at the speed of sound (Chapter 49) for compressible flows and oceanic Boussinesq flows, whereas they move with infinite speed for fully incompressible fluids. In contrast, potential vorticity, for those cases where we can remove the effects of the baroclinicity vector, does not directly feel the impacts from pressure fluctuations. Hence, potential vorticity, much like vorticity in a barotropic fluid, evolves much slower and more locally than momentum. This dynamical difference offers a key reason that potential vorticity offers added insights into fluid flows beyond that afforded by momentum.

Potential vorticity for non-divergent barotropic flow

A non-standard, but relevant, choice for the function χ used to define potential vorticity is given by the vertical coordinate

$$\chi = z, \tag{42.21}$$

in which case

$$\rho\, Q = \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{z}} = \zeta_{\mathrm{a}}. \tag{42.22}$$

In Chapter 39, we consider the two-dimensional non-divergent barotropic model, in which case ρ is a constant and

$$w = \frac{\mathrm{D}z}{\mathrm{D}t} = 0. \tag{42.23}$$

The corresponding materially invariant potential vorticity is the vertical component of the absolute vorticity divided by the constant density. Ignoring the constant density leads to the potential vorticity in this flow given by the absolute vorticity

$$q = \zeta_{\mathrm{a}} = \zeta + f. \tag{42.24}$$

42.2 Potential vorticity and seawater

As seen in Section 42.1, material invariance of potential vorticity for a perfect fluid requires a materially invariant scalar field to annihilate the baroclinicity vector. There is no such scalar field for the ocean with a realistic seawater equation of state. Nonetheless, there are important approximate cases that allow for material potential vorticity invariance, and we explore such cases in this section.

42.2.1 Baroclinicity vector

Recall the baroclinicity vector given by (Sections 41.2 and 41.4)

$$\boldsymbol{B} = \frac{\nabla\rho \times \nabla p}{\rho^2}. \tag{42.25}$$

If we take the *in situ* density as the scalar field to define potential vorticity, then $\boldsymbol{B} \cdot \nabla\rho = 0$. However, *in situ* density is not a conserved scalar in the ocean due to pressure effects. Namely, with *in situ* density having the function dependence $\rho = \rho(S, \Theta, p)$ (see Section 31.3), its material time derivative is

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{\partial\rho}{\partial S}\frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial\rho}{\partial\Theta}\frac{\mathrm{D}\Theta}{\mathrm{D}t} + \frac{\partial\rho}{\partial p}\frac{\mathrm{D}p}{\mathrm{D}t}. \tag{42.26}$$

Even when salinity and Conservative Temperature are materially constant, $\mathrm{D}S/\mathrm{D}t = 0$ and $\mathrm{D}\Theta/\mathrm{D}t = 0$, the *in situ* density has a nonzero material time derivative due to material pressure changes, $\mathrm{D}p/\mathrm{D}t \neq 0$. Material changes in the pressure of a fluid element arise even in the absence of irreversible mixing. In general, such *mechanical changes* arise due to the gradients in the pressure field that the fluid element feels. Given that pressure affects *in situ* density, with such effects occuring even in a perfect fluid, we conclude that *in situ* density is not an appropriate scalar for developing a materially invariant potential vorticity. For the same reason, we do not consider pressure as a suitable scalar field.

42.2.2 Potential vorticity based on potential density, ϱ

Potential density is commonly used in oceanography (see Section 31.3.4), with potential density the *in situ* density referenced to a chosen pressure.[2] We write potential density as in equation (31.18)

$$\varrho(S, \Theta) = \rho(S, \Theta, p = p_{\mathrm{ref}}), \tag{42.27}$$

[2]Oceanographers often choose the reference pressure as the standard atmospheric sea level pressure. However, that is not required for the following formalism to hold; any reference pressure is suitable.

so that its material time derivative is

$$\frac{\mathrm{D}\varrho}{\mathrm{D}t} = \frac{\partial \varrho}{\partial S}\frac{\mathrm{D}S}{\mathrm{D}t} + \frac{\partial \varrho}{\partial \Theta}\frac{\mathrm{D}\Theta}{\mathrm{D}t}, \tag{42.28}$$

which vanishes in the absence of irreversible material changes to salinity and Conservative Temperature. When using potential density as the scalar field for potential vorticity, the baroclinicity vector projects onto the diapycnal direction according to

$$\begin{aligned}
\rho^2 \boldsymbol{B} \cdot \nabla \varrho &= (\nabla \rho \times \nabla p) \cdot \nabla \varrho && (42.29a)\\
&= (\nabla \varrho \times \nabla \rho) \cdot \nabla p && (42.29b)\\
&= [(\varrho_S \nabla S + \varrho_\Theta \nabla \Theta) \times (\rho_S \nabla S + \rho_\Theta \nabla \Theta + \rho_p \nabla p)] \cdot \nabla p && (42.29c)\\
&= [(\varrho_S \nabla S + \varrho_\Theta \nabla \Theta) \times (\rho_S \nabla S + \rho_\Theta \nabla \Theta)] \cdot \nabla p && (42.29d)\\
&= [\varrho_S \nabla S \times \rho_\Theta \nabla \Theta + \varrho_\Theta \nabla \Theta \times \rho_S \nabla S] \cdot \nabla p && (42.29e)\\
&= (\varrho_S \rho_\Theta - \varrho_\Theta \rho_S)(\nabla S \times \nabla \Theta) \cdot \nabla p, && (42.29f)
\end{aligned}$$

where we used the shorthand notation for partial derivatives

$$\rho_S = \frac{\partial \rho}{\partial S} \quad \text{and} \quad \varrho_S = \frac{\partial \varrho}{\partial S} \tag{42.30a}$$

$$\rho_\Theta = \frac{\partial \rho}{\partial \Theta} \quad \text{and} \quad \varrho_\Theta = \frac{\partial \varrho}{\partial \Theta}. \tag{42.30b}$$

Note that the triple product, $(\nabla S \times \nabla \Theta) \cdot \nabla p$, also appears in the discussion of neutral helicity in Section 31.6 (see equation (31.64)). Equation (42.29f) allows us to identify cases where the baroclinicity vector is annihilated, $\boldsymbol{B} \cdot \nabla \varrho = 0$, thus yielding a materially invariant potential vorticity in the absence of irreversible processes.

- UNIFORM SALINITY OR UNIFORM CONSERVATIVE TEMPERATURE: If salinity or Conservative Temperature are spatially uniform, then $\boldsymbol{B} \cdot \nabla \varrho = 0$.

- ADDITIVE PRESSURE DEPENDENCE TO THE *in situ* DENSITY: There is a materially invariant potential vorticity with a vanishing thermodynamic pre-factor in equation (42.29f), $\varrho_S \rho_\Theta - \varrho_\Theta \rho_S$. This term does not generally vanish since the ocean has a pressure dependent equation of state, and this pressure dependence generally means that $\boldsymbol{B} \cdot \nabla \varrho \neq 0$. Even so, we can annihilate the baroclinicity vector if the *in situ* density has a pressure dependence that is additive, in which case we can write

$$\rho(S, \Theta, p) = \varrho(S, \Theta) + F(p) - F(p_{\mathrm{ref}}) \Longrightarrow \varrho_S \rho_\Theta - \varrho_\Theta \rho_S = 0. \tag{42.31}$$

  Notably, we did not assume a linear equation of state; only that it has the special functional form in equation (42.31). For some cases, we may assume F to be a constant, in which case there is no pressure dependence so that *in situ* density is the same as potential density.

42.2.3 An example EOS admitting a materially invariant PV

An explicit realization of the equation of state (42.31) can be found by taking a Taylor series expansion of the *in situ* density around the reference pressure, and evaluating the derivatives in the expansion in terms of a chosen reference pressure, reference salinity, and

reference Conservative Temperature

$$\rho(S,\Theta,p) \approx \varrho(S,\Theta) + \underbrace{(p-p_{\mathrm{ref}})\left[\frac{\partial\rho}{\partial p}\right]_{S=S_{\mathrm{ref}},\Theta=\Theta_{\mathrm{ref}},p=p_{\mathrm{ref}}} + H.O.T.}_{F(p)-F(p_{\mathrm{ref}})} \tag{42.32}$$

where

$$\varrho(S,\Theta) = \rho(S,\Theta,p_{\mathrm{ref}}) \tag{42.33}$$

is the potential density referenced to $p = p_{\mathrm{ref}}$, and where $H.O.T.$ symbolizes higher order terms. This approach ignores the salinity and Conservative Temperature dependence of terms in the Taylor series expansion. Ignoring this dependence is a rather good approximation for many purposes since the ocean sound speed is not far from a constant

$$c_{\mathrm{s}}^{-2} = \frac{\partial\rho}{\partial p} \approx \text{constant}. \tag{42.34}$$

In this case, the equation of state takes the form

$$\rho(S,\Theta,p) \approx \varrho(S,\Theta) + \frac{p-p_{\mathrm{ref}}}{c_{\mathrm{s}}^2}, \tag{42.35}$$

42.2.4 Further reading

The presentation given here follows that given in Section 4.5.4 of *Vallis* (2017). *Straub* (1999) focuses on the source of potential vorticity arising from a nonzero thermobaricity parameter, $\mathcal{T} = \partial_p(\alpha/\beta)$ (see Section 67.3.4). In Section 42.6 we reconsider the notions presented here by suggesting the relevance of an alternative potential vorticity field that is attached to a finite sized region rather than to a fluid particle.

42.3 Potential vorticity evolution in real fluids

Thus far we have considered perfect fluids, with the use of Kelvin's circulation theorem a suitable framework to derive the material invariance of potential vorticity. In this section we consider a real fluid that contains non-conservative processes. Potential vorticity is no longer materially invariant when exposed to non-conservative processes such as mixing, friction, and diabatic sources.

To develop the potential vorticity budget in the presence of non-conservative processes, we pursue an algebraic approach that starts from the vorticity equation (41.42)

$$\rho\,\frac{\mathrm{D}(\boldsymbol{\omega}_{\mathrm{a}}/\rho)}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla)\,\boldsymbol{v} + \boldsymbol{B} + \nabla\times\boldsymbol{F}, \tag{42.36}$$

where $\boldsymbol{F}$ is the acceleration from non-conservative forces and $\boldsymbol{B}$ the baroclinicity vector. Furthermore, we introduce a scalar field that generally has a nonzero material evolution

$$\frac{\mathrm{D}\chi}{\mathrm{D}t} = \dot{\chi}, \tag{42.37}$$

with $\dot{\chi}$ arising from diffusion, sources, boundary fluxes, or other processes that lead to material evolution of χ.

As part of the manipulations in this section, we make use of the identity

$$(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla) \frac{\mathrm{D}\chi}{\mathrm{D}t} = \boldsymbol{\omega}_{\mathrm{a}} \cdot \frac{\mathrm{D}\,(\nabla\chi)}{\mathrm{D}t} + [(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v}] \cdot \nabla\chi, \tag{42.38}$$

which is readily proven by expanding terms and assuming Cartesian coordinates. Rearrangement, and use of the scalar equation (42.37), leads to

$$\boldsymbol{\omega}_{\mathrm{a}} \cdot \frac{\mathrm{D}\,(\nabla\chi)}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\dot{\chi} - [(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v}] \cdot \nabla\chi. \tag{42.39}$$

Now project the vorticity equation (42.36) onto the direction normal to the χ isosurfaces

$$\rho\,\nabla\chi \cdot \frac{\mathrm{D}(\boldsymbol{\omega}_{\mathrm{a}}/\rho)}{\mathrm{D}t} = \nabla\chi \cdot [(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\boldsymbol{v}] + \nabla\chi \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}). \tag{42.40}$$

The sum of equations (42.39) and (42.40) leads to

$$\rho\,\frac{\mathrm{D}(\nabla\chi \cdot \boldsymbol{\omega}_{\mathrm{a}}/\rho)}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\dot{\chi} + \nabla\chi \cdot (\boldsymbol{B} + \nabla \times \boldsymbol{F}). \tag{42.41}$$

This equation is general so that it applies to any scalar field.

To simplify the source terms on the right hand side of equation (42.41), follow the discussion from Section 42.1.4 by assuming that χ annihilates the baroclinicity vector.[3] This scalar field is typically given by potential temperature, specific entropy, buoyancy, or potential density. We thus have

$$\nabla\chi \cdot \boldsymbol{B} = 0, \tag{42.42}$$

which in turn leads to the potential vorticity equation in the presence of irreversible processes such as friction and mixing

$$\rho\,\frac{\mathrm{D}Q}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\dot{\chi} + \nabla\chi \cdot (\nabla \times \boldsymbol{F}), \tag{42.43}$$

where the potential vorticity is again given by

$$Q = \frac{\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla\chi}{\rho}. \tag{42.44}$$

If χ is a thermodynamic scalar such as potential entropy, then the material evolution of potential vorticity is affected by diabatic processes (heating and cooling) as well as friction. Hence, the potential vorticity of a fluid element can be either generated or destroyed depending on details of these irreversible process. Such processes are often localized to areas of mixing as well as to boundaries where strong mechanical and/or buoyancy processes are active. The study of how potential vorticity is materially modified by irreversible processes forms an important area of research in potential vorticity dynamics. We have more to say on this notion when studying budgets of potential vorticity in Chapter 43.

42.4 Flux-form potential vorticity budget

The material invariance of potential vorticity is an example of a material or Lagrangian conservation property of perfect fluids, with the material conservation statement $\rho\,\mathrm{D}Q/\mathrm{D}t = 0$ having

[3] In Section 43.3 we study what happens when no such scalar exists.

its flux-form expression

$$\partial_t(\rho\, Q) + \nabla\cdot(\rho\, \boldsymbol{v}\, Q) = 0 \qquad \text{perfect fluid.} \tag{42.45}$$

Following the formalism established for material tracers in Section 21.2, the flux-form local conservation law (42.45) leads to conservation properties over finite regions, which we refer to as *global conservation* laws. In this section we examine the flux-form budget in the presence of non-conservative processes. In particular, we show that the Eulerian evolution of potential vorticity continues to be determined by the convergence of a flux, thus allowing for natural extensions to global conservation laws and budget analyses.

42.4.1 Deriving the flux-form potential vorticity budget

To transform the material evolution equation (42.43) into a flux-form equation we make use of the following identities

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla \qquad \text{relating material and Eulerian time changes} \tag{42.46a}$$

$$\frac{\mathrm{D}\rho}{\mathrm{D}t} = -\rho\,\nabla\cdot\boldsymbol{v} \qquad \text{mass conservation} \tag{42.46b}$$

$$(\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla)\,\dot{\chi} = \nabla\cdot(\boldsymbol{\omega}_{\mathrm{a}}\,\dot{\chi}) \qquad \text{absolute vorticity is non-divergent: } \nabla\cdot\boldsymbol{\omega}_{\mathrm{a}} = 0 \tag{42.46c}$$

$$\nabla\chi\cdot(\nabla\times\boldsymbol{F}) = \nabla\cdot(\boldsymbol{F}\times\nabla\chi) \qquad \text{divergence of curl vanishes.} \tag{42.46d}$$

The identity (42.46d) follows from

$$\nabla\chi\cdot(\nabla\times\boldsymbol{F}) = \nabla\cdot(\chi\,\nabla\times\boldsymbol{F}) = \nabla\cdot[\nabla\times(\chi\,\boldsymbol{F}) - \nabla\chi\times\boldsymbol{F}] = \nabla\cdot(\boldsymbol{F}\times\nabla\chi), \tag{42.47}$$

where a vanishing divergence of a curl is needed to reach the first and third equalities. These identities then lead to the material evolution equation

$$\rho\,\frac{\mathrm{D}Q}{\mathrm{D}t} = \nabla\cdot(\boldsymbol{\omega}_{\mathrm{a}}\,\dot{\chi} + \boldsymbol{F}\times\nabla\chi). \tag{42.48}$$

Now converting the material time derivative into its Eulerian expression, and making use of mass conservation, renders the flux-form potential vorticity budget equation

$$\partial_t(\rho\, Q) + \nabla\cdot[\rho\, Q\,\boldsymbol{v} - \boldsymbol{\omega}_{\mathrm{a}}\,\dot{\chi} - \boldsymbol{F}\times\nabla\chi] = 0. \tag{42.49}$$

42.4.2 PV-substance and the potential vorticity flux

The budget equation (42.49) says that the density-weighted potential vorticity

$$\rho\, Q = \boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi \tag{42.50}$$

has a local time tendency determined by the convergence of the potential vorticity flux vector

$$\partial_t(\rho\, Q) = -\nabla\cdot\boldsymbol{J}_{\mathrm{Q}} \qquad \text{with} \qquad \boldsymbol{J}_{\mathrm{Q}} = \rho\, Q\,\boldsymbol{v} - \boldsymbol{\omega}_{\mathrm{a}}\,\dot{\chi} - \boldsymbol{F}\times\nabla\chi. \tag{42.51}$$

The budget (42.49) follows a form similar to material tracers detailed in Chapter 21, though here with some particularly specific terms in the potential vorticity flux vector, $\boldsymbol{J}_{\mathrm{Q}}$. The correspondence suggests that one consider equation (42.49) as the local budget for *PV-substance*, with Q the concentration of PV-substance and $\boldsymbol{J}_{\mathrm{Q}}$ its flux. This interpretation is pursued further in Chapter

43 when exposing the rather novel properties of budgets for PV-substance when integrated over regions bounded by isentropes.

The first term in the PV-substance flux vector (42.51) arises from the advection of PV-substance; the second contribution arises from processes leading to material evolution of χ; and the third from a friction acceleration that is not parallel to $\nabla\chi$. Note that the form of the friction contribution suggests that we think of the friction as contributing to a torque that rotates the χ isosurfaces as it modifies the PV-substance (see Figure 42.4).

FIGURE 42.4: The contribution from friction to the potential vorticity flux is given by $\boldsymbol{J}_{\text{friction}} = \nabla\chi \times \boldsymbol{F}$. This cross product is nonzero only when the frictional acceleration is not fully aligned with $\nabla\chi$. Friction creates potential vorticity by rotating χ isosurfaces. Hence, if friction is aligned with $\nabla\chi$, or when there is no spatial structure to $\nabla\chi \times \boldsymbol{F}$ (i.e., zero divergence), then friction does not contribute to potential vorticity evolution. This interpretation is analogous to that given to the effects from baroclinicity on vorticity given in Section 41.4.

42.4.3 Gauge freedom

As seen by the potential vorticity equation (42.51), the time tendency for PV-substance, $\partial_t(\rho Q)$, is unchanged by adding the curl of a vector to the PV-substance flux, $\boldsymbol{J}_{\text{Q}}$. This ambiguity manifests a *gauge freedom*. We here exhibit the gauge freedom associated with $\boldsymbol{J}_{\text{Q}}$, and expose yet another gauge freedom associated with the potential vorticity itself. We offer more discussion of gauge freedom in Section 22.5.1 and further the use of gauge freedom for the study of potential vorticity in Section 42.5 as well as throughout Chapter 43.

Gauge freedom associated with the PV-substance flux

One way to further expose gauge freedom is by writing

$$\rho Q = \nabla\chi \cdot \boldsymbol{\omega}_{\text{a}} = \nabla \cdot (\chi\, \boldsymbol{\omega}_{\text{a}}), \tag{42.52}$$

so that

$$\partial_t(\rho Q) = \partial_t[\nabla \cdot (\chi\, \boldsymbol{\omega}_{\text{a}})] = \nabla \cdot [\partial_t(\chi\, \boldsymbol{\omega}_{\text{a}})], \tag{42.53}$$

where the time derivative commutes with the divergence operator. We can thus write the potential vorticity equation (42.51) in the form

$$\nabla \cdot [\partial_t(\chi\, \boldsymbol{\omega}_{\text{a}}) + \boldsymbol{J}_{\text{Q}}] = 0. \tag{42.54}$$

This equation means that $\partial_t(\chi\,\boldsymbol{\omega}_{\rm a})$ and $\boldsymbol{J}_{\rm Q}$ differ by the curl of a vector

$$\partial_t(\chi\,\boldsymbol{\omega}_{\rm a}) + \boldsymbol{J}_{\rm Q} = -\nabla\times\boldsymbol{A}, \tag{42.55}$$

with $\boldsymbol{A}$ referred to as a *gauge function*. The minus sign is arbitrary and is introduced to correspond to the discussion in Section 42.5.

Gauge freedom arising from the non-divergent nature of vorticity

The divergence form of PV-substance given by equation (42.52) reveals that $\rho\,Q$ remains unchanged if we add a total curl to the argument of the divergence operator. In particular, consider the identities[4]

$$\chi\,\boldsymbol{\omega}_{\rm a} = \chi\,(\nabla\times\boldsymbol{v} + 2\,\boldsymbol{\Omega}) \qquad \text{since } \boldsymbol{\omega}_{\rm a} = \boldsymbol{\omega} + 2\,\boldsymbol{\Omega} \tag{42.56a}$$

$$= \nabla\times(\chi\,\boldsymbol{v}) - \nabla\chi\times\boldsymbol{v} + \chi\,2\,\boldsymbol{\Omega} \qquad \text{move gradient operator.} \tag{42.56b}$$

We have thus moved the curl operation acting on the velocity field (to compute relative vorticity) onto a gradient of the scalar field, with a total curl making up the difference. Since $\nabla\cdot[\nabla\times(\chi\,\boldsymbol{v})] = 0$, we are led to the equivalent expressions for PV-substance

$$\rho\,Q = \nabla\chi\cdot\boldsymbol{\omega}_{\rm a} = \nabla\cdot(\chi\,2\,\boldsymbol{\Omega} + \chi\,\boldsymbol{\omega}) = \nabla\cdot(2\,\boldsymbol{\Omega}\,\chi - \nabla\chi\times\boldsymbol{v}) = \nabla\chi\cdot(2\,\boldsymbol{\Omega}) - \nabla\cdot(\nabla\chi\times\boldsymbol{v}). \tag{42.57}$$

The result of these manipulations is an expression for the Ertel potential vorticity that does not involve the relative vorticity, but is instead written as the convergence of a flux

$$\rho\,Q = -\nabla\cdot(-2\,\boldsymbol{\Omega}\,\chi + \nabla\chi\times\boldsymbol{v}). \tag{42.58}$$

This form involves the component of the velocity that is parallel to χ isosurfaces since

$$(\nabla\chi\times\boldsymbol{v})\cdot\nabla\chi = 0. \tag{42.59}$$

Besides offering a curious expression for potential vorticity that does not require the relative vorticity, we show in Section 43.4 how the formulation (42.58) can be especially useful for developing budgets of integrated PV-substance.

In the manipulations (42.56a)-(42.56b), we did not touch the planetary vorticity term. We certainly could do so, in which case

$$\chi\,2\,\boldsymbol{\Omega} = \chi\,\nabla\times(\boldsymbol{\Omega}\times\boldsymbol{x}) = \nabla\times(\chi\,\boldsymbol{\Omega}\times\boldsymbol{x}) - \nabla\chi\times(\boldsymbol{\Omega}\times\boldsymbol{x}). \tag{42.60}$$

The term $\nabla\times(\chi\,\boldsymbol{\Omega}\times\boldsymbol{x})$ drops out when taking the divergence. However, the term $\boldsymbol{\Omega}\times\boldsymbol{x}$ requires us to evaluate the position vector, $\boldsymbol{x}$, for each point in the fluid, and doing so is not generally convenient. For this reason, we do not modify the planetary vorticity contribution to the potential vorticity, preferring to keep the form $\chi\,2\,\boldsymbol{\Omega}$ in equation (42.58).

42.5 A hydrostatic primitive equation and Boussinesq ocean

Building on the vorticity budget in Section 41.7, we here develop the PV-substance budget for a hydrostatic primitive equation Boussinesq ocean in the presence of diabatic and frictional forcing.

[4] We encounter similar mathematical manipulations in Section 64.6 when studying the connection between advection and skew diffusion in the tracer equation.

For that purpose, recall the vorticity equation for a hydrostatic and Boussinesq ocean (41.146)

$$\frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}}{\mathrm{D}t} = \underbrace{(\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla)\, \boldsymbol{v}}_{\text{stretching + tilting}} + \underbrace{\nabla \times \hat{\boldsymbol{z}}\, b}_{\text{baroclinicity}} + \underbrace{\nabla \times \boldsymbol{F}}_{\text{friction curl}}, \tag{42.61}$$

where b is the Archimedean buoyancy used in our discussion of the Boussinesq ocean in Chapter 30, and

$$\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} = \boldsymbol{\omega}^{\mathrm{hy}} + f\, \hat{\boldsymbol{z}} = \nabla \times \boldsymbol{u} + f\, \hat{\boldsymbol{z}} \tag{42.62}$$

is the absolute vorticity for the hydrostatic fluid (see equations (41.135) and (41.144)).

42.5.1 Potential vorticity

Baroclinicity is eliminated from the vorticity equation (42.61) by projecting the absolute vorticity onto the direction normal to buoyancy surfaces

$$\nabla b \cdot \frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}}{\mathrm{D}t} = \nabla b \cdot [(\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla)\, \boldsymbol{v}] + \nabla b \cdot (\nabla \times \boldsymbol{F}), \tag{42.63}$$

where we used

$$\nabla b \cdot (\nabla \times \hat{\boldsymbol{z}}\, b) = \nabla b \cdot (\nabla b \times \hat{\boldsymbol{z}}) = 0. \tag{42.64}$$

We next make use of the identity

$$\frac{\mathrm{D}(\partial b/\partial x^i)}{\mathrm{D}t} = \frac{\partial}{\partial x^i}\left[\frac{\mathrm{D}b}{\mathrm{D}t}\right] - \nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial x^i} = \frac{\partial \dot{b}}{\partial x^i} - \nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial x^i}, \tag{42.65}$$

so that

$$\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \left[\frac{\mathrm{D}\,\nabla b}{\mathrm{D}t}\right] = \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla \dot{b} - \nabla b \cdot [(\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla)\, \boldsymbol{v}]. \tag{42.66}$$

Making use of this result in equation (42.63) renders

$$\nabla b \cdot \frac{\mathrm{D}\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}}{\mathrm{D}t} + \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \frac{\mathrm{D}\nabla b}{\mathrm{D}t} = \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla \dot{b} + \nabla b \cdot (\nabla \times \boldsymbol{F}), \tag{42.67}$$

which leads to

$$\frac{\mathrm{D}Q}{\mathrm{D}t} = \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla \dot{b} + \nabla b \cdot (\nabla \times \boldsymbol{F}) \tag{42.68}$$

where

$$Q = \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla b = \boldsymbol{\omega}^{\mathrm{hy}} \cdot \nabla b + f\, \partial_z b \tag{42.69}$$

is the potential vorticity for a rotating hydrostatic Boussinesq ocean. Potential vorticity is materially invariant for the inviscid and adiabatic case, in which $\boldsymbol{F} = 0$ and $\dot{b} = 0$.

It is sometimes useful to split the hydrostatic vorticity into its vertical and horizontal terms as per equation (41.135). In this way, potential vorticity takes on the form

$$Q = \frac{\partial u}{\partial z}\frac{\partial b}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b}{\partial x} + (\zeta + f)\,\frac{\partial b}{\partial z} = \hat{\boldsymbol{z}} \cdot \left[\frac{\partial \boldsymbol{u}}{\partial z} \times \nabla b\right] + (\zeta + f)\,\frac{\partial b}{\partial z}. \tag{42.70}$$

This expression plays an important role in characterizing flows with order unity Rossby number, where the term $\hat{\boldsymbol{z}} \cdot (\partial_z \boldsymbol{u} \times \nabla b)$ can become comparable to $(\zeta + f)\,\partial_z b$, particularly in regions of strong horizontal buoyancy fronts such as those studied by *Thomas et al.* (2008) and *Thomas et al.* (2013).

42.5.2 Potential vorticity flux vector

The material form of the potential vorticity equation (42.68) is converted into its flux-form via

$$\partial_t Q + \nabla\cdot(\boldsymbol{v}\,Q) = \boldsymbol{\omega}_{\rm a}^{\rm hy}\cdot\nabla\dot{b} + \nabla b\cdot(\nabla\times\boldsymbol{F}) \tag{42.71a}$$
$$= \nabla\cdot[\dot{b}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + b\,(\nabla\times\boldsymbol{F})] \tag{42.71b}$$
$$= \nabla\cdot[\dot{b}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + \nabla\times(b\,\boldsymbol{F}) - \nabla b\times\boldsymbol{F}] \tag{42.71c}$$
$$= \nabla\cdot(\dot{b}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} - \nabla b\times\boldsymbol{F}), \tag{42.71d}$$

where we used

$$\nabla\cdot\boldsymbol{v} = 0 \qquad \text{Boussinesq flow is non-divergent} \tag{42.72a}$$
$$\nabla\cdot\boldsymbol{\omega}_{\rm a}^{\rm hy} = 0 \qquad \text{vorticity always has zero divergence} \tag{42.72b}$$
$$\nabla\cdot(\nabla\times\boldsymbol{F}) = 0 \qquad \text{divergence of curl vanishes} \tag{42.72c}$$
$$\nabla\cdot[\nabla\times(b\,\boldsymbol{F})] = 0 \qquad \text{divergence of curl vanishes.} \tag{42.72d}$$

The conservation equation (42.71d) allows us to identify a potential vorticity flux vector

$$\boldsymbol{J}_{\rm Q} = \boldsymbol{v}\,Q - \dot{b}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + \nabla b\times\boldsymbol{F} + \nabla\times\boldsymbol{A}, \tag{42.73}$$

so that the potential vorticity equation takes the form

$$\partial_t Q + \nabla\cdot\boldsymbol{J}_{\rm Q} = 0. \tag{42.74}$$

The potential vorticity flux (42.73) is comprised of an advective term

$$\boldsymbol{J}_{\rm advective} = \boldsymbol{v}\,Q, \tag{42.75}$$

and non-advective terms arising from diabatic and frictional forcing,

$$\boldsymbol{J}_{\rm non\text{-}advective} = -\dot{b}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + \nabla b\times\boldsymbol{F}, \tag{42.76}$$

as well as a gauge term,

$$\boldsymbol{J}_{\rm gauge} = \nabla\times\boldsymbol{A}, \tag{42.77}$$

whose form remains unspecified.

42.5.3 Kinematic derivation of the PV-substance flux

Following the discussion in Section 42.4.3, we consider a purely kinematic derivation of the potential vorticity flux vector. For that purpose write the hydrostatic Boussinesq potential vorticity in the form

$$Q = \boldsymbol{\omega}_{\rm a}^{\rm hy}\cdot\nabla b = \nabla\cdot(b\,\boldsymbol{\omega}_{\rm a}^{\rm hy}), \tag{42.78}$$

which follows since $\nabla\cdot\boldsymbol{\omega}_{\rm a}^{\rm hy} = 0$. Taking the Eulerian time derivative then leads to

$$\partial_t Q = \nabla\cdot\left[\frac{\partial b}{\partial t}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + b\,\frac{\partial\boldsymbol{\omega}_{\rm a}^{\rm hy}}{\partial t}\right] = \nabla\cdot\left[\frac{\partial b}{\partial t}\,\boldsymbol{\omega}_{\rm a}^{\rm hy} + \frac{\partial\boldsymbol{u}}{\partial t}\times\nabla b\right], \tag{42.79}$$

which made use of the identities

$$\frac{\partial\boldsymbol{\omega}_{\rm a}^{\rm hy}}{\partial t} = \frac{\partial\boldsymbol{\omega}^{\rm hy}}{\partial t} = \frac{\partial(\nabla\times\boldsymbol{u})}{\partial t} \qquad \text{and} \qquad \nabla\cdot[\nabla\times(b\,\boldsymbol{u})] = 0. \tag{42.80}$$

Evidently, potential vorticity evolves according to

$$\partial_t Q = -\nabla \cdot \widetilde{\boldsymbol{J}}_{\mathrm{Q}} \tag{42.81}$$

where the potential vorticity flux is given by

$$\widetilde{\boldsymbol{J}}_{\mathrm{Q}} = -\frac{\partial b}{\partial t}\,\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} - \frac{\partial \boldsymbol{u}}{\partial t} \times \nabla b. \tag{42.82}$$

This form of the potential vorticity flux manifests the impermeability property of Chapter 43 since

$$\hat{\boldsymbol{n}} \cdot (\widetilde{\boldsymbol{J}}_{\mathrm{Q}}/Q) = -\frac{1}{|\nabla b|}\,\frac{\partial b}{\partial t} = \hat{\boldsymbol{n}} \cdot \boldsymbol{v}_{b\perp}, \tag{42.83}$$

where $\hat{\boldsymbol{n}} = \nabla b\,|\nabla b|^{-1}$ is the unit normal for a buoyancy surface, and with $\boldsymbol{v}_{b\perp}$ the velocity of a point on the isopycnal that satisfies

$$\partial_t b + \boldsymbol{v}_{b\perp} \cdot \nabla b = 0. \tag{42.84}$$

We return in Chapter 43 to help clarify this particular point about impermeability.

42.5.4 A potential vorticity flux vector suited to steady flows

Schär (1993) provided a generalization of Bernoulli's Theorem for understanding steady geophysical flows, with *Marshall* (2000), *Marshall et al.* (2001), and *Polton and Marshall* (2007) applying this theorem to oceanic contexts within a hydrostatic and Boussinesq ocean.[5] We here derive the potential vorticity flux vector for a hydrostatic and Boussinesq ocean. The manipulations offer experience with the variety of gauge choices available when studying potential vorticity fluxes, with certain gauge choices aligned with particular analysis goals. The presentation here is a warm-up to the non-Boussinesq and non-hydrostatic case studied in Section 43.3.1, where we also provide example uses for the formulation.

Momentum equation

We start by exposing the Boussinesq form of the Bernoulli potential within the vector-invariant velocity equation. For this purpose, return to the horizontal momentum equation (41.141), and expand the expressions for the perturbation pressure and the buoyancy

$$\begin{aligned}
\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{f} + \boldsymbol{\omega}^{\mathrm{hy}}) \times \boldsymbol{v} &= -\nabla\,(\varphi + |\boldsymbol{u}|^2/2) + \hat{\boldsymbol{z}}\,b + \boldsymbol{F} && (42.85a)\\
&= -\nabla\,(|\boldsymbol{u}|^2/2) - \frac{1}{\rho_0}\nabla(p - p_0) - \hat{\boldsymbol{z}}\left[\frac{g\,(\rho - \rho_0)}{\rho_0}\right] + \boldsymbol{F} && (42.85b)\\
&= -\nabla\,(|\boldsymbol{u}|^2/2) - \frac{1}{\rho_0}\nabla p - \hat{\boldsymbol{z}}\,\frac{g\,\rho}{\rho_0} + \boldsymbol{F} && (42.85c)\\
&= -\nabla\left[\frac{|\boldsymbol{u}|^2}{2} + \frac{p}{\rho_0}\right] - \hat{\boldsymbol{z}}\left[\frac{g\,\rho - g\,\rho_o + g\,\rho_0}{\rho_0}\right] + \boldsymbol{F} && (42.85d)\\
&= -\nabla\left[\frac{|\boldsymbol{u}|^2}{2} + \frac{p}{\rho_0} + g\,z\right] - \hat{\boldsymbol{z}}\left[\frac{g\,(\rho - \rho_o)}{\rho_0}\right] + \boldsymbol{F} && (42.85e)\\
&= -\nabla\,\mathcal{B} + \hat{\boldsymbol{z}}\,b + \boldsymbol{F}, && (42.85f)
\end{aligned}$$

[5] We studied the Bernoulli potential and Bernoulli theorem in Section 27.9.3.

where we introduced the Bernoulli potential for a hydrostatic and Boussinesq fluid[6]

$$\mathcal{B} = \frac{|\boldsymbol{u}|^2}{2} + \frac{p}{\rho_0} + g\,z. \tag{42.86}$$

Potential vorticity flux

The flux-form potential vorticity conservation statement remains as given by equation (42.71d), and the PV-substance flux is given by equation (42.73). However, we can make use of the gauge invariance of the PV-substance flux to write it in a manner conducive to analyzing steady state conditions. For this purpose, operate with $\nabla b \times$ on the velocity equation (42.85f) to have

$$\nabla b \times \frac{\partial \boldsymbol{u}}{\partial t} + \nabla b \times (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \times \boldsymbol{v}) = -\nabla b \times \nabla \mathcal{B} + \nabla b \times \hat{\boldsymbol{z}}\, b + \nabla b \times \boldsymbol{F}. \tag{42.87}$$

Now make use of the identity

$$\nabla b \times (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \times \boldsymbol{v}) = (\nabla b \cdot \boldsymbol{v})\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} - (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla b)\, \boldsymbol{v} \tag{42.88}$$

in equation (42.87) to yield

$$(\boldsymbol{v} \cdot \nabla b)\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} - (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla b)\, \boldsymbol{v} = -\nabla b \times \frac{\partial \boldsymbol{u}}{\partial t} - \nabla b \times \nabla \mathcal{B} + \nabla b \times \hat{\boldsymbol{z}}\, b + \nabla b \times \boldsymbol{F}. \tag{42.89}$$

We next make use of this identity for the purpose of manipulating the potential vorticity flux given by equation (42.73)

$$\begin{aligned}
\boldsymbol{J}_{\mathrm{Q}} &= \boldsymbol{v}\, Q - \dot{b}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A} && \text{(42.90a)}\\
&= \boldsymbol{v}\, (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla b) - \left[\frac{\partial b}{\partial t} + \boldsymbol{v} \cdot \nabla b\right] \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A} && \text{(42.90b)}\\
&= [\boldsymbol{v}\, (\boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \cdot \nabla b) - (\boldsymbol{v} \cdot \nabla b)\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}}] - \frac{\partial b}{\partial t}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A} && \text{(42.90c)}\\
&= \left[\nabla b \times \frac{\partial \boldsymbol{u}}{\partial t} + \nabla b \times \nabla \mathcal{B} - \nabla b \times \hat{\boldsymbol{z}}\, b - \nabla b \times \boldsymbol{F}\right] - \frac{\partial b}{\partial t}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A} && \text{(42.90d)}\\
&= \nabla b \times \frac{\partial \boldsymbol{u}}{\partial t} - \frac{\partial b}{\partial t}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla b \times \nabla \mathcal{B} - \nabla b \times \hat{\boldsymbol{z}}\, b + \nabla \times \boldsymbol{A}. && \text{(42.90e)}\\
&= \nabla b \times \left[\frac{\partial \boldsymbol{u}}{\partial t} + \nabla \mathcal{B}\right] - \frac{\partial b}{\partial t}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} + \nabla \times \left(\boldsymbol{A} - \hat{\boldsymbol{z}}\, b^2/2\right). && \text{(42.90f)}
\end{aligned}$$

Choosing the gauge function

$$\boldsymbol{A} = \hat{\boldsymbol{z}}\, (b^2/2) \tag{42.91}$$

renders the flux vector

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{ss}} = \nabla b \times \left(\frac{\partial \boldsymbol{u}}{\partial t} + \nabla \mathcal{B}\right) - \frac{\partial b}{\partial t}\, \boldsymbol{\omega}_{\mathrm{a}}^{\mathrm{hy}} \tag{42.92}$$

We have now reached our goal whereby the steady state version of the potential vorticity flux (42.92) takes the rather elegant form

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{ss}} = \nabla b \times \nabla \mathcal{B} = \nabla \times b\, \nabla \mathcal{B} = -\nabla \times \mathcal{B}\, \nabla b \qquad \text{steady state.} \tag{42.93}$$

Hence, the steady state potential vorticity flux is aligned with the intersection of surfaces of

[6]See Section 27.9 for the non-Boussinesq Bernoulli potential.

constant buoyancy and Bernoulli potential

$$\nabla b \cdot \boldsymbol{J}_{\mathrm{Q}}^{\mathrm{ss}} = 0 \quad \text{and} \quad \nabla \mathcal{B} \cdot \boldsymbol{J}_{\mathrm{Q}}^{\mathrm{ss}} = 0 \qquad \text{steady state.} \tag{42.94}$$

Recalling our discussion of vector streamfunctions in Section 22.5.3, where here see that the buoyancy and Bernoulli potential serve as the two scalar functions that build the vector streamfunction for the steady state potential vorticity flux. Mapping surfaces of constant buoyancy and constant Bernoulli potential, and determining their intersections, then determine the potential vorticity flux pathways operating in a steady state. Figure 42.5 offer a schematic based on the analogous situation for a velocity streamfunction shown in Figure 22.3. This result is the Boussinesq/hydrostatic form of the more general non-Boussinesq/non-hydrostatic case derived in Section 43.3.3.

FIGURE 42.5: Isosurfaces of constant buoyancy, b, and Bernoulli potential, $\mathcal{B}$, serving as the two scalar functions building the vector streamfunction for potential vorticity flux, $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{ss}}$, in the steady state (see equation (42.94)). Streamlines are defined by the intersections of the b and $\mathcal{B}$ isosurfaces, as shown by four streamlines along the corners of this particular volume. The transport of PV-substance through the surface, $\mathcal{S}$, is determined by the line integral, $\oint_{\partial\mathcal{S}} \mathcal{B}\,\mathrm{d}b = -\oint_{\partial\mathcal{S}} b\,\mathrm{d}\mathcal{B} = (\mathcal{B}_1 - \mathcal{B}_2)\,(b_2 - b_1)$, around the boundary circuit.

42.6 Conservation of pancake potential vorticity

In Section 42.2, we detailed why there is no materially invariant potential vorticity for a realistic equation of state for seawater, in which $\rho = \rho(S, \Theta, p)$. A similar limitation holds for the atmosphere, where the specific entropy is a function of pressure, density, and moisture concentration. We here build from our discussion of Kelvin's circulation theorem in Section 41.2 to consider a finite volume *pancake potential vorticity*. Rather than being a property carried by each fluid particle, the pancake potential vorticity is carried by a finite fluid region and it is materially invariant for perfect fluid flows, even for a realistic equation of state. The discussion here follows that given by *Kooloth et al.* (2022).

Our starting point is the potential vorticity equation written as in equation (42.41)

$$\rho \frac{\mathrm{D}Q}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla)\,\dot{\chi} + \nabla\chi \cdot [\nabla \times (-\rho^{-1}\,\nabla p)] + \nabla\chi \cdot (\nabla \times \boldsymbol{F}) \quad \text{with} \quad Q = \rho^{-1}\,\nabla\chi \cdot \boldsymbol{\omega}_{\mathrm{a}}. \tag{42.95}$$

The key step in the derivation is to replace the pressure gradient acceleration with its equivalent in terms of specific enthalpy and its partial derivatives.[7] For this purpose we write the specific

[7] We made use of a similar approach when studying circulation in Section 41.2.5.

enthalpy as a function of Conservative Temperature, salinity, and pressure

$$\mathcal{H} = \mathcal{H}(\Theta, S, p), \tag{42.96}$$

which leads to the spatial gradient[8]

$$\nabla\mathcal{H} = \rho^{-1}\,\nabla p + \left[\frac{\partial\mathcal{H}}{\partial\Theta}\right]_{p,S}\nabla\Theta + \left[\frac{\partial\mathcal{H}}{\partial S}\right]_{\Theta,p}\nabla S, \tag{42.97}$$

which then leads to the expression for the pressure gradient acceleration

$$-\rho^{-1}\,\nabla p = -\nabla\mathcal{H} + \mathcal{H}_\Theta\,\nabla\Theta + \mathcal{H}_S\,\nabla S, \tag{42.98}$$

where we introduced the shorthand notation

$$\mathcal{H}_\Theta = \left[\frac{\partial\mathcal{H}}{\partial\Theta}\right]_{p,S} \quad \text{and} \quad \mathcal{H}_S = \left[\frac{\partial\mathcal{H}}{\partial S}\right]_{\Theta,p}. \tag{42.99}$$

Use of the identity (42.98) within the potential vorticity equation (42.95) leads to

$$\rho\,\frac{\mathrm{D}Q}{\mathrm{D}t} = (\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla)\,\dot{\chi} + \nabla\chi\cdot\nabla\times\left[\mathcal{H}_\Theta\,\nabla\Theta + \mathcal{H}_S\,\nabla S + \boldsymbol{F}\right], \tag{42.100}$$

where we set $\nabla\times\nabla\mathcal{H} = 0$. Now make use of the following vector identity

$$\nabla\chi\cdot(\nabla\times\boldsymbol{A}) = \nabla\cdot(\chi\,\nabla\times\boldsymbol{A}) = \nabla\cdot[\nabla\times(\chi\,\boldsymbol{A}) - \nabla\chi\times\boldsymbol{A}] = -\nabla\cdot(\nabla\chi\times\boldsymbol{A}), \tag{42.101}$$

to bring the potential vorticity equation (42.100) to

$$\rho\,\frac{\mathrm{D}Q}{\mathrm{D}t} = \nabla\cdot\left[\boldsymbol{\omega}_{\mathrm{a}}\,\dot{\chi} - \nabla\chi\times(\mathcal{H}_\Theta\,\nabla\Theta + \mathcal{H}_S\,\nabla S + \boldsymbol{F})\right]. \tag{42.102}$$

Equation (42.102) is quite general. To reduce by one the terms on the right hand side, we can either choose $\chi = \Theta$ or $\chi = S$. Let us choose $\chi = \Theta$, in which case

$$\rho\,\frac{\mathrm{D}Q^{(\Theta)}}{\mathrm{D}t} = \nabla\cdot\left[\mathcal{H}_S\,\nabla S\times\nabla\Theta + \boldsymbol{F}\times\nabla\Theta + \boldsymbol{\omega}_{\mathrm{a}}\,\dot{\Theta}\right] \quad \text{with} \quad Q^{(\Theta)} = \rho^{-1}\,\nabla\Theta\cdot\boldsymbol{\omega}_{\mathrm{a}}. \tag{42.103}$$

We still have the reversible term, $\mathcal{H}_S\,\nabla S\times\nabla\Theta$, contributing to the material time evolution of $Q^{(\Theta)}$, and this term vanishes only for particularly idealized forms of the fluid thermodynamics. Rather than pursue material invariance for potential vorticity along a fluid particle, consider an integration of $Q^{(\Theta)}$ over a finite region that moves with the flow, and take its time derivative

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathcal{S}(\boldsymbol{v})}\rho\,Q^{(\Theta)}\,\mathrm{d}V = \int_{\mathcal{S}(\boldsymbol{v})}\rho\,\frac{\mathrm{D}Q^{(\Theta)}}{\mathrm{D}t}\,\mathrm{d}V \tag{42.104a}$$

$$= \int_{\mathcal{S}(\boldsymbol{v})}\nabla\cdot\left[\mathcal{H}_S\,\nabla S\times\nabla\Theta + \boldsymbol{F}\times\nabla\Theta + \boldsymbol{\omega}_{\mathrm{a}}\,\dot{\Theta}\right]\mathrm{d}V \tag{42.104b}$$

$$= \oint_{\partial\mathcal{S}(\boldsymbol{v})}\left[\mathcal{H}_S\,\nabla S\times\nabla\Theta + \boldsymbol{F}\times\nabla\Theta + \boldsymbol{\omega}_{\mathrm{a}}\,\dot{\Theta}\right]\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{42.104c}$$

The first and second terms on the right hand side vanish if we choose a volume whose boundary has an outward unit normal vector, $\hat{\boldsymbol{n}}$, parallel to $\nabla\Theta$ at every point around the closed region. This

[8] We performed a similar manipulation in Section 27.6.2.

sort of Θ-bubble is uncommon in a stably stratified fluid, though it may occur over relatively small scales in turbulent flows. Another arrangement to consider is where salinity has a closed contour on Conservative Temperature surfaces. We thus take a pancake/disk region with $\hat{\boldsymbol{n}}$ parallel to $\nabla\Theta$ on its top and bottom and $\hat{\boldsymbol{n}}$ parallel to ∇S on the sides. For this region, the $\nabla S \times \nabla\Theta$ contribution vanishes along all the boundaries, and the contribution from friction only appears on the sides where $\hat{\boldsymbol{n}}$ is parallel to ∇S. We can take a complementary approach by setting $\chi = S$, in which case the previous discussion holds yet with Θ and S interchanged. Either of these pancake regions preserves the materially integrated potential vorticity for inviscid flows with S and Θ both materially invariant.

42.7 Exercises

EXERCISE 42.1: POTENTIAL VORTICITY FOR A PERFECT NON-HYDROSTATIC BOUSSINESQ OCEAN
Consider a perfect tangent plane Boussinesq ocean whose governing equations are given by

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + f\,(\hat{\boldsymbol{z}} \times \boldsymbol{v}) = -\nabla\varphi + b\,\hat{\boldsymbol{z}} \tag{42.105}$$

$$\nabla \cdot \boldsymbol{v} = 0 \tag{42.106}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \tag{42.107}$$

$$b = -\frac{g\,(\rho - \rho_0)}{\rho_0} = g\,\alpha\,\theta, \tag{42.108}$$

where θ is the potential temperature and $\alpha > 0$ is a constant thermal expansion coefficient, and we assumed a linear equation of state for density whereby

$$\rho = \rho_0\,(1 - \alpha\,\theta). \tag{42.109}$$

Further details are provided in Section 30.1.6. Some of this exercise follows the hydrostatic Boussinesq discussion in Section 42.5, though they differ in important places, so be careful!

(a) Derive the equation for the material time evolution of potential vorticity in this fluid system. Show all steps in the derivation.

(b) The baroclinicity vector appearing in the Boussinesq vorticity equation is $\boldsymbol{B} = \nabla \times \hat{\boldsymbol{z}}\,b = \nabla b \times \hat{\boldsymbol{z}}$ (see Section 41.7.1 to check the derivation in part (a) above). Show that this vector results upon making the Boussinesq approximation to the non-Boussinesq expression $\boldsymbol{B} = (\nabla\rho \times \nabla p)/\rho^2$. Hint: drop the $\delta\rho$ and δp product given that it is a higher order quantity.

(c) Show that the vertical portion of Q^{bouss} can be written

$$Q^{\text{bouss}}_{\text{vert}} = (\zeta + f)\,N^2 \tag{42.110}$$

where $\zeta = \partial_x v - \partial_y u$ is the vertical component to the relative vorticity and $N^2 = \partial b/\partial z$ is the squared buoyancy frequency (Section 31.5.4). Hint: this is not tough to show; there is no trick here.

(d) If flow maintains hydrostatic and geostrophic balance, show that the horizontal portion of Q^{bouss} can be written

$$Q^{\text{bouss}}_{\text{horz}} = \boldsymbol{\omega} \cdot \nabla_z b \approx -f^{-1} |\nabla_z b|^2. \tag{42.111}$$

Hint: recall that for hydrostatic and geostrophic flow, the vertical velocity is much smaller than horizontal.

EXERCISE 42.2: POTENTIAL VORTICITY FOR DIABATIC AND FRICTIONAL NON-HYDROSTATIC BOUSSINESQ OCEAN

Reconsider Exercise 42.1 in the presence of irreversible friction and buoyancy sources so that the governing tangent plane equations are

$$\frac{\mathrm{D}\boldsymbol{v}}{\mathrm{D}t} + f\,(\hat{\boldsymbol{z}} \times \boldsymbol{v}) = -\nabla\varphi + b\,\hat{\boldsymbol{z}} + \boldsymbol{F} \tag{42.112}$$

$$\nabla \cdot \boldsymbol{v} = 0 \tag{42.113}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = \dot{b} \tag{42.114}$$

$$b = -\frac{g\,(\rho - \rho_0)}{\rho_0} = g\,\alpha\,\theta. \tag{42.115}$$

In these equations we assumed a linear equation of state for density whereby

$$\rho = \rho_0\,(1 - \alpha\,\theta), \tag{42.116}$$

with $\alpha > 0$ a constant thermal expansion coefficient. Hence, material time changes to the buoyancy are given by

$$\frac{\mathrm{D}b}{\mathrm{D}t} = \dot{b} = g\,\alpha\,\dot{\theta}, \tag{42.117}$$

where $\dot{\theta}$ is a diabatic heating source/sink. We also included $\boldsymbol{F}$ to the velocity equation (42.112), which represents a non-conservative acceleration such as from friction or boundary stresses.

(a) Derive the equation for the material time evolution of potential vorticity in this fluid system, including the irreversible contributions from friction and heating.

(b) Derive an equation for the potential vorticity time tendency (i.e., Eulerian time derivative), written in the form

$$\partial_t Q = -\nabla \cdot \boldsymbol{J}_{\text{Q}}. \tag{42.118}$$

What is the potential vorticity flux $\boldsymbol{J}_{\text{Q}}$? Note that your answer is unique up to the curl of an arbitrary vector (gauge symmetry). Also note that for a Boussinesq flow we drop the constant reference density in the definition of $\boldsymbol{J}_{\text{Q}}$.

(c) A common diabatic process is written in the form of a damping source

$$\dot{b} = -\mu\,(b - b^*), \tag{42.119}$$

where μ is a constant Newtonian damping coefficient (dimensions of inverse time), and b^* is a specified buoyancy profile. This form of a buoyancy source acts to damp the buoyancy towards a specified profile b^*. Show that Newtonian damping of buoyancy corresponds to potential vorticity damping towards $Q^* = \boldsymbol{\omega}_{\text{a}} \cdot \nabla b^*$.

(d) A form for the friction operator is given by Rayleigh drag

$$\boldsymbol{F} = -\gamma\,\boldsymbol{v}, \tag{42.120}$$

with γ a constant Rayleigh damping coefficient with dimension of inverse time. Show that Rayleigh drag in the momentum equation, which acts to damp velocity towards zero, corresponds to a damping of potential vorticity towards its planetary geostrophic form, $Q^{\text{pg}} = f\,N^2$, where $N^2 = \partial b/\partial z$ is the squared buoyancy frequency.

(e) Discuss the balance needed between forcing terms in $\boldsymbol{J}_{\text{Q}}$ to arrive at a steady state (i.e., zero Eulerian time tendency). Continue to assume the friction is in the form of Rayleigh drag and heating is in the form of Newtonian damping.

Chapter 43

Potential vorticity budgets

In Chapter 42 we studied properties of potential vorticity, Q, with $\rho Q = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla \chi$ the projection of the absolute vorticity, $\boldsymbol{\omega}_{\mathrm{a}}$, onto a direction determined by a smooth scalar field, χ. If χ annihilates the baroclinicity vector and is materially invariant, then Q is materially invariant: $\mathrm{D}Q/\mathrm{D}t = 0$. In geophysical fluid mechanics, it is common to define potential vorticity with χ equal to the specific entropy (for the atmosphere) or Archimedean buoyancy (for the ocean), in which case Q is referred to as the *Ertel potential vorticity*. Specific entropy and buoyancy are preferred given their intimate connection to dynamics, and since they annihilate baroclinicity in interesting and relevant special cases.

In this chapter we develop finite volume budgets for potential vorticity substance, with such budgets fundamentally affected by the *impermeability theorem* respected by potential vorticity fluxes. Impermeability says that for potential vorticity defined according to a scalar field, χ, there is identically zero potential vorticity flux crossing χ-isosurfaces. This property holds even when there are mass and thermal fluxes crossing χ-isosurfaces. Such generality signals its kinematic nature, which ultimately follows from the non-divergent nature of vorticity. It offers further insight into why, as developed in Section 43.4, the volume integrated PV-substance, ρQ, changes only when χ surfaces intersect a boundary.

These points are fundamental to potential vorticity and yet easily confused, thus motivating us to summarize them here.

- Material invariance of potential vorticity, Q, holds for a perfect fluid and for Q that is defined according to a materially invariant scalar field, χ, that annihilates baroclinicity.
- Impermeability of the flux of ρQ (PV-substance) holds for potential vorticity defined according to an arbitrary scalar, χ, even in the presence of irreversible processes. This property is purely kinematic and it follows from the non-divergent nature of absolute vorticity.

CHAPTER GUIDE

The goal of this chapter is to fill in the conceptual and technical details needed to understand the above points about impermeability, and in turn to develop an understanding of finite volume budgets of potential vorticity. We build from the potential vorticity mechanics introduced in Chapter 42, and make use of many elements of vector calculus summarized in Chapter 2. This chapter is an essential read for those interested in potential vorticity theory and potential vorticity budgets.

- *Callies and Ferrari* (2018) and bottom mixing induced circulation. Connect the thermal wind next to the bottom, inducing flow counter to Kelvin waves, to the potential vorticity boundary fluxes in Section 43.5.3. Discuss the spin up experiment in Section 4 of *Callies and Ferrari* (2018) from a potential vorticity perspective. Note the role of bottom friction in enabling the bottom buoyancy mixing to impart potential vorticity to the flow. without friction then there would be no way to introduce potential vorticity to the flow. That then couples the buoyancy mixing to the friction. *Callies and Ferrari* (2018) also note that to satisfy $\hat{\boldsymbol{n}} \cdot \nabla b = 0$ requires friction. I do not understand that fully, but must be related to this potential vorticity argument.

43.2 Variations on the impermeability theorem

In this section we derive the impermeabity theorem satisfied by the potential vorticity flux vector. We illustrate the theorm for a variety of potential vorticity flux vectors that differ by a gauge function. So although these fluxes have identical divergences, the physical content of the fluxes is distinct. Consequently, one may choose to use a particular flux depending on the context of their use. We return to this point in Section 43.5.6.

43.2.1 Impermeability for the Haynes-McIntyre potential vorticity flux

We start with the flux-form evolution equation for PV-substance given by equation (42.49)

$$\partial_t(\rho\, Q) + \nabla \cdot \boldsymbol{J}_{\mathrm{Q}} = 0 \qquad \text{with} \qquad \boldsymbol{J}_{\mathrm{Q}} = \rho\, \boldsymbol{v}\, Q - \dot{\chi}\, \boldsymbol{\omega}_{\mathrm{a}} + \nabla \chi \times \boldsymbol{F}, \tag{43.1}$$

with $\dot{\chi} = \mathrm{D}\chi/\mathrm{D}t$, and with the PV-substance flux vector, $\boldsymbol{J}_{\mathrm{Q}}$, given in the form examined in *Haynes and McIntyre* (1987).[1] Following the derivation in *Haynes and McIntyre* (1987), we decompose the velocity into two components, one oriented parallel to constant χ surfaces and one oriented perpendicular

$$\boldsymbol{v}_{\parallel} = \boldsymbol{v} - \hat{\boldsymbol{n}}\,(\boldsymbol{v}\cdot\hat{\boldsymbol{n}}) \qquad \text{and} \qquad \boldsymbol{v}_{\perp} = -\frac{\hat{\boldsymbol{n}}\,\partial\chi/\partial t}{|\nabla\chi|} \qquad \Longrightarrow \boldsymbol{v} = \boldsymbol{v}_{\parallel} + \boldsymbol{v}_{\perp} + \frac{\hat{\boldsymbol{n}}\,\dot{\chi}}{|\nabla\chi|} \tag{43.2}$$

where

$$\hat{\boldsymbol{n}} = \nabla\chi/|\nabla\chi| \tag{43.3}$$

is the unit normal vector for χ-isosurfaces. By construction, the velocity $\boldsymbol{v}_{\perp}$ satisfies

$$\frac{\partial\chi}{\partial t} + \boldsymbol{v}_{\perp}\cdot\nabla\chi = 0. \tag{43.4}$$

Hence, according to the kinematics detailed in Section 20.4.2,

$$\boldsymbol{v}_{\perp}\cdot\hat{\boldsymbol{n}} = \boldsymbol{v}_{\chi}\cdot\hat{\boldsymbol{n}}, \tag{43.5}$$

where $\boldsymbol{v}_{\chi}$ is the velocity of a point fixed on a constant χ surface. That is, $\boldsymbol{v}_{\perp}$ provides a measure of the velocity for a point following a constant χ surface, even as that surface moves through the fluid. We make use of this key identity below.

With the velocity decomposition (43.2), the PV-substance flux vector takes the form

$$\begin{aligned}
\boldsymbol{J}_{\mathrm{Q}} &= \rho\,\boldsymbol{v}\,Q - \dot{\chi}\,\boldsymbol{\omega}_{\mathrm{a}} + \nabla\chi\times\boldsymbol{F} && \text{(43.6a)}\\
&= \left[\boldsymbol{v}_{\parallel} + \boldsymbol{v}_{\perp} + \frac{\dot{\chi}\,\nabla\chi}{|\nabla\chi|^2}\right]\rho\,Q - \dot{\chi}\,\boldsymbol{\omega}_{\mathrm{a}} + \nabla\chi\times\boldsymbol{F} && \text{(43.6b)}\\
&= (\boldsymbol{v}_{\parallel} + \boldsymbol{v}_{\perp})\,\rho Q - \dot{\chi}\,[\boldsymbol{\omega}_{\mathrm{a}} - (\boldsymbol{\omega}_{\mathrm{a}}\cdot\hat{\boldsymbol{n}})\,\hat{\boldsymbol{n}}] + \nabla\chi\times\boldsymbol{F} && \text{(43.6c)}\\
&= (\boldsymbol{v}_{\parallel} + \boldsymbol{v}_{\perp})\,\rho Q - \dot{\chi}\,(\boldsymbol{\omega}_{\mathrm{a}})_{\parallel} + \nabla\chi\times\boldsymbol{F} && \text{(43.6d)}\\
&= \underbrace{\boldsymbol{v}_{\perp}\,\rho Q}_{\boldsymbol{J}_{\perp}} + \underbrace{\left[\rho Q\,\boldsymbol{v}_{\parallel} - \dot{\chi}\,(\boldsymbol{\omega}_{\mathrm{a}})_{\parallel}\right] + \nabla\chi\times\boldsymbol{F}}_{\boldsymbol{J}_{\parallel}} && \text{(43.6e)}\\
&\equiv \boldsymbol{J}_{\perp} + \boldsymbol{J}_{\parallel}, && \text{(43.6f)}
\end{aligned}$$

where

$$(\boldsymbol{\omega}_{\mathrm{a}})_{\parallel} = \boldsymbol{\omega}_{\mathrm{a}} - (\boldsymbol{\omega}_{\mathrm{a}}\cdot\hat{\boldsymbol{n}})\,\hat{\boldsymbol{n}} = \boldsymbol{\omega}_{\mathrm{a}} - \left[\frac{\boldsymbol{\omega}_{\mathrm{a}}\cdot\nabla\chi}{|\nabla\chi|^2}\right]\nabla\chi = \boldsymbol{\omega}_{\mathrm{a}} - \frac{\rho\,Q}{|\nabla\chi|}\,\hat{\boldsymbol{n}}. \tag{43.7}$$

The above results motivate us to write the PV-substance budget equation (43.1) in the form

$$\frac{\partial(\rho\,Q)}{\partial t} + \nabla\cdot(\boldsymbol{v}_{\mathrm{Q}}\,\rho\,Q) = 0, \tag{43.8}$$

[1] Following *Haynes and McIntyre* (1987), we set the gauge function, $\boldsymbol{A}$, to zero in equation (43.1).

where

$$\boldsymbol{v}_{\mathrm{Q}} \equiv \frac{\boldsymbol{J}_{\mathrm{Q}}}{\rho\, Q} \qquad \text{definition of } \boldsymbol{v}_{\mathrm{Q}} \tag{43.9a}$$

$$= \boldsymbol{v} + \frac{-\dot{\chi}\, \boldsymbol{\omega}_{\mathrm{a}} + \nabla\chi \times \boldsymbol{F}}{\rho\, Q} \qquad \text{equation (43.1)} \tag{43.9b}$$

$$= \boldsymbol{v}_{\perp} + \boldsymbol{v}_{\parallel} + \frac{-\dot{\chi}\, (\boldsymbol{\omega}_{\mathrm{a}})_{\parallel} + \nabla\chi \times \boldsymbol{F}}{\rho\, Q} \qquad \text{equation (43.6e)}, \tag{43.9c}$$

so that $\boldsymbol{v}_{\mathrm{Q}}$ is the velocity that advects the PV-substance through the fluid. A direct calculation shows that $\boldsymbol{v}_{\mathrm{Q}}$ satisfies the following property

$$\boldsymbol{v}_{\mathrm{Q}} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v}_{\perp} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v}_{\chi} \cdot \hat{\boldsymbol{n}}, \tag{43.10}$$

where the final equality made use of the identity (43.5). As a result, the velocity, $\boldsymbol{v}_{\mathrm{Q}}$, has a normal component that is identical to that of the velocity of a point fixed on the χ surface

$$\partial_t \chi + \boldsymbol{v}_{\mathrm{Q}} \cdot \nabla\chi = 0. \tag{43.11}$$

We depict this result in Figure 43.1, whereby the PV-substance flux never crosses the χ-isosurface, even as the surface moves and even in the presence of processes that allow for matter and thermal properties to cross the surface. This result holds since the χ-isosurface moves in a way to precisely track the PV-substance flux. In general, χ surfaces are permeable to matter and thermal properties but, as we have just shown, are impermeable to PV-substance. This is a rather remarkable kinematic result that has important implications for budgets of PV-substance within regions bounded by constant χ surfaces.

FIGURE 43.1: The flux, $\boldsymbol{J}_{\mathrm{Q}}$, of PV-substance, $\rho\, Q = \nabla \cdot (\chi\, \boldsymbol{\omega}_{\mathrm{a}})$, does not penetrate a surface of constant χ. This kinematic result follows since the effective velocity of PV-substance, $\boldsymbol{v}_{\mathrm{Q}} = \boldsymbol{J}_{\mathrm{Q}}/(\rho\, Q)$, has the same normal component as a point fixed on a χ surface, $\boldsymbol{v}_{\mathrm{Q}} \cdot \hat{\boldsymbol{n}} = \boldsymbol{v}_{\chi} \cdot \hat{\boldsymbol{n}}$. Consequently, the χ surface moves in a manner so that no flux of PV-substance crosses the surface, even in the presence of irreversible processes. This result is known as the impermeability theorem since χ surfaces are impermeable to the flux of PV-substance, even though they are permeable to matter and thermal properties.

43.2.2 A kinematic derivation of impermeability

The derivation of impermeability in Section 43.2.1 follows that given by *Haynes and McIntyre* (1987). We now complement that derivation by an alternative that emphasizes the kinematic origins of impermeability. For that purpose, we make no use of the vorticity equation or the

equation for χ. Instead, we merely use the definition of potential vorticity and the non-divergence property of absolute vorticity. This derivation follows our discussion of gauge freedom introduced in Section 42.4.3, as well as the discussion of potential vorticity for a hydrostatic Boussinesq ocean in Section 42.5.

The key identity we need was already given by equation (42.11)

$$\rho\, Q = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla \chi = \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, \chi), \tag{43.12}$$

thus revealing that $\rho\, Q$ is a pure divergence. Taking the Eulerian time derivative then leads to

$$\partial_t(\rho\, Q) = -\nabla \cdot \boldsymbol{J}_{\mathrm{Q}}^{\mathrm{kin}}, \tag{43.13}$$

where

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{kin}} = -\partial_t(\boldsymbol{\omega}_{\mathrm{a}}\, \chi) \tag{43.14}$$

is the kinematic form of the PV-substance flux. By construction, this flux vanishes in the steady state

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{kin}} = 0 \qquad \text{in steady state,} \tag{43.15}$$

which certainly contrasts to the steady state Haynes-McIntyre flux given by equation (43.1).

Introducing the velocity seen from an inertial reference frame (also called the absolute velocity (Section 13.7.1)

$$\boldsymbol{v}_{\mathrm{a}} = \boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x} \tag{43.16}$$

leads to

$$-\frac{\partial \boldsymbol{\omega}_{\mathrm{a}}}{\partial t}\, \chi = -\frac{\partial(\nabla \times \boldsymbol{v}_{\mathrm{a}})}{\partial t}\, \chi = -\left[\nabla \times \frac{\partial \boldsymbol{v}_{\mathrm{a}}}{\partial t}\right] \chi = -\nabla \times \left[\frac{\partial \boldsymbol{v}_{\mathrm{a}}}{\partial t}\, \chi\right] + \nabla \chi \times \frac{\partial \boldsymbol{v}_{\mathrm{a}}}{\partial t}. \tag{43.17}$$

Dropping the total curl (which amounts to choosing a gauge function) yields the modified kinematic form for the PV-substance flux

$$\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}} = -\frac{\partial \boldsymbol{v}_{\mathrm{a}}}{\partial t} \times \nabla \chi - \boldsymbol{\omega}_{\mathrm{a}}\, \frac{\partial \chi}{\partial t}. \tag{43.18}$$

It follows that

$$\widetilde{\boldsymbol{v}}_{\mathrm{Q}}^{\mathrm{kin}} \cdot \hat{\boldsymbol{n}} = \frac{\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}} \cdot \hat{\boldsymbol{n}}}{\rho\, Q} = -\frac{\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla \chi}{\rho\, Q}\, \frac{\partial \chi}{\partial t}\, \frac{1}{|\nabla \chi|} = -\frac{\partial \chi}{\partial t}\, \frac{1}{|\nabla \chi|} = \boldsymbol{v}_{\chi} \cdot \hat{\boldsymbol{n}}, \tag{43.19}$$

which is the same result (43.10) as found for the Haynes-McIntyre flux. This result allows us to conclude that $\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}}$ satisfies the impermeability theorem. We again emphasize that there has been no use of the dynamical equations for vorticity or for χ. Instead, this expression of impermeability only used the definition of potential vorticity, along with the non-divergent nature of vorticity, $\nabla \cdot \boldsymbol{\omega}_{\mathrm{a}} = 0$.

Throughout this discussion, we assumed χ to be an arbitrary smooth scalar field. Hence, *any* scalar field used to project out a component of the absolute vorticity has its iso-surfaces impenetrable to the flux of the corresponding component of absolute vorticity. This result trivializes the impermeability theorem from a mathematical perspective. In Section 41.3.4 we somewhat anticipated this result when studying the Cartesian components of the absolute vorticity (see also Section 5 of *Haynes and McIntyre* (1987)). However, this result does not reduce the importance of the entropic potential vorticity impermeability theorem for studying stratified flows. The importance holds since this particular potential vorticity has direct connection to dynamics and

thermodynamics.

43.2.3 Comments

The impermeability theorem was introduced by *Haynes and McIntyre* (1987). Their paper was met by some confusion thus prompting them to write *Haynes and McIntyre* (1990). Besides exposing the purely kinematic aspects of impermeability, the presentation in this section reveals that there are multiple potential vorticity flux vectors that satisfy impermeability, with the vectors differing by a gauge transformation. Which flux vector is prefered depends on the application, with *Bretherton and Schär* (1993), *Davies-Jones* (2003a), and *Marshall et al.* (2001) proposing criteria favoring one form over another. We pursue such considerations in Section 43.3.

43.3 Impermeability theorem for seawater

As seen from Section 43.2.2, impermeability holds for any component of vorticity and the corresponding scalar isosurface. In contrast, material invariance of potential vorticity requires a materially conserved scalar to annihilate the baroclinicity vector (e.g., Section 42.1.4). Consequently, material invariance is much tougher to satisfy than impermeability. Indeed, as shown in Section 42.2, there is no materially invariant potential vorticity for an ocean with a realistic nonlinear equation of state (EOS). Hence, there is no materially invariant potential vorticity for the ocean even in the absence of irreversible processes. Nevertheless, one can define an ocean potential vorticity according to any scalar field, such as potential density, and still make use of the impermeability theorem when performing a potential vorticity budget. We here expose the details.

43.3.1 Ocean potential vorticity in terms of potential density

Following *Marshall et al.* (2001), we introduce an ocean potential vorticity field according to

$$Q^{\text{ocn}} = \frac{\nabla b \cdot \boldsymbol{\omega}_{\text{a}}}{\rho}, \tag{43.20}$$

where the Archimedean buoyancy field, b, is approximated by a chosen potential density (see Section 31.3.4). As shown in Section 42.2, a globally defined buoyancy does not annihilate the baroclinicity vector for a realistic seawater equation of state

$$\boldsymbol{B} \cdot \nabla b = [-\nabla(1/\rho) \times \nabla p] \cdot \nabla b \neq 0. \tag{43.21}$$

Consequently, $\mathrm{D}Q^{\text{ocn}}/\mathrm{D}t \neq 0$ even in the absence of irreversible processes. Nonetheless, the Eulerian budget for PV-substance satisfies

$$\partial_t(\rho\, Q^{\text{ocn}}) = -\nabla \cdot \widetilde{\boldsymbol{J}}_{\text{Q}}^{\text{ocn}}, \tag{43.22}$$

and $\widetilde{\boldsymbol{J}}_{\text{Q}}^{\text{ocn}}$ satisfies the impermeability theorem for b-surfaces. A flux-form budget equation greatly facilitates the study of budgets for PV-substance even within an ocean with a realistic equation of state. Derivation of the flux-form equation (43.22) follows from the discussion in Section 43.2.2, where we know that the kinematic flux

$$\widetilde{\boldsymbol{J}}_{\text{Q}}^{\text{ocn}} = -\frac{\partial \boldsymbol{v}_{\text{a}}}{\partial t} \times \nabla b - \boldsymbol{\omega}_{\text{a}} \frac{\partial b}{\partial t} = -\frac{\partial \boldsymbol{v}}{\partial t} \times \nabla b - \boldsymbol{\omega}_{\text{a}} \frac{\partial b}{\partial t} \tag{43.23}$$

satisfies the impermeability theorem for b-surfaces and whose convergence drives the time tendency for the PV-substance. Note that the second equality in equation (43.23) follows since

$$\partial_t \boldsymbol{v}_{\mathrm{a}} = \partial_t(\boldsymbol{v} + \boldsymbol{\Omega} \times \boldsymbol{x}) = \partial_t \boldsymbol{v}, \tag{43.24}$$

given that the Eulerian time derivative is computed at a fixed position, $\boldsymbol{x}$, and the planetary rotation is assumed constant, $\partial_t \boldsymbol{\Omega} = 0$.

43.3.2 A modified PV-substance flux

The kinematic flux (43.23) vanishes in the steady state. We here motivate a gauge transformed flux that leads to the same flux divergence yet that renders a nonzero steady state flux. For this purpose, make use of the vector-invariant velocity equation (equation (41.33))

$$\partial_t \boldsymbol{v} + \boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v} = -\rho^{-1} \nabla p - \nabla \mathcal{M} + \boldsymbol{F}, \tag{43.25}$$

where

$$\mathcal{M} = \boldsymbol{v} \cdot \boldsymbol{v}/2 + \Phi \tag{43.26}$$

is the mechanical energy per mass of a fluid element. Bringing the pressure term inside of the gradient operator leads to

$$\partial_t \boldsymbol{v} + \boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v} = p \, \nabla(1/\rho) - \nabla(\mathcal{M} + p/\rho) + \boldsymbol{F}. \tag{43.27}$$

Following our treatment of the hydrostatic Boussinesq ocean in Section 42.5.4, we introduce the Bernoulli function[2]

$$B = \mathcal{M} + p/\rho. \tag{43.28}$$

The vector-invariant velocity equation (43.27) thus leads to the cross-product

$$\begin{aligned}
\partial_t \boldsymbol{v} \times \nabla b &= -(\boldsymbol{\omega}_{\mathrm{a}} \times \boldsymbol{v}) \times \nabla b + [p \, \nabla(1/\rho) - \nabla(\mathcal{M} + p/\rho) + \boldsymbol{F}] \times \nabla b && (43.29\mathrm{a}) \\
&= -(\nabla b \cdot \boldsymbol{\omega}_{\mathrm{a}}) \, \boldsymbol{v} + (\nabla b \cdot \boldsymbol{v}) \, \boldsymbol{\omega}_{\mathrm{a}} + [p \, \nabla(1/\rho) - \nabla(\mathcal{M} + p/\rho) + \boldsymbol{F}] \times \nabla b && (43.29\mathrm{b}) \\
&= -\boldsymbol{v} \, \rho \, Q^{\mathrm{ocn}} + (\dot{b} - \partial_t b) \, \boldsymbol{\omega}_{\mathrm{a}} + [p \, \nabla(1/\rho) - \nabla(\mathcal{M} + p/\rho) + \boldsymbol{F}] \times \nabla b. && (43.29\mathrm{c})
\end{aligned}$$

Use of this result leads to the flux (43.23)

$$\begin{aligned}
\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{ocn}} &= -\partial_t \boldsymbol{v} \times \nabla b - \boldsymbol{\omega}_{\mathrm{a}} \, \partial_t b && (43.30\mathrm{a}) \\
&= \boldsymbol{v} \, \rho \, Q^{\mathrm{ocn}} - \dot{b} \, \boldsymbol{\omega}_{\mathrm{a}} - \boldsymbol{F} \times \nabla b + [\nabla(\mathcal{M} + p/\rho) - p \, \nabla(1/\rho)] \times \nabla b && (43.30\mathrm{b}) \\
&= \boldsymbol{J}_{\mathrm{Q}} + [\nabla(\mathcal{M} + p/\rho) - p \, \nabla(1/\rho)] \times \nabla b, && (43.30\mathrm{c})
\end{aligned}$$

where $\boldsymbol{J}_{\mathrm{Q}}$ is the Haynes-McIntyre form of the PV-substance flux given by equation (43.1). The term

$$\nabla(\mathcal{M} + p/\rho) \times \nabla b = \nabla \times [(\mathcal{M} + p/\rho) \, \nabla b] \tag{43.31}$$

is a total curl and as such it can be moved around without altering the evolution of PV-substance; i.e., it is a "do nothing" flux. Furthermore, since it is parallel to buoyancy isosurfaces it does not alter the impermeability properties of the PV-substance flux.

[2]The Bernoulli potential, $\mathcal{B}$, arises from an analysis of the total energy budget as in equation (27.104), where we see that the Bernoulli potential in a compressible (non-Boussinesq) fluid, $\mathcal{B} = \mathcal{M} + p/\rho + \mathcal{I}$, also includes the internal energy per mass, $\mathcal{I}$. However, the internal energy is missing from equation (43.28), thus motivating our use of the terminology "a Bernoulli function" rather than "the Bernoulli potential".

Marshall et al. (2001) focused attention on the flux

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}} = \widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{ocn}} - \nabla(\mathcal{M} + p/\rho) \times \nabla b = -[\partial_t \boldsymbol{v} + \nabla(\mathcal{M} + p/\rho)] \times \nabla b - \boldsymbol{\omega}_{\mathrm{a}}\, \partial_t b. \tag{43.32}$$

Diagnostically desirable features of $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}$ include the following:

- $\nabla b \cdot \boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}/(\rho\, Q) = \partial_t b$, thus satisfying the impermeability theorem.
- $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}$ has no explicit reference to irreversible processes. Consequently, in some cases it can be simpler to diagnose than the Haynes-McIntyre flux, $\boldsymbol{J}_{\mathrm{Q}}$.
- In a steady state, the flux is given by

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}} = \nabla b \times \nabla(\mathcal{M} + p/\rho) = \nabla \times [b\, \nabla(\mathcal{M} + p/\rho)]. \tag{43.33}$$

  Consequently, $\mathcal{M} + p/\rho$ provides a streamfunction for the steady state flux on buoyancy surfaces. As emphasized by *Schär* (1993), this result holds even when there are irreversible processes, thus providing useful diagnostics even in the presence of dissipation.

43.3.3 Integral constraints for steady state

The steady state PV-substance flux in the form (43.33) can be used to develop some integral constraints on the steady flow. For this purpose consider the steady form of $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}$ and integrate over an arbitrary simply connected area making use of Stokes' theorem

$$\int_{\mathcal{S}} \nabla \times [b\, \nabla B] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \oint_{\partial \mathcal{S}} b\, \nabla B \cdot \mathrm{d}\boldsymbol{r} = \oint_{\partial \mathcal{S}} b\, \mathrm{d}B = -\oint_{\partial \mathcal{S}} B\, \mathrm{d}b. \tag{43.34a}$$

The first equality made use of Stokes' theorem; the second make use of the identity for exact differentials

$$\nabla B \cdot \mathrm{d}\boldsymbol{r} = \mathrm{d}B; \tag{43.35}$$

and the final equality made use of

$$b\, \mathrm{d}B = \mathrm{d}(b\, B) - B\, \mathrm{d}b \tag{43.36}$$

and noted that the closed loop integral of an exact differential vanishes, so that

$$\oint_{\partial \mathcal{S}} \mathrm{d}(B\, b) = 0. \tag{43.37}$$

If we can find a closed contour where either B is a constant ($\mathrm{d}B = 0$), or the buoyancy is a constant ($\mathrm{d}b = 0$), then we have the steady state constraint

$$\int_{\mathcal{S}} \boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0 \qquad \text{area enclosed by contour with } \mathcal{M} + p/\rho \text{ constant or } b \text{ constant.} \tag{43.38}$$

In regions where there are such closed contours, this constraint offers useful insight into the steady state balances. *Marshall* (2000) and *Polton and Marshall* (2007) make particular use of closed B contours on constant depth surfaces (so that $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$) in a Boussinesq ocean.

43.3.4 Further study

Marshall et al. (2001) builds from the generalized Bernoulli theorem of *Schär* (1993) and *Bretherton and Schär* (1993). We also consider these topics for a hydrostatic Boussinesq ocean in Section

42.5.4.

43.4 Integrated potential vorticity substance

In this section we derive some properties of integrated potential vorticity, with these properties merely the result of how potential vorticity is defined. We write potential vorticity using a global buoyancy field, b, as in our discussion of ocean potential vorticity in Section 43.3

$$\rho\, Q = \boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla b = \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, b) = \nabla \cdot [(\boldsymbol{\omega} + 2\,\boldsymbol{\Omega})\, b]. \tag{43.39}$$

The following points are central to the results derived in this section, and they all follow from the non-divergent nature of the absolute vorticity.

- The divergence form given in the second and third equalities of equation (43.39) is the starting point for the derivations in this section. Indeed, as emphasized by *Morel et al.* (2019), the divergence form is appropriate for deriving discrete approximations since in this case the discrete potential vorticity also satisfies the properties developed in this section.
- As emphasized in Section 43.2, the properties in this section hold for any smooth scalar field that is used to define the potential vorticity.
- The properties in this section hold even when there is no materially invariant potential vorticity since we only make use of the non-divergent nature of the absolute vorticity.

43.4.1 The primary role of boundaries

Integral in terms of boundary vorticity and boundary buoyancy

We consider Q to be an intensive fluid propery measuring the amount of PV-substance per unit mass (i.e., the concentration of PV-substance), and correspondingly with $\rho\, Q$ the amount of PV-substance per volume.[3] With this interpretation, the amount of PV-substance within an arbitrary finite region is determined by the volume integral of $\rho\, Q$

$$\mathcal{I} = \int_{\mathcal{R}} Q\, \rho\, \mathrm{d}V = \int_{\mathcal{R}} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, b)\, \mathrm{d}V = \oint_{\partial\mathcal{R}} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{43.40}$$

where the final equality used Gauss's divergence theorem. Hence, the volume integrated PV-substance in a region is determined solely by values of the absolute vorticity and buoyancy on the region boundary. This property is strikingly distinct from material tracers. In practice it can be useful to decompose the absolute vorticity into the relative vorticity plus planetary vorticity

$$\mathcal{I} = \int_{\mathcal{R}} Q\, \rho\, \mathrm{d}V = \oint_{\partial\mathcal{R}} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{R}} b\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \oint_{\partial\mathcal{R}} b\, 2\,\boldsymbol{\Omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.41}$$

Integral in terms of boundary velocity and boundary buoyancy gradient

We follow *Morel et al.* (2019) by deriving an alternative expression for $\mathcal{I}$ in equation (43.41), with this alternative expression more convenient in some cases. For this purpose we write

$$b\, \boldsymbol{\omega} = b\, \nabla \times \boldsymbol{v} = \nabla \times (b\, \boldsymbol{v}) - \nabla b \times \boldsymbol{v}, \tag{43.42}$$

[3] Recall our discussion of extensive and intensive fluid properties in Section 21.2.1.

FIGURE 43.2: Integrating PV-substance over regions bounded by constant buoyancy surfaces that do not intersect the ground. Here we show a single buoyancy surface, $b = b_2$, bounding the bubble-like fluid region $\mathcal{R}$. Notably, the region inside the bubble generally has nontrivial buoyancy distribution. The only assumption is that it is wholly contained inside the $b = b_2$ contour. There is identically zero domain integrated potential vorticity in $\mathcal{R}$. Hence, if there is any nontrivial distribution of potential vorticity in either domain, there must be as much integrated positive values as there are negative.

and use the divergence theorem to eliminate the total curl term (see Section 2.7.6)

$$\oint_{\partial\mathcal{R}} \nabla \times (b\,\boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla \cdot [\nabla \times (b\,\boldsymbol{v})]\,\mathrm{d}V = 0. \tag{43.43}$$

We are thus led to the equivalent expressions for the integrated potential vorticity substance

$$\mathcal{I} = \int_{\mathcal{R}} Q\,\rho\,\mathrm{d}V = \oint_{\partial\mathcal{R}} b\,\boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + 2\oint_{\partial\mathcal{R}} b\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\oint_{\partial\mathcal{R}} (\nabla b\times\boldsymbol{v})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + 2\oint_{\partial\mathcal{R}} b\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{43.44}$$

In effect, the alternative forms move the derivative operator between the boundary velocity (for computing the relative vorticity) and the boundary buoyancy. One formulation may be more convenient than the other, depending on the boundary conditions. We emphasize that once a particular formulation is chosen, it is necessary to use that formulation for all of the domain boundaries. We must do so since the curl term that moves us from one form to the other vanishes only when integrating over the full domain boundary.

43.4.2 Region bounded by a single buoyancy surface

Consider a volume of fluid bounded by a single buoyancy surface as shown in the bubble-like region in Figure 43.2. Since the outer boundary of the region is set by a constant b-surface, we can pull b outside of the surface integral in equation (43.44) so that

$$\mathcal{I} = \oint_{\partial\mathcal{R}} \boldsymbol{\omega}_{\mathrm{a}}\,b \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = b_2 \oint_{\partial\mathcal{R}} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{43.45}$$

We can now use the divergence theorem to return to the volume integral, only now with b outside of the integral

$$\mathcal{I} = b_2 \int_{\mathcal{R}} \nabla \cdot \boldsymbol{\omega}_{\mathrm{a}}\,\mathrm{d}V = 0, \tag{43.46}$$

where $\nabla \cdot \boldsymbol{\omega}_{\mathrm{a}} = 0$ led to the final equality. Equivalently, we can use Stokes' theorem to convert the closed area integral, $\oint_{\partial\mathcal{R}} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}$, to a line integral around the boundary. However, there is no boundary for the closed area since it covers the sphere, thus again showing that $\mathcal{I} = 0$ (see also Section 2.7.6).

Yet another way to derive the identity (43.46) is to make use of the alternative expression for

FIGURE 43.3: Integrating PV-substance over regions bounded by constant buoyancy surfaces that do not intersect the ground. Here we show a buoyancy layer or shell, $\mathcal{R}_{12}$, bounded by two buoyancy isosurfaces, $b_1 < b_2$, surrounding the earth, with neither surface intersecting the ground. There is identically zero domain integrated potential vorticity in $\mathcal{R}_{12}$. Hence, if there is any nontrivial distribution of potential vorticity in either domain, there must be as much integrated positive values as there are negative.

$\mathcal{I}$ given by equation (43.44)

$$\mathcal{I} = -\oint_{\partial\mathcal{R}} (\nabla b \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} + 2 \oint_{\partial\mathcal{R}} b \, \boldsymbol{\Omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S}. \tag{43.47}$$

Since the domain is bounded by a constant b surface, the outward normal is parallel to ∇b so that the first integral vanishes. Furthermore, since b is a constant in the second integral we are led to consider

$$\oint_{\partial\mathcal{R}} 2 \, \boldsymbol{\Omega} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \oint_{\partial\mathcal{R}} [\nabla \times (\boldsymbol{\Omega} \times \boldsymbol{x})] \cdot \hat{\boldsymbol{n}} \, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}} \nabla \cdot [\nabla \times (\boldsymbol{\Omega} \times \boldsymbol{x})] \, \mathrm{d}V = 0, \tag{43.48}$$

which made use of the divergence theorem and the vanishing divergence of a curl.

The identity (43.46) says that there is zero integrated PV-substance contained within any region bounded by a single buoyancy surface; i.e., a bubble. The result holds whether there are reversible or irreversible processes acting on the buoyancy surface, and it holds if the b-surface is moving in space. Hence, within the domain there is just as much positive PV-substance as there is negative PV-substance. So if potential vorticity changes locally within the domain, then somewhere else it must experience an oppositely signed change so to leave a zero net integrated PV-substance. We emphasize that this result holds at each time instance.

43.4.3 Region bounded by two buoyancy surfaces

The identity (43.46) has a corollary, in which we consider a region bounded by two b-surfaces such as the region $\mathcal{R}_{12}$ shown in Figure 43.3. The above arguments hold for that region as well, since we can decompose the surface integral into two integrals separately over b_1 and b_2

$$\mathcal{I} = \int_{\mathcal{R}_{12}} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}} \, b) \, \mathrm{d}V = \int_{\mathcal{R}_2} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}} \, b) \, \mathrm{d}V - \int_{\mathcal{R}_1} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}} \, b) \, \mathrm{d}V, \tag{43.49}$$

where the domain $\mathcal{R}_1$ extends from the ground up to b_1 and $\mathcal{R}_2$ extends from the ground up to b_2. Integration over the region below b_1 cancels through the subtraction. Indeed, the region below b_1 could be anything without changing the result. So let that region be filled with fluid throughout (i.e., ignore the earth) to allow us to extend both integrals throughout the spherical region just like in the buoyancy bubble $\mathcal{R}$ in Figure 43.3. Invoking the buoyancy bubble result we see that

FIGURE 43.4: A fluid region, $\mathcal{R}_{AB}$, bounded by two buoyancy surfaces, $\mathcal{S}_A$ and $\mathcal{S}_B$. The upper surface, $\mathcal{S}_A$, is defined by a buoyancy isosurface, $b = b_A$, with this surface intersecting the ground. The lower surface, $\mathcal{S}_B$, is along the ground (which is generally not flat, as shown here) and has a buoyancy that is a function of space and time, $b = b_B(\boldsymbol{x}, t)$.

both integrals separately vanish. We are thus led to a vanishing integral for the layer

$$\mathcal{I} = \int_{\mathcal{R}_{12}} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, b)\, \mathrm{d}V = 0. \tag{43.50}$$

Again, the key assumption is that no buoyancy surface intersects land, in which case we are able to ignore the presence of land altogether and thus make use of the buoyancy bubble result. The identity (43.50) also follows from the second form of equation (43.44).

43.4.4 Region bounded by land and a buoyancy surface

We now consider a domain consisting of fluid bounded by a buoyancy surface that intersects (incrops) the ground, such as the region shown in Figure 43.4. This atmospheric example can be turned over to produce an ocean example with buoyancy surfaces outcropping at the ocean surface. Using the vorticity form of the integrated potential vorticity in equation (43.44) leads to

$$\mathcal{I} = \int_{\mathcal{R}_{AB}} \nabla \cdot (\boldsymbol{\omega}_{\mathrm{a}}\, b)\, \mathrm{d}V \tag{43.51a}$$

$$= \int_{\mathcal{S}_A} \boldsymbol{\omega}_{\mathrm{a}}\, b \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{S}_B} \boldsymbol{\omega}_{\mathrm{a}}\, b \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.51b}$$

$$= b_A \int_{\mathcal{S}_A} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{S}_B} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.51c}$$

$$= b_A \left[\int_{\mathcal{S}_A} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{S}_B} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\mathcal{S}_B} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \right] + \int_{\mathcal{S}_B} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.51d}$$

$$= b_A \int_{\mathcal{R}_{AB}} \nabla \cdot \boldsymbol{\omega}_{\mathrm{a}}\, \mathrm{d}V + \int_{\mathcal{S}_B} (b - b_A)\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.51e}$$

$$= \int_{\mathcal{S}_B} (b - b_A)\, (\boldsymbol{\omega} + 2\,\boldsymbol{\Omega}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{43.51f}$$

where we made use of $\nabla \cdot \boldsymbol{\omega}_{\mathrm{a}} = 0$ to reach the final equality. As both the ground and the ocean surface have buoyancy gradients, they contribute to the PV-substance within the region they bound.

For this domain it can be quite useful to use the second form of the integral in equation

(43.44). For this purpose we write

$$\int_{\mathcal{S}_B} (b - b_A)\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}_B + \mathcal{S}_A} (b - b_A)\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.52a}$$

$$= - \int_{\mathcal{S}_B + \mathcal{S}_A} (\nabla b \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.52b}$$

$$= - \int_{\mathcal{S}_B} (\nabla b \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.52c}$$

Equation (43.52a) follows from

$$\int_{\mathcal{S}_A} (b - b_A)\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = 0 \qquad \text{since } b = b_A \text{ on } \mathcal{S}_A. \tag{43.53}$$

Equation (43.52b) follows from the divergence theorem

$$\int_{\mathcal{S}_B + \mathcal{S}_A} \nabla \times [(b - b_A)\, \boldsymbol{v}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{R}_{AB}} \nabla \cdot (\nabla \times [(b - b_A)\, \boldsymbol{v}])\, \mathrm{d}V = 0. \tag{43.54}$$

And equation (43.52c) holds since $\hat{\boldsymbol{n}} \times \nabla b = 0$. The expression (43.52c) is particularly convenient for the case of a no-slip boundary condition (Section 26.10.3), whereby the velocity vanishes along $\mathcal{S}_B$ so that we are left with the rather tidy expression

$$\mathcal{I} = 2 \int_{\mathcal{S}_B} (b - b_A)\, \boldsymbol{\Omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \qquad \text{no-slip condition on } \mathcal{S}_B. \tag{43.55}$$

43.4.5 A layer outcropping at the ocean surface

Figure 43.5 depicts a buoyancy layer that outcrops at the ocean surface at both of its ends. Following the derivation in Section 43.4.4 leads to the integrated PV-substance

$$\mathcal{I}_A \equiv \int_{\mathcal{S}_1 + \mathcal{S}_2 + \mathcal{S}_3 + \mathcal{S}_A} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}_1 + \mathcal{S}_2 + \mathcal{S}_3} (b - b_A)\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} \tag{43.56a}$$

$$\mathcal{I}_B \equiv \int_{\mathcal{S}_2 + \mathcal{S}_B} b\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} = \int_{\mathcal{S}_2} (b - b_B)\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{43.56b}$$

with the difference leading to the integrated potential vorticity within the layer $\mathcal{R}_{AB}$

$$\mathcal{I}_{AB} \equiv \mathcal{I}_A - \mathcal{I}_B = \int_{\mathcal{R}_{AB}} \rho\, Q\, \mathrm{d}V = \int_{\mathcal{S}_1 + \mathcal{S}_3} (b - b_A)\, \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + (b_B - b_A) \int_{\mathcal{S}_2} \boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.57}$$

The relation (43.57) requires information about the absolute vorticity over the region $\mathcal{S}_2$ that lies outside the outcrop regions. To instead only make use of information over the outcrop areas, $\mathcal{S}_1$ and $\mathcal{S}_3$, we consider buoyancy gradients when considering the contributions from the relative vorticity

$$\int_{\mathcal{S}_1 + \mathcal{S}_2 + \mathcal{S}_3 + \mathcal{S}_A} b\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} - \int_{\mathcal{S}_2 + \mathcal{S}_B} b\, \boldsymbol{\omega} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}$$
$$= - \int_{\mathcal{S}_1 + \mathcal{S}_2 + \mathcal{S}_3 + \mathcal{S}_A} (\nabla b \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\mathcal{S}_2 + \mathcal{S}_B} (\nabla b \times \boldsymbol{v}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.58}$$

We can drop the integrals along $\mathcal{S}_A$ and $\mathcal{S}_B$ since their respective normals are parallel to ∇b, in

FIGURE 43.5: This figure depicts a buoyancy layer in the ocean that outcrops at both ends of the layer. The boundaries for the layer are given by the following surfaces. Surfaces $\mathcal{S}_A$ and $\mathcal{S}_B$ are defined by buoyancy isosurfaces with $b_A < b_B$. The sea surface is decomposed into three regions, $\mathcal{S}_1, \mathcal{S}_2$, and $\mathcal{S}_3$ according to the outcrop locations of $\mathcal{S}_A$ and $\mathcal{S}_B$.

which case

$$\int_{\mathcal{S}_1+\mathcal{S}_2+\mathcal{S}_3+\mathcal{S}_A} b\,\boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} - \int_{\mathcal{S}_2+\mathcal{S}_B} b\,\boldsymbol{\omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} = -\int_{\mathcal{S}_1+\mathcal{S}_3} (\nabla b\times\boldsymbol{v})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{43.59}$$

We are thus led to write the layer integrated PV-substance in the form

$$\mathcal{I}_{AB} = -\int_{\mathcal{S}_1+\mathcal{S}_3} (\nabla b\times\boldsymbol{v})\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + \int_{\mathcal{S}_1+\mathcal{S}_3} (b-b_A)\,2\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S} + (b_B-b_A)\int_{\mathcal{S}_2} 2\,\boldsymbol{\Omega}\cdot\hat{\boldsymbol{n}}\,\mathrm{d}\mathcal{S}. \tag{43.60}$$

As desired, this alternative formulation only requires information about the flow field and buoyancy field over the outcrop surfaces, $\mathcal{S}_1$ and $\mathcal{S}_3$. For the region between the outcrops, we only need to know its area and outward normal, with $\hat{\boldsymbol{n}} \approx \hat{\boldsymbol{z}}$ an accurate approximation.

43.4.6 Further study

Section 4.8 of *Vallis* (2017) discusses the integrated PV-substance in terms of the vorticity formulation, whereas *Morel et al.* (2019) introduced the dual perspective based on the buoyancy gradient formulation. *Morel et al.* (2019) also provide details for the practical diagnosis of potential vorticity in a numerical ocean model or from observational based measurements.

43.5 Boundary fluxes of PV-substance

In Section 43.4 we developed kinematic expressions for the PV-substance integrated over a selection of volumes. That discussion illustrated how the volume integrated potential vorticity has contributions only from boundaries; e.g., where an atmospheric region intersects the ground or ocean, and where an oceanic region intersects the ground or the atmosphere. In this section we further our understanding of budgets for PV-substance by examining a buoyancy layer within the ocean that intersects the bottom on one side and the atmosphere on the other (Figure 43.6). We garner further understanding of the physical processes affecting changes to the PV-substance by here unpacking the boundary fluxes.

A buoyancy layer generally moves as it expands and contracts due to both reversible and irreversible processes (waves, currents, mixing). The impermeability theorem means that the total potential vorticity substance for the layer changes only through exchanges at the boundaries,

including the bottom (boundary between the solid earth and the fluid) and air-sea boundaries. Removing interior interfaces from the layer PV-substance budget simplifies the budget analysis, as already revealed in Section 43.4. As per the discussion of Section 43.3, the results in this section apply even when there is no materially invariant potential vorticity. All we require is a flux-form budget along with the impermeability theorem, which holds for potential vorticity defined according to an arbitrary smooth scalar field (Section 43.2.2).

FIGURE 43.6: A buoyancy layer of seawater denoted by $\mathcal{R}$, with the layer intersecting bottom topography on one side and the atmosphere on the other. The interior boundaries of the layer are formed by constant buoyancy surfaces.

43.5.1 Layer integrated budget

In addition to waves, currents, mixing, and sources affecting the layer interfaces, there is movement of the intersection of the layer with the side boundaries, thus changing the vertical and horizontal extents of these intersections. As a formulational framework, we derive the layer potential vorticity budget making use of the Leibniz-Reynolds transport theorem derived in Section 21.2.4. Just as for the layer integrated tracer budget considered in Section 21.5, applying Leibniz-Reynolds to the layer integrated potential vorticity budget renders

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, Q\, \mathrm{d}V\right] = \int_{\mathcal{R}} \partial_t(\rho\, Q)\, \mathrm{d}V + \oint_{\partial\mathcal{R}} \rho\, Q\, \dot{\boldsymbol{x}} \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}, \tag{43.61}$$

where $\mathcal{R}$ is the domain defined by the layer (Figure 43.6), $\partial\mathcal{R}$ is its boundary, and

$$\dot{\boldsymbol{x}} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} \tag{43.62}$$

is the velocity for a point on the boundary. Making use of the potential vorticity equation,

$$\partial_t(\rho\, Q) = -\nabla \cdot \boldsymbol{J}_{\mathrm{Q}}, \tag{43.63}$$

and the divergence theorem renders

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathcal{R}} \rho\, Q\, \mathrm{d}V\right] = \oint_{\partial\mathcal{R}} (-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.64}$$

This result holds around the full domain boundary. Now we decompose that boundary into portions defined by layer interfaces and those along the air-sea and land-sea boundaries.

43.5.2 Impermeability across interior layer interfaces

Rather than invoking the impermeability theorem derived in Section 43.2, we rederive it within the present context to further our confidence in its use. We thus consider the following for interior layer interfaces, here making use of the Haynes-McIntyre form (43.1) of the potential vorticity flux vector

$$[-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}] \cdot \hat{\boldsymbol{n}} = \Big[\rho\, Q\, (\dot{\boldsymbol{x}} - \boldsymbol{v}) + \dot{b}\, \boldsymbol{\omega}_{\mathrm{a}} - \nabla b \times \boldsymbol{F}\Big] \cdot \hat{\boldsymbol{n}} \tag{43.65a}$$

$$= \Big[(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla b)\, (\dot{\boldsymbol{x}} - \boldsymbol{v}) + \dot{b}\, \boldsymbol{\omega}_{\mathrm{a}}\Big] \cdot \hat{\boldsymbol{n}} \tag{43.65b}$$

$$= [(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla b)\, (\dot{\boldsymbol{x}} - \boldsymbol{v}) + (\partial_t b + \boldsymbol{v} \cdot \nabla b)\, \boldsymbol{\omega}_{\mathrm{a}}] \cdot \hat{\boldsymbol{n}} \tag{43.65c}$$

$$= [(\boldsymbol{\omega}_{\mathrm{a}} \cdot \nabla b)\, \dot{\boldsymbol{x}} + \boldsymbol{\omega}_{\mathrm{a}}\, \partial_t b] \cdot \hat{\boldsymbol{n}}, \tag{43.65d}$$

where

$$\hat{\boldsymbol{n}} = \nabla b / |\nabla b| \tag{43.66}$$

is the outward unit normal vector pointing to regions of higher buoyancy. Now recall that the velocity of a point fixed on an layer interface has a normal component that satisfies equation (43.10) (here applied to buoyancy surfaces)

$$\dot{\boldsymbol{x}} \cdot \hat{\boldsymbol{n}} = -\partial_t b / |\nabla b|. \tag{43.67}$$

This result then leads to the impermeability statement for isopycnal interfaces in the fluid interior

$$(-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = 0. \tag{43.68}$$

We thus conclude that changes to the layer integrated potential vorticity occur only via transfer across the land-sea boundary and the air-sea boundary

$$\frac{\mathrm{d}}{\mathrm{d}t}\left[\int_{\mathscr{R}} \rho\, Q\, \mathrm{d}V\right] = \int_{\text{land-sea}} [-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S} + \int_{\text{air-sea}} [-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}] \cdot \hat{\boldsymbol{n}}\, \mathrm{d}\mathcal{S}. \tag{43.69}$$

We now separately consider these two boundaries.

43.5.3 Potential vorticity flux at a land-sea boundary

We here evaluate the potential vorticity flux from equation (43.6a) at a land-sea boundary

$$-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}} = \rho\, Q\, (\dot{\boldsymbol{x}} - \boldsymbol{v}) + \dot{b}\, \boldsymbol{\omega}_{\mathrm{a}} - \nabla b \times \boldsymbol{F}. \tag{43.70}$$

At a solid and static boundary, the no-normal flow boundary condition (Section 20.4.1) means that $\hat{\boldsymbol{n}} \cdot \boldsymbol{v} = 0$. Likewise, the velocity of a point along the boundary moves along the tangent to the boundary so that $\dot{\boldsymbol{x}} \cdot \hat{\boldsymbol{n}} = 0$. Hence, the bottom boundary condition is solely comprised of irreversible processes

$$(-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = (\dot{b}\, \boldsymbol{\omega}_{\mathrm{a}} - \nabla b \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}}. \tag{43.71}$$

If this boundary flux is positive, then it acts to increase the integrated PV-substance of the region, and conversely if the boundary flux is negative.

In many parts of the ocean bottom, geothermal heating is negligible so that there is no

buoyancy input at the bottom, thus leaving just the contribution from friction

$$\text{no geothermal heating} \Longrightarrow (-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = -(\nabla b \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} = (\nabla b \times \hat{\boldsymbol{n}}) \cdot \boldsymbol{F}. \tag{43.72}$$

Furthermore, in the absence of geothermal heating the buoyancy satisfies a no-flux boundary condition, which can be ensured by having the buoyancy satisfying

$$\text{no geothermal heating} \Longrightarrow \hat{\boldsymbol{n}} \cdot \nabla b = 0. \tag{43.73}$$

Buoyancy isolines thus intersect the bottom parallel to the bottom outward normal, as shown in Figure 43.7.[4] Correspondingly, $(\nabla b \times \hat{\boldsymbol{n}}) \cdot \boldsymbol{F}$ projects onto that component of the friction vector pointing parallel to the bottom. Assuming buoyancy increases upward along the sloping bottom, as per a stably stratified fluid, then $\nabla b \times \hat{\boldsymbol{n}}$ points counter-clockwise around bowls and clockwise around bumps (see Figure 43.7).

Within the bottom boundary layer, quadratic bottom drag is a common parameterization of the acceleration associated with turbulent frictional processes

$$\boldsymbol{F} = -C_{\mathrm{d}}\, |\boldsymbol{u}|\, \boldsymbol{u}, \tag{43.74}$$

where C_{d} is a non-dimensional drag coefficient and $\boldsymbol{u}$ is the horizontal velocity. In this case the boundary condition for potential vorticity takes the form

$$(-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = (\nabla b \times \hat{\boldsymbol{n}}) \cdot \boldsymbol{F} = -C_{\mathrm{d}}\, |\boldsymbol{u}|\, (\nabla b \times \hat{\boldsymbol{n}}) \cdot \boldsymbol{u}. \tag{43.75}$$

We see that the sign of the bottom boundary potential vorticity flux depends on the relative orientation of the bottom flow and the vector $\nabla b \times \hat{\boldsymbol{n}}$. To help understand the sign, consider an abyssal bowl with buoyancy increasing upward along the sloping bottom, in which case $\nabla b \times \hat{\boldsymbol{n}}$ points counter-clockwise around the bowl. A bottom boundary flow that is also oriented counter-clockwise carries a positive curvature relative vorticity (Section 38.8). This positive relative vorticity is damped by the bottom friction, which corresponds to the negative potential vorticity source as per equation (43.75). Conversely, a bottom boundary flow that is oriented clockwise around the abyssal bowl carries a negative curvature relative vorticity. This negative relative vorticity is damped by the bottom friction, which corresponds to the positive potential vorticity source as per equation (43.75).

Consider a component to the bottom flow that is parallel to ∇b. Theis flow provides a zero potential vorticity source since $\nabla b \times \boldsymbol{F} = 0$ (again, assuming $\boldsymbol{F} = -C_{\mathrm{d}}\, |\boldsymbol{u}|\, \boldsymbol{u}$). This result is expected from the discussion in Section 42.4 and Figure 42.4, where we note that friction changes potential vorticity by rotating buoyancy surfaces, with that rotation realized only when friction is not aligned with ∇b.

43.5.4 Potential vorticity flux at the air-sea boundary

For the permeable air-sea boundary, we make use of the kinematic boundary condition derived in Section 20.4.3, where the boundary condition (20.63) leads to

$$\rho\, \hat{\boldsymbol{n}} \cdot (\dot{\boldsymbol{x}} - \boldsymbol{v}) = \mathcal{Q}_{\mathrm{m}} \qquad \text{air-sea boundary}, \tag{43.76}$$

[4] There is ongoing research aimed at determining the thickness of the region over which the boundary condition (43.73) is accurate. The boundary condition presumably holds within a molecular sublayer. But the question is whether larger scale motions near the ocean bottom allow for this condition to hold over a thicker region. See the review chapter by *Polzin and McDougall* (2021) for discussion.

FIGURE 43.7: Depicting a buoyancy isosurface that intersects the bottom. As discussed in Section 21.5 and depicted in Figure 21.5, in the absence of geothermal heating, a buoyancy isosurface satisfies the no-normal flux bottom boundary condition, $\hat{\boldsymbol{n}} \cdot \nabla b = 0$. This boundary condition requires buoyancy isosurfaces to be orthogonal to the bottom. Assuming buoyancy increases upward along the sloping bottom, then $\nabla b \times \hat{\boldsymbol{n}}$ points counterclockwise around bowls and clockwise around bumps (when viewed from above). This structure for the buoyancy surfaces affects how friction impacts on the layer-integrated potential vorticity budget, with details provided in Section 43.5.3.

with $\mathcal{Q}_{\mathrm{m}}$ the mass per time per surface area of matter that crosses the air-sea boundary. We are thus led to the air-sea boundary condition

$$(-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = Q\, \mathcal{Q}_{\mathrm{m}} + (\dot{b}\, \boldsymbol{\omega}_{\mathrm{a}} - \nabla b \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}}. \tag{43.77}$$

Besides the irreversible processes, potential vorticity is affected at the air-sea interface by the transfer of matter across the boundary via the term $Q\, \mathcal{Q}_{\mathrm{m}}$. We can think of this term as an advection of potential vorticity across the boundary via the boundary mass transport. More generally, we can think of the full boundary flux (43.77) as acting to stretch/compress the fluid column so to alter vorticity and hence the potential vorticity.

To help interpret the friction term appearing in the flux (43.77), write

$$(\dot{b}\, \boldsymbol{\omega}_{\mathrm{a}} - \nabla b \times \boldsymbol{F}) \cdot \hat{\boldsymbol{n}} = (\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})\, (\partial_t b + \boldsymbol{v} \cdot \nabla b) + (\hat{\boldsymbol{n}} \times \boldsymbol{F}) \cdot \nabla b \tag{43.78a}$$

$$= (\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})\, [\partial_t b + (\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}}) \cdot \nabla b]\,, \tag{43.78b}$$

where we introduced the *generalized Ekman velocity*

$$\boldsymbol{v}_{\mathrm{E}} \equiv \frac{\boldsymbol{F} \times \hat{\boldsymbol{n}}}{\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}}}, \tag{43.79}$$

thus bringing the air-sea boundary potential vorticity flux (43.77) to the form

$$(-\boldsymbol{J}_{\mathrm{Q}} + \rho\, Q\, \dot{\boldsymbol{x}}) \cdot \hat{\boldsymbol{n}} = Q\, \mathcal{Q}_{\mathrm{m}} + (\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})\, [\partial_t b + (\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}}) \cdot \nabla b]\,. \tag{43.80}$$

Note that for the special case of a vertical outward normal, $\hat{\boldsymbol{n}} = \hat{\boldsymbol{z}}$, and weak relative vorticity, $f + \zeta \approx f$, we have

$$\boldsymbol{v}_{\mathrm{E}} \approx f^{-1}\, \boldsymbol{F} \times \hat{\boldsymbol{z}}, \tag{43.81}$$

which is the Ekman velocity given by equation (34.4). We thus see that the sign of the $(\boldsymbol{\omega}_{\mathrm{a}} \cdot \hat{\boldsymbol{n}})$ portion of the potential vorticity flux is determined by whether the surface buoyancy is increasing or decreasing in time following the velocity difference, $\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}}$, along the air-sea boundary. We can interpret $\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}}$ as the inviscid portion of the velocity since it removes that portion arising from

friction.[5]

43.5.5 Thought experiments

The surface potential vorticity flux (43.77), or its rewritten form in equation (43.80), provide an explicit expression for how surface boundary fluxes affect the potential vorticity budget within a buoyancy layer outcropping at the ocean surface. It contains a wealth of physics that can be explored via thought experiments.

Potential vorticity generation in a fluid with zero initial baroclinicity

Consider a fluid region initially with zero baroclinicity and zero flow so that the initial potential vorticity is given by $f\,N^2$, with N^2 the squared buoyancy frequency. The surface potential vorticity flux (43.77) creates potential vorticity via the mass flux term and through heating/cooling. If this term alone affected the potential vorticity, and it did so uniformly in space, then it would alter potential vorticity only via changes in the vertical stratification. More generally, both the mass term and the diabatic term create horizontal buoyancy gradients, which then generate currents and vorticity that generate further contributions to the potential vorticity flux.

Potential vorticity generation in a fluid that is initially homogeneous

Consider an initially homogenous box of seawater with zero potential vorticity. In this case it is only the buoyancy term, $\dot{b}\,f$, that contributes to initial changes in potential vorticity. Northern hemisphere ($f > 0$) surface cooling ($\dot{b} < 0$) adds negative potential vorticity to the box. Cooling also initiates gravitational instability that mixes the water and in turn spreads the negative potential vorticity boundary source throughout the fluid. Cooling adds structure to the buoyancy field by inflating the formerly zero thickness buoyancy layers, with layer inflation originating from the boundary. Once inflated, the impermeability theorem dictates that the layer integrated PV-substance changes only via boundary interactions, whereas stirring and mixing transport potential vorticity into the fluid interior. Notably, a region with $f\,Q < 0$ is locally unstable to symmetric instability, with the generated symmetric instability acting to locally bring the flow towards a state with zero potential vorticity. However, the constraints from impermeability mean that the net PV-substance remains unchanged within a buoyancy layer, even in the presence of mixing.

43.5.6 Is there a preferred form of the PV-substance flux?

Analysis in this section made use of the Haynes-McIntyre form of the PV-substance flux (equation (43.1))

$$\boldsymbol{J}_{\mathrm{Q}} = \rho\,\boldsymbol{v}\,Q - \dot{b}\,\boldsymbol{\omega}_{\mathrm{a}} + \nabla b \times \boldsymbol{F}. \tag{43.82}$$

We could have instead chosen to work with the Marshall form (equation (43.32))

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}} = -\left[\partial_t \boldsymbol{v} + \nabla(\mathcal{M} + p/\rho)\right] \times \nabla b - \boldsymbol{\omega}_{\mathrm{a}}\,\partial_t b, \tag{43.83}$$

or the modified kinematic form (equation (43.18))

$$\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}} = -\partial_t \boldsymbol{v}_{\mathrm{a}} \times \nabla b - \boldsymbol{\omega}_{\mathrm{a}}\,\partial_t b. \tag{43.84}$$

[5] The velocity difference, $\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}}$, is not equal to the inviscid velocity that would appear in an inviscid (perfect) fluid. Rather, $\boldsymbol{v} = \boldsymbol{v}_{\mathrm{E}} + (\boldsymbol{v} - \boldsymbol{v}_{\mathrm{E}})$ is an interpretational decomposition akin to that studied in Chapter 34 for Ekman mechanics. See the comment after equation (34.4) for more on this point.

These fluxes differ by a gauge choice and yet they each satisfy the impermeability theorem. Subjective choices determine which one is preferred. Importantly, once chosen, we can use only a single form of the flux throughout the budget analysis in order to remain self-consistent with the form of the total curl that is removed by the divergence operator.

The PV-substance budget, though invariant to the choice of flux, has distinct physical pictures depending on the choice of the flux. As a particularly clear example consider a steady state budget in which the fluxes take the form

$$\boldsymbol{J}_{\mathrm{Q}} = \rho\, \boldsymbol{v}\, Q - (\boldsymbol{v} \cdot \nabla b)\, \boldsymbol{\omega}_{\mathrm{a}} + \nabla b \times \boldsymbol{F} \tag{43.85}$$

$$\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}} = -\nabla(\mathcal{M} + p/\rho) \times \nabla b \tag{43.86}$$

$$\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}} = 0. \tag{43.87}$$

The physical picture for $\widetilde{\boldsymbol{J}}_{\mathrm{Q}}^{\mathrm{kin}}$ is rather trivial, whereby the PV-substance stays constant within buoyancy layers and there are zero PV-substance fluxes across *all* boundaries of the layer. In contrast, a steady state budget when working with $\boldsymbol{J}_{\mathrm{Q}}$ or $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}$ afford a physical picture of PV-substance entering, leaving, and transported through the buoyancy layers. *Marshall et al.* (2001) developed a rather elegant analysis framework using $\boldsymbol{J}_{\mathrm{Q}}^{\mathrm{marshall}}$ for steady budgets, and we explore facets of that approach in Section 42.5 for the special case of a Boussinesq hydrostatic fluid.

Nevertheless, our use of the Haynes-McIntyre PV-substance flux in the present section is motivated by its utility for describing how boundary forcing can change the sign of the potential vorticity. Such forcing exposes the flow to a variety of local instabilities (e.g., symmetric, centrifugal, gravitational). *Thomas et al.* (2008) offer a pedagogical review for the ocean; *Thomas et al.* (2013) provides a thorough study of the upper reaches of the Gulf Stream; and *Naveira Garabato et al.* (2019) provide evidence for such boundary forcing in regions of strong abyssal flows. Each of these studies points to the need to further understand details of the boundary potential vorticity flux and to furthermore ensure it is properly formulated within numerical models (e.g., *Hallberg and Rhines* (1996)).

43.5.7 Further study

The study of boundary potential vorticity fluxes is incredibly rich and generally requires careful analysis of the multitude of processes active in the boundary layer. The interested reader can find ocean examples of these analyses in *Benthuysen and Thomas* (2012) and *Wenegrat et al.* (2018), and the references therein.

Part VIII

Nearly geostrophic flows

Fluid motion dominated by rotation is characterized by a small Rossby number. To zeroth order in an asymptotic expansion in Rossby number, the flow maintains geostrophic balance, which is a balance between the Coriolis acceleration and pressure gradient acceleration. As seen in Chapter 32, the geostrophic balance is diagnostic so that it offers no means to compute the time evolution of the fluid. To obtain a prognostic equation requires going to next order in Rossby number within the asymptotic expansion. The resulting prognostic equation makes use of ageostrophic motions, though only as an intermediate step towards an evolution equation involving just zeroth order geostrophically balanced fields.

The nuts and bolts of this part of the book involve methods of scaling analysis and asymptotic analysis via perturbation series. In Chapter 44, we use these tools to derive equations for planetary geostrophy (PG) and quasi-geostrophy (QG) within the shallow water system, and then extend that discussion to continuously stratified flows in Chapters 45 and 46 . Planetary geostrophy quasi-geostrophy are very useful theoretical models lending insights into ocean and atmosphere fluid mechanics. In particular, planetary geostrophy is commonly used to study features of the large-scale laminar ocean circulation. In contrast, quasi-geostrophy is ubiquitous in studies of both oceanic and atmospheric flows at or near the deformation radius, particularly when concerned with transients such as waves, instabilities, and turbulence.

One central property of balanced flow is that knowledge of the relevant balanced version of potential vorticity is sufficient to determine the flow field. A way to appreciate this property is to consider a horizontally non-divergent barotropic flow (Chapter 39), in which the Laplacian of the streamfunction gives the relative vorticity, $\zeta = \nabla^2\psi$. Conversely, if we know the vorticity then we can invert the Laplacian (with suitable boundary conditions) to yield the streamfunction and hence the velocity. In our discussion of quasi-geostrophy in Chapter 46, we extend this result to three-dimensional quasi-geostrophic flow, where the prognostic fields are the horizontal components to the geostrophic flow, plus the buoyancy field. Such methods of *potential vorticity inversion* are routinely used to study atmospheric flows given maps of potential vorticity (see *Hoskins* (1991) for a review).

Chapter 44

Models of nearly geostrophic flows

Rotation, as manifested by the Coriolis acceleration, is a primary feature of geophysical fluid flows. To probe the physics of such flows, it is very useful to develop mathematical models where rotation is a prominent facet of the equations of motion, and extraneous elements are absent. Systematically deriving such models is the focus of this chapter, where we develop the mechanical equations for planetary geostrophy (PG) and quasi-geostrophy (QG) within the shallow water fluid. We also work through the non-dimensionalization of the stratified Boussinesq equations, thus providing the foundations for the equations of stratified planetary geostrophy in Chapter 45 and stratified quasi-geostrophy in Chapter 46.

READER'S GUIDE FOR THIS CHAPTER

This chapter is technical in nature, making use of tools from dimensional analysis, scale analysis, and asymptotic methods to derive approximate geostrophic equations. The derivations require elements from dimensional analysis and asymptotic methods, with salient details introduced and mathematical steps exposed. We assume an understanding of the equations for a single layer of shallow water fluid as derived in Chapter 36, as well as the Boussinesq ocean equations from Chapter 30. We follow this work with further studies of the continuously stratified planetary geostrophy in Chapter 45 and quasi-geostrophy in Chapter 46.

44.2 Scaling analysis and the Buckingham-Π theorem

Scale analysis is ubiquitous in physics, with the Buckingham-Π theorem providing a useful framework. The theorem states that the number of dimensionless parameters in a physical system is a function of the number of dimensional parameters or scales, K_{scales} (e.g., scales for the velocity, rotation rate, pressure force, friction force, gravitational acceleration) and the number of physical dimensions, $K_{\text{dimensions}}$ (e.g., time, length, mass). Precisely, Buckingham-Π states that the number of dimensionless parameters is

$$N_{\text{dimensionless}} = K_{\text{scales}} - K_{\text{dimensions}}. \tag{44.1}$$

Different physical systems possessing the same suite of dimensionless parameters are isomorphic. For example, a laboratory study of flow around a cylinder contains two dimensionless parameters: the drag coefficient, C_{d}, and the Reynolds number, Re. If the problem is scaled up to a building with the same shape, then so long as the values for the dimensionless parameters are the same (e.g., same drag coefficient and same Reynolds number), one can make use of the laboratory analog for determining suitability of the building architecture. Similar isomorphisms exist between flows in a rotating tank and flows in the ocean and atmosphere.

The Buckingham-Π theorem does not provide the form of the dimensionless parameters. Nor does the theorem determine their values. This information comes only after introducing physical prejudices surrounding a regime of chosen interest. Additionally, Buckingham-Π does not offer information about how the dimensionless parameters might be related. Instead, any such relations arise from the mechanical and thermodynamical equations describing the system. Consequently, mechanical and thermodynamical equations generally mean that fewer than $N_{\text{dimensionless}}$ non-dimensional numbers are independent.

We focus in this chapter on the regime of large-scale atmospheric and oceanic flow where the shallow water fluid is close to geostrophic balance. That choice then guides the length and time

scales, which in turn determines the size of the dimensionless parameters. In many cases, one is able to identify dimensionless parameters that are large or small in particular regimes, which in turn suggests asymptotic analyses to render equations specific to the regime of interest.

44.3 Shallow water equations

A single-layer of inviscid shallow water fluid of thickness h is governed by the velocity and thickness equations (Chapter 36)

$$\partial_t \boldsymbol{u} + (\boldsymbol{u} \cdot \nabla)\, \boldsymbol{u} + \boldsymbol{f} \times \boldsymbol{u} = -g \nabla \eta \tag{44.2a}$$

$$\partial_t h + \nabla \cdot (h\, \boldsymbol{u}) = 0, \tag{44.2b}$$

where $\boldsymbol{u}$ is the horizontal velocity that is independent of depth within the layer ($\partial_z \boldsymbol{u} = 0$). The vertical bounds for the layer are specified by the free surface height, $z = \eta(x, y, t)$, and bottom topography, $z = \eta_{\mathrm{b}}(x, y)$ (see Figure 36.1). They are related according to

$$\eta = \eta_{\mathrm{b}} + h = H + \overline{\eta_{\mathrm{b}}} + \eta' = \overline{h} + \overline{\eta_{\mathrm{b}}} + \eta', \tag{44.3}$$

where $H = \overline{h}$ is the area average layer thickness, $\overline{\eta_{\mathrm{b}}}$ is the area average of the bottom topography, $\eta' = \eta - \overline{\eta}$ is the deviation of the surface height from its area average, $\overline{\eta} = \overline{\eta_{\mathrm{b}}} + H$. We also find occasion to write the layer thickness in the form

$$h = \eta - \eta_{\mathrm{b}} = H + (\overline{\eta_{\mathrm{b}}} - \eta_{\mathrm{b}}) + \eta' = \overline{h} - \eta_{\mathrm{b}}' + \eta' = \overline{h} + h', \tag{44.4}$$

where $\eta_{\mathrm{b}}' = \eta_{\mathrm{b}} - \overline{\eta_{\mathrm{b}}}$ is the deviation of the bottom topography from its area mean, and we introduced the thickness deviation from the area mean

$$h' = h - \overline{h} = \eta' - \eta_{\mathrm{b}}'. \tag{44.5}$$

Dexterity with the geometrical relations (44.3)-(44.5) is assumed in the following.

44.3.1 Dimensional scales

We identify the following nine dimensional parameters for the shallow water layer.

- LENGTH SCALES
  - ⋆ H = depth scale of the fluid layer, which we take equal to the area average layer thickness (see Figure 36.1).
  - ⋆ L = horizontal/lateral length scale of motions under consideration. We assume both horizontal directions to have the same length scale. This assumption is not necessarily valid on a rotating planet, where flows in the zonal (east-west) direction can have length scales longer than meridional (north-south) flow scales. Nonetheless, this choice does not preclude the dynamical emergence of anisotropic length scales.
  - ⋆ R_{e} = radius of the planet. We include this scale anticipating that for length scales small compared to the earth's radius, the Coriolis parameter may be approximated by a constant (f-plane) or linear function of latitude (β-plane).
  - ⋆ $\mathcal{H}$ = scale for deviations of the free surface height, η, relative to its area average, $\overline{\eta}$, so that $\eta' = \eta - \overline{\eta} \sim \mathcal{H}$.

- ⋆ $\mathcal{B}$ = scale for deviations of the bottom topography, $\eta_{\rm b}$, relative to its area average, $\overline{\eta_{\rm b}}$, so that $\eta'_{\rm b} = \eta_{\rm b} - \overline{\eta_{\rm b}} \sim \mathcal{B}$.

- VELOCITY SCALES

  - ⋆ U = velocity scale for horizontal fluid particle motion; i.e., the speed for horizontal currents or winds.
  - ⋆ c = wave speed scale. For the shallow water model, the wave speed scale is given by the shallow water gravity wave (Section 53.5.1)

$$c = \sqrt{g\,H}. \tag{44.6}$$

  We introduce the wave speed anticipating the presence of distinct flow regimes depending on whether the fluid particle speed is larger or smaller than the wave speed. The ratio of the wave speed to particle speed is known as the *Froude number* (Section 44.3.4).

- BODY FORCES: There are two body forces acting on the fluid; one from gravity and one from Coriolis. These two forces are scaled according to the following two parameters:

  - ⋆ g = gravitational acceleration
  - ⋆ f = Coriolis frequency.

If we were interested in other forces, such as electromagnetic or frictional forces, then we need to add further dimensional parameters corresponding to these forces.

44.3.2 Physical dimensions

There are two physical dimensions in the shallow water system: length, L, and time, T. Notably, there is no mass in the shallow water system. The reason is that the fluid density is assumed uniform within a shallow water layer so that mass is described by area times thickness

$$M = \int \rho\,\mathrm{d}V \;[\equiv]\; L^2 H\,\rho, \tag{44.7}$$

where $[\equiv]$ is read "has dimensions".

44.3.3 Number of non-dimensional parameters

The Buckingham-Π theorem then says there are

$$N_{\rm dimensionless} = 9 - 2 = 7 \tag{44.8}$$

non-dimensional parameters. So we expect to find seven non-dimensional parameters arise as part of the analysis. Yet how do we know that we properly counted the physical dimensions or the dimensional scales/parameters? Fortunately, the process of determining the non-dimensional parameters is largely self-correcting. Namely, if one left out a physical dimension or a physical parameter, then it would appear somewhere in the subsequent analysis, often not until near the end where something mathematically or physically inconsistent appears. One must remain cognizant of the need to self-correct when performing dimensional analysis.

44.3.4 Choosing the non-dimensional parameters

There is no unique choice for the non-dimensional parameters. Our choice is guided by experience, interest, and what parameters might be available to experimental control or measurement.

1. VERTICAL TO HORIZONTAL/LATERAL ASPECT RATIO: The ratio of the vertical scale to the horizontal/lateral[1] scale defines the aspect ratio

$$\delta_{\text{vertical/horizontal}} = \frac{\text{vertical length scale}}{\text{horizontal length scale}} = \frac{H}{L}. \tag{44.9}$$

2. RATIO OF HORIZONTAL/LATERAL SCALE TO PLANETARY SCALE: The ratio of the horizontal length scale to the planet radius is

$$\delta_{\text{horizontal/planet}} = \frac{\text{horizontal length scale}}{\text{planetary length scale}} = \frac{L}{R_{\text{e}}}. \tag{44.10}$$

3. RATIO OF FREE SURFACE UNDULATION TO VERTICAL LENGTH SCALE: The ratio of the free surface undulation scale to the vertical length scale is

$$\delta_{\text{free surface/depth}} = \frac{\text{free surface undulation scale}}{\text{vertical length scale}} = \frac{\mathcal{H}}{H}. \tag{44.11}$$

4. RATIO OF BOTTOM TOPOGRAPHY UNDULATION TO VERTICAL LENGTH: The ratio of the bottom topography undulation scale to the vertical length scale is

$$\delta_{\text{bottom/depth}} = \frac{\text{bottom topography undulation scale}}{\text{vertical length scale}} = \frac{\mathcal{B}}{H}. \tag{44.12}$$

5. FROUDE NUMBER: The Froude number is the ratio of the fluid particle speed to the wave speed. For the shallow water system, this ratio is

$$\text{Fr} = \frac{U}{c} = \frac{U}{\sqrt{g\,H}}. \tag{44.13}$$

6. ROSSBY NUMBER: The Rossby number is the ratio of the fluid particle acceleration scale to the Coriolis acceleration scale

$$\text{Ro} = \frac{\text{particle acceleration}}{\text{Coriolis acceleration}}. \tag{44.14}$$

The particle acceleration scale is determined by the local time tendency plus advection

$$\text{particle acceleration} = \frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\,\boldsymbol{u} \sim \frac{U}{T} + \frac{U^2}{L}. \tag{44.15}$$

The local time tendency and advection generally have distinct scales, thus leading to the potential for two Rossby numbers

$$\text{Ro}^{\text{local}} = \frac{1}{T\,f} \quad \text{and} \quad \text{Ro}^{\text{adv}} = \frac{U}{L\,f}. \tag{44.16}$$

[1] The terms "lateral" and "horizontal" are used interchangeably, referring to motion at constant vertical position either on the sphere or on the plane.

In the following we consider these two Rossby numbers to have the same scale, which is realized by advective contributions to material time evolution being comparable to local time changes. We refer to this choice as an *advective time scale*, whereby

$$T = \frac{L}{U} \Longrightarrow \frac{U^2}{L} = \frac{U}{T}, \tag{44.17}$$

so that there is only one Rossby number

$$\mathrm{Ro} = \frac{1}{f\,T} = \frac{U}{f\,L}. \tag{44.18}$$

Another interpretation for the Rossby number is the ratio of the relative vorticity to the planetary vorticity

$$\mathrm{Ro} = \frac{\text{relative vorticity}}{\text{planetary vorticity}}. \tag{44.19}$$

With the relative vorticity scaling as U/L and the planetary vorticity scaling as f, we recover the expression (44.18) for the Rossby number.

7. Geostrophic number: We define the geostrophic number as the ratio of the Coriolis acceleration scale to the scale of the pressure gradient acceleration

$$\mathrm{Ge} = \frac{\text{Coriolis acceleration}}{\text{pressure gradient acceleration}}. \tag{44.20}$$

The Coriolis acceleration scales as

$$\text{Coriolis acceleration} \sim f\,U, \tag{44.21}$$

whereas the pressure gradient acceleration, $-g\,\nabla\eta$, scales as

$$\text{pressure gradient acceleration} \sim \frac{g\,\mathcal{H}}{L}, \tag{44.22}$$

so that

$$\mathrm{Ge} = \frac{\text{Coriolis acceleration}}{\text{pressure gradient acceleration}} = \frac{f\,U}{(g/L)\,\mathcal{H}}. \tag{44.23}$$

44.3.5 Assumed values for the non-dimensional parameters

We now enumerate the assumed values for the non-dimensional parameters. These values are based on the chosen physical regime of flow that is of interest for the analysis.

1. small vertical to horizontal aspect ratio: The aspect ratio is generally small for large-scale atmospheric and oceanic fluid systems

$$\delta_{\text{vertical/horizontal}} = H/L \ll 1. \tag{44.24}$$

This assumption was made when formulating the shallow water system, which is based on hydrostatic balance (see Section 36.2). We thus retain this assumption as we further scale the shallow water system.

2. small or order one ratio of horizontal/lateral to planetary scales: The ratio of the lateral length scale to the planet radius is small for quasi-geostrophic systems and

order unity for planetary geostrophy

$$\delta_{\text{horizontal/planet}} = L/R_{\text{e}} \ll 1 \quad \text{quasi-geostrophy} \tag{44.25a}$$

$$\delta_{\text{horizontal/planet}} = L/R_{\text{e}} \sim 1 \quad \text{planetary geostrophy.} \tag{44.25b}$$

3. RATIO OF FREE SURFACE UNDULATION TO VERTICAL LENGTH SCALE: The ratio $\mathcal{H}/H$ is implied by assuming a unit geostrophic number below.

4. RATIO OF BOTTOM TOPOGRAPHY UNDULATION TO VERTICAL LENGTH SCALE: For quasi-geostrophy, we assume that undulations in the bottom topography are small relative to the vertical length scale, whereas there is no restriction for planetary geostrophy. "Small" in the present context is determined by the Rossby number, in which case

$$\delta_{\text{bottom/depth}} = \mathcal{B}/H = \text{Ro} \quad \text{for quasi-geostrophy.} \tag{44.26}$$

5. FROUDE NUMBER: We find that the Froude number is implied by scales assumed for the other non-dimensional numbers.

6. SMALL ROSSBY NUMBER: The Rossby number is assumed small

$$\text{Ro} = U/(f\,L) \ll 1, \tag{44.27}$$

which means that the Coriolis acceleration is a leading order term in the horizontal velocity equation (44.2a).

7. UNIT GEOSTROPHIC NUMBER: The geostrophic number is assumed to be order unity

$$\text{Ge} \sim 1. \tag{44.28}$$

This assumption means that the Coriolis acceleration and pressure gradient acceleration scale together

$$f\,U \sim (g/L)\,\mathcal{H}. \tag{44.29}$$

Making use of the velocity equation (44.2a), we see that this scaling is consistent only so long as the Rossby number is small, $\text{Ro} \ll 1$. Furthermore, this scaling constrains the scale of the free surface undulation, $\mathcal{H}$, as we discuss in Section 44.3.6.

44.3.6 Deformation radius and the free surface undulation scale

We determine the scale for the free surface height undulation, $\mathcal{H}$, by making use of the assumed order unity geostrophy number. For this purpose, start from the geostrophic scaling of Coriolis and pressure gradient accelerations, (44.29), to express the free surface undulation scale according to

$$\eta' \sim \mathcal{H} = \frac{f\,U\,L}{g} = \text{Ro}\,\frac{f^2\,L^2}{g} = \text{Ro}\,H\,\frac{f^2\,L^2}{g\,H} = \text{Ro}\,H\left[\frac{L}{L_{\text{d}}}\right]^2. \tag{44.30}$$

In the final equality we introduced the *deformation radius*

$$L_{\text{d}} = \sqrt{g\,H}/f = c_{\text{grav}}/f, \tag{44.31}$$

where c_{grav} is the shallow water gravity wave speed (Section 53.5.1). The deformation radius decreases toward the poles, so that rotational effects are felt by smaller scales in the high latitudes than in the tropics. In Section 44.6.2 we see how the deformation radius acts as a regime boundary

between relative vorticity and vortex stretching for the quasi-geostrophic potential vorticity. We again encounter the shallow water deformation radius when discussing shallow water waves in Chapter 53.

We can use $L_{\rm d}$ to rewrite the Froude number as the ratio of the advection speed to the rotation speed

$$\mathrm{Fr} = \frac{U}{\sqrt{g\,H}} = \frac{U}{f\,L_{\rm d}} = \mathrm{Ro}\,\frac{L}{L_{\rm d}}. \tag{44.32}$$

Furthermore, the squared ratio of the deformation radius to the lateral length scale is termed the *Burger number*

$$\mathrm{Bu} = \left[\frac{L_{\rm d}}{L}\right]^2. \tag{44.33}$$

Use of the Burger number allows us to write the Froude number in terms of the Rossby number and Burger number

$$\mathrm{Fr} = \frac{\mathrm{Ro}}{\sqrt{\mathrm{Bu}}}. \tag{44.34}$$

Likewise, the free surface height undulation scale can be written

$$\mathscr{H} = H\,\mathrm{Ro}\left[\frac{L}{L_{\rm d}}\right]^2 = H\,\frac{\mathrm{Ro}}{\mathrm{Bu}} = H\,\frac{\mathrm{Fr}^2}{\mathrm{Ro}}. \tag{44.35}$$

Hence, the ratio of the free surface undulations to the layer thickness (depth) scale is given by

$$\delta_{\text{free surface/depth}} = \frac{\mathscr{H}}{H} = \mathrm{Ro}\left[\frac{L}{L_{\rm d}}\right]^2 = \frac{\mathrm{Ro}}{\mathrm{Bu}} = \frac{\mathrm{Fr}^2}{\mathrm{Ro}}. \tag{44.36}$$

Again, this scaling is implied by making the dynamical assumption of a unit geostrophic number, which means that the pressure gradient acceleration scales according to the Coriolis acceleration.

44.3.7 Non-dimensional shallow water equations

To non-dimensionalize the shallow water equations we introduce non-dimensional variables for space, time, velocity, and Coriolis parameter as adorned with a widehat[2]

$$t = T\,\widehat{t} \qquad (x,y) = L\,(\widehat{x},\widehat{y}) \qquad \partial_t = \partial_{\widehat{t}}/T \qquad \nabla = \widehat{\nabla}/L \qquad (u,v) = U\,(\widehat{u},\widehat{v}) \qquad f = f_0\,\widehat{f}, \tag{44.37}$$

where f_0 is the Coriolis parameter at the central latitude for the β-plane approximation (Section 25.5). We also require non-dimensional variables for the surface and bottom undulations

$$\eta' = \mathscr{H}\,\widehat{\eta} \qquad \eta'_{\rm b} = \mathscr{B}\,\widehat{\eta}_{\rm b} \qquad h = H + \eta' - \eta'_{\rm b} = H + \mathscr{H}\,\widehat{\eta} - \mathscr{B}\,\widehat{\eta}_{\rm b}, \tag{44.38}$$

where we used equation (44.4) for the layer thickness. Importantly, we assume that the non-dimensional variables (the widehat variables) are order unity. That assumption is critical for organizing terms in the asymptotic expansion.

[2]The LaTeX widehat symbol is used for non-dimensional variables, such as the non-dimensional velocity, $\widehat{\boldsymbol{u}}$. The widehat is distinguished from the hat used for unit vectors, such as for the vertical unit vector, $\hat{\boldsymbol{z}}$. We also use widehats for thickness weighted means in Chapter 63, but that usage is completely distinct from the non-dimensionalization usage in the present chapter.

Non-dimensional velocity equation

Introducing the above variables into the shallow water velocity equation (44.2a) renders

$$\frac{U}{T}\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + \frac{U^2}{L}\left(\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}\right)\widehat{\boldsymbol{u}} + f_0\,U\left(\widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}}\right) = -\frac{g\,\mathcal{H}}{L}\,\widehat{\nabla}\widehat{\eta}. \tag{44.39}$$

As before, we assume the time scale is given by the advection time

$$T = L/U = 1/(\mathrm{Ro}\,f_0), \tag{44.40}$$

so that dividing by $f_0\,U$ leads to

$$\mathrm{Ro}\left[\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + \left(\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}\right)\widehat{\boldsymbol{u}}\right] + \left(\widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}}\right) = -\left[\frac{g\,H}{f_0\,L\,U}\frac{\mathrm{Ro}}{\mathrm{Bu}}\right]\widehat{\nabla}\widehat{\eta}, \tag{44.41}$$

where we set $\mathcal{H} = H\,(\mathrm{Ro}/\mathrm{Bu})$ according to equation (44.36). We reduce the factor on the right hand side according to

$$\frac{g\,H}{f_0\,L\,U}\frac{\mathrm{Ro}}{\mathrm{Bu}} = \frac{g\,H}{f_0\,L\,U}\frac{U}{f_0\,L}\frac{L^2}{L_\mathrm{d}^2} = \frac{g\,H}{f_0\,L\,U}\frac{U}{f_0\,L}\frac{L^2\,f_0^2}{g\,H} = 1. \tag{44.42}$$

Hence, the non-dimensional inviscid shallow water velocity equation takes on the rather elegant form

$$\mathrm{Ro}\left[\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + \left(\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}\right)\widehat{\boldsymbol{u}}\right] + \widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}} = -\widehat{\nabla}\widehat{\eta}. \tag{44.43}$$

Introducing the non-dimensional material time derivative

$$\frac{\mathrm{D}}{\mathrm{D}\widehat{t}} = \frac{\partial}{\partial \widehat{t}} + \widehat{\boldsymbol{u}}\cdot\widehat{\nabla} \tag{44.44}$$

brings the velocity equation to

$$\mathrm{Ro}\,\frac{\mathrm{D}\widehat{\boldsymbol{u}}}{\mathrm{D}\widehat{t}} + \widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}} = -\widehat{\nabla}\widehat{\eta}. \tag{44.45}$$

We see that the velocity equation is consistent with a unit geostrophy number (i.e., Coriolis acceleration balances pressure gradient acceleration) if and only if the Rossby number is small, thus eliminating the material acceleration.

Non-dimensional thickness equation

The thickness equation (44.2b) can be written

$$\frac{\partial \eta'}{\partial t} + \nabla\cdot\left[\left(H + \eta' - \eta_\mathrm{b}'\right)\boldsymbol{u}\right] = 0, \tag{44.46}$$

which takes on the non-dimensional form

$$\frac{\mathcal{H}}{T}\frac{\partial \widehat{\eta}}{\partial \widehat{t}} + \frac{U\,H}{L}\,\widehat{\nabla}\cdot\left[\left(1 + \widehat{\eta}\,\mathcal{H}/H - \widehat{\eta}_\mathrm{b}\,\mathcal{B}/H\right)\widehat{\boldsymbol{u}}\right] = 0. \tag{44.47}$$

The advective time scaling $T = L/U$ brings the thickness equation to

$$\frac{\mathcal{H}}{H}\frac{\partial \widehat{\eta}}{\partial \widehat{t}} + \widehat{\nabla}\cdot\left[\left(1 + \widehat{\eta}\,\mathcal{H}/H - \widehat{\eta}_\mathrm{b}\,\mathcal{B}/H\right)\widehat{\boldsymbol{u}}\right] = 0. \tag{44.48}$$

We further specialize this equation depending on the assumed horizontal length scale of the flow.

44.4 Shallow water planetary geostrophy

We make use of the non-dimensional equations derived in Section 44.3.7 to derive the dynamical equations for planetary geostrophy. We already encountered facets of planetary geostrophy for the continuously stratified case in Section 32.5 and for the shallow water in Sections 40.7, 40.8, and 40.9. We pursue the continuously stratified theory in Chapter 45, where we develop theoretical notions of particular use for understanding the large-scale ocean circulation. For these reasons, our presentation here is rather brief.

Planetary geostrophy is realized by dropping the fluid particle acceleration from the momentum equation (44.45), given that it is one order of Rossby number smaller than the Coriolis and pressure gradient accelerations. This assumption means that the velocity equation reduces to the geostrophic balance

$$\widehat{\boldsymbol{f}} \times \widehat{\boldsymbol{u}} = -\widehat{\nabla}\widehat{\eta}. \tag{44.49}$$

We furthermore assume that the Rossby number and Burger numbers scale together

$$\mathrm{Ro} \sim \mathrm{Bu} = (L_{\mathrm{d}}/L)^2 \ll 1, \tag{44.50}$$

so that the horizontal length scale for the planetary geostrophic flow is much larger than the deformation radius

$$L \gg L_{\mathrm{d}}. \tag{44.51}$$

This assumption is consistent with dropping the material acceleration term in the velocity equation. Although the velocity equation is greatly simplified, we make no assumption concerning the thickness equation. Consequently, the free surface and bottom undulations are unconstrained with planetary geostrophic flows, so long as the flow maintains the hydrostatic balance.

In summary, the thickness equation for the planetary geostrophic fluid retains its full unapproximated form, whereas the velocity equation reduces to geostrophy. Reintroducing dimensions leads to the planetary geostrophic equations

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\,\nabla\eta \quad \text{and} \quad \frac{\mathrm{D}h}{\mathrm{D}t} = -h\,\nabla\cdot\boldsymbol{u} \quad \text{and} \quad h = \eta - \eta_{\mathrm{b}}. \tag{44.52}$$

Since the Coriolis parameter retains its spatial dependence, and so includes the beta effect, the horizontal velocity field is divergent

$$f\,\nabla\cdot\boldsymbol{u} = -\beta\,(g/f)\,\partial_x\eta = -\beta\,v. \tag{44.53}$$

As shown in Exercise 44.1, the shallow water planetary geostrophic equations are equivalent to

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -g\,\nabla\eta \quad \text{and} \quad \frac{\mathrm{D}Q}{\mathrm{D}t} = 0 \quad \text{with} \quad Q = \frac{f}{h}. \tag{44.54}$$

44.5 Shallow water quasi-geostrophy

In this section we develop the quasi-geostrophic equations for a single shallow water fluid layer. Doing so requires more work than for the planetary geostrophic equations. In particular, we use rudimentary asymptotic methods with the Rossby number acting as the small parameter.

44.5.1 Quasi-geostrophic scaling

Quasi-geostrophic scaling is based on the following assumptions, with the first and second shared with planetary geostrophy whereas the remaining are distinct.

1. SMALL ROSSBY NUMBER: $\mathrm{Ro} \ll 1$, which is fundamental to geostrophic scaling.

2. ADVECTIVE TIME SCALE: $T \sim L/U$; that is, the time scale is determined by advection, which is how we scale time throughout this chapter.

3. ORDER ROSSBY NUMBER BETA EFFECT: $|\beta\, L| \ll |f_0|$, which means that the Coriolis frequency does not vary much from its central value. To incorporate this assumption into the asymptotics, we expand the non-dimensional Coriolis parameter in terms of the Rossby number[3]
$$\widehat{f} = f/f_0 = (1 + \beta\, y/f_0) \equiv (\widehat{f}_0 + \mathrm{Ro}\,\widehat{\beta}\,\widehat{y}). \tag{44.55}$$
Making use of the scaling for time as in equation (44.40) renders[4]
$$\widehat{\beta}\,\widehat{y} = \beta\, y/(\mathrm{Ro}\, f_0) = T\,\beta\, y \quad \text{and} \quad \widehat{f}_0 = f_0/f_0 = 1. \tag{44.56}$$
The non-dimensional Coriolis parameter (44.55) and the scaling (44.56) are motivated by assuming the horizontal scales of motion are on the same order as the deformation radius, and that the Coriolis parameter does not vary much from its central value. Quasi-geostrophy is thus formulated within the beta plane approximation discussed in Section 25.5.

4. BURGER NUMBER ORDER ONE: $\mathrm{Bu} \sim 1$, which means that the horizontal scales of motion for the quasi-geostrophic flows are on the same order as the deformation radius, $L \sim L_{\mathrm{d}}$.

5. ORDER ROSSBY NUMBER FREE SURFACE UNDULATIONS: From equation (44.36), an order unity Burger number means that undulations of the free surface height scale according to the Rossby number: $\mathscr{H}/H = \mathrm{Ro}$, so that free surface height undulations are small.

6. ORDER ROSSBY NUMBER BOTTOM TOPOGRAPHY UNDULATIONS: As seen in Section 44.6.6, for the quasi-geostrophic potential vorticity to correspond to the small Rossby number version of the shallow water potential vorticity requires the topography undulations to scale as $\mathscr{B}/H = \mathrm{Ro}$. The assumed scaling for the bottom topography undulation pairs with that for the free surface, so that the layer thickness undulations, $h' = \eta' - \eta'_{\mathrm{b}}$, also scale as Ro. We are thus able to take a sensible Ro expansion of the $1/h$ factor appearing in the shallow water potential vorticity (Section 44.6.6). It is useful to maintain a direct connection to the shallow water model as doing so helps to ensure that the resulting asymptotic theory is self-consistent. In particular, it ensures that quasi-geostrophic energetics are physically sensible since there is a direct lineage to the shallow water energetics.

   The $\mathscr{B}/H = \mathrm{Ro}$ scaling is consistent with the assumption that the planetary beta effect is small. Together, the two scalings
$$\mathscr{B}/H = \mathrm{Ro} \quad \text{and} \quad \mathscr{H}/H = \mathrm{Ro} \tag{44.57}$$
   mean that the effective beta effect (arising from both planetary and topographic variations; see Section 44.6.1 below) are small.

[3] One could conceive of another small parameter that scales the beta effect, but the resulting asymptotics would be more difficult to manage given the need to keep track of two small parameters.

[4] Although $\widehat{f}_0 = 1$ in equation (44.56), it is useful to retain this term as a placeholder in the manipulations to follow.

44.5.2 Outlining the asymptotic method

To derive the equations for the quasi-geostrophic shallow water model, we employ an asymptotic method with the Rossby number as the small parameter. Furthermore, we stop at the first non-trivial order. For this purpose, recall the non-dimensional shallow water equations from Section 44.3.7, and make use of the assumed Bu ~ 1 scaling

$$\mathrm{Ro}\,\frac{\mathrm{D}\widehat{\boldsymbol{u}}}{\mathrm{D}\widehat{t}} + (\widehat{\boldsymbol{f}} \times \widehat{\boldsymbol{u}}) = -\widehat{\nabla}\widehat{\eta} \tag{44.58a}$$

$$\mathrm{Ro}\left[\frac{\partial(\widehat{\eta} - \widehat{\eta}_{\mathrm{b}})}{\partial \widehat{t}} + \widehat{\nabla} \cdot [(\widehat{\eta} - \widehat{\eta}_{\mathrm{b}})\,\widehat{\boldsymbol{u}}]\right] = -\widehat{\nabla} \cdot \widehat{\boldsymbol{u}}. \tag{44.58b}$$

Note that we brought the time independent bottom topography, $\widehat{\eta}_{\mathrm{b}}$, into the time derivative for the thickness equation as doing so provides some symmetry with $\widehat{\eta}$.

Asymptotic expansion of prognostic fields

Asymptotic methods are ideally suited for non-dimensional equations since we can unambiguously determine scales via the size of non-dimensional parameters. We here assume the Rossby number to be small, in which case we are led to perform an asymptotic expansion of the prognostic fields in terms of the Rossby number. There are three prognostic fields, $\widehat{u}, \widehat{v}, \widehat{\eta}$, and corresponding vertical velocity, $\widehat{w}$, which we assume can be written as an asymptotic series

$$\widehat{u} = \widehat{u}_0 + \mathrm{Ro}\,\widehat{u}_1 + \mathrm{Ro}^2\,\widehat{u}_2 + \ldots \tag{44.59a}$$

$$\widehat{v} = \widehat{v}_0 + \mathrm{Ro}\,\widehat{v}_1 + \mathrm{Ro}^2\,\widehat{v}_2 + \ldots \tag{44.59b}$$

$$\widehat{w} = \widehat{w}_0 + \mathrm{Ro}\,\widehat{w}_1 + \mathrm{Ro}^2\,\widehat{w}_2 + \ldots \tag{44.59c}$$

$$\widehat{\eta} = \widehat{\eta}_0 + \mathrm{Ro}\,\widehat{\eta}_1 + \mathrm{Ro}^2\,\widehat{\eta}_2 + \ldots \tag{44.59d}$$

We thus refer to the zeroth, first, second, etc. "order" of the asymptotic expansion. The three components of the velocity satisfy the non-divergence condition at each order of Rossby number

$$\nabla \cdot \widehat{\boldsymbol{v}}_n = 0 \quad \forall\, n. \tag{44.60}$$

Practical goal

The practical goal of asymptotic analysis is to develop a closed set of prognostic equations for functions appearing in the asymptotic expansions (44.59a)-(44.59d). For our purposes, we are content to stop at the lowest nontrivial order, meaning the point at which there is a prognostic equation that provides a means to move the system forward in time. Motivation for asymptotic analysis is to produce an equation set offering a means to focus analysis on dynamics most active under the regime determined by the chosen non-dimensional parameters. Each higher order in asymptotic expansion generally requires more complex algebraic manipulations. Hence, pursuit of higher order expansions should be undertaken only after first determining that the lower order equation set remains physically lacking.

Enabling the machinery

At this point we enable the machinery by "turning the crank". To do so, we insert the asymptotic expansions (44.59a)-(44.59d) into the non-dimensional partial differential equations (44.58a) and (44.58b). Since Ro is arbitrarily small, and all non-dimensional fields are order unity regardless their order, the only means to maintain self-consistency is for terms to balance at equal order in

Rossby number. Hence, we do not mix terms from different orders of Rossby number. This point is basic to asymptotic methods.

Again, our goal is to establish a set of prognostic equations that allows us to evolve a state that is arbitrarily close to geostrophic balance. We anticipate that at zeroth order, the asymptotic method offers us just the geostrophic balance, which has no prognostic value. Hence, we need to go at least to order Ro^1, and hopefully no further since the algebraic tedium increases with order. With that anticipation and hope, we only keep track of terms of order Ro^0 and Ro^1, in which the momentum and continuity equations become

$$\mathrm{Ro}\,\frac{\mathrm{D}\widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + (\widehat{f}_0 + \mathrm{Ro}\,\widehat{\beta}\,\widehat{y})\,\hat{\boldsymbol{z}} \times (\widehat{\boldsymbol{u}}_0 + \mathrm{Ro}\,\widehat{\boldsymbol{u}}_1) = -\widehat{\nabla}(\widehat{\eta}_0 + \mathrm{Ro}\,\widehat{\eta}_1) \tag{44.61a}$$

$$\mathrm{Ro}\left[\frac{\partial\widehat{\eta}_0}{\partial\widehat{t}} + \widehat{\nabla}\cdot[(\widehat{\eta}_0 - \widehat{\eta}_\mathrm{b})\,\widehat{\boldsymbol{u}}_0] + \widehat{\nabla}\cdot\widehat{\boldsymbol{u}}_1\right] = -\widehat{\nabla}\cdot\widehat{\boldsymbol{u}}_0. \tag{44.61b}$$

44.5.3 Order Ro^0 asymptotic equations

Terms in equations (44.61a) and (44.61b) balancing at order Ro^0 are given by

$$\widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}\widehat{\eta}_0 \tag{44.62a}$$

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{u}}_0 = 0. \tag{44.62b}$$

The zeroth order velocity equation (44.62a) is the f-plane geostrophic balance. The vertical component to the curl of this equation leads to the horizontal non-divergence condition

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{u}}_0 = 0, \tag{44.63}$$

which is identical to the zeroth order thickness equation (44.62b). Hence, the zeroth order horizontal velocity is given by f-plane geostrophy.

Given the non-divergence condition (44.62b), the zeroth order velocity field can be written in terms of a *geostrophic streamfunction*

$$\widehat{u}_0 = -\frac{\partial\widehat{\psi}_0}{\partial\widehat{y}} \qquad \text{and} \qquad \widehat{v}_0 = \frac{\partial\widehat{\psi}_0}{\partial\widehat{x}} \qquad \text{and} \qquad \widehat{\zeta}_0 = \widehat{\nabla}^2\widehat{\psi}_0, \tag{44.64}$$

where the zeroth order streamfunction is the ratio of the zeroth order surface height to zeroth order Coriolis parameter

$$\widehat{\psi}_0 = \widehat{\eta}_0/\widehat{f}_0. \tag{44.65}$$

We also introduced the zeroth order vorticity, $\widehat{\zeta}_0$, which plays a role in the order Ro^1 equations. The corresponding dimensionful quantities are

$$\psi = (U\,L)\,\widehat{\psi}_0 \quad \text{and} \quad \zeta = (U/L)\,\widehat{\zeta}_0. \tag{44.66}$$

We dropped the asymptotic label on the dimensional quantities to reduce clutter and since we only evolve the zeroth order fields. In the following, the higher order fields are referred to as *ageostrophic* fields, whereas the zeroth order fields are the geostrophic fields.

44.5.4 Order Ro^1 asymptotic equations

The zeroth order equations do not render a prognostic equation, prompting us to consider equations at order Ro^1

$$\frac{\mathrm{D}_0 \widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + \widehat{f}_0\, \hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_1 + \widehat{\beta}\, \widehat{y}\, \hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}\widehat{\eta}_1 \tag{44.67a}$$

$$\frac{\mathrm{D}_0(\widehat{\eta}_0 - \widehat{\eta}_{\mathrm{b}})}{\mathrm{D}\widehat{t}} = -\widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1. \tag{44.67b}$$

At this order, the material time derivative makes use of *only* the zeroth order geostrophic horizontal velocity

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}} = \frac{\partial}{\partial \widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}. \tag{44.68}$$

The set of first order equations (44.67a) and (44.67b) appear to be unclosed because the evolution equation for zeroth order (geostrophic) terms is dependent on first order (ageostrophic) terms. However, the ageostrophic terms can be eliminated using two steps. First, we produce the vorticity equation from the momentum equation, which removes the ageostrophic pressure gradient, $-\widehat{\nabla}\widehat{\eta}_1$. Second, combine the vorticity equation and continuity equation to eliminate the horizontal convergence of the ageostrophic velocity, $-\widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1$. The second step leads to the quasi-geostrophic potential vorticity equation. Although details are specific to our study of shallow water quasi-geostrophy, similar steps are frequently encountered in other balanced geophysical fluid systems.

The geostrophic vorticity equation

Taking the curl of the momentum equation (44.67a) eliminates the ageostrophic pressure gradient, $\widehat{\nabla}\widehat{\eta}_1$, thus producing the vorticity equation

$$\frac{\partial \widehat{\zeta}_0}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\, (\widehat{\zeta}_0 + \widehat{\beta}\, \widehat{y}) = -\widehat{f}_0\, \widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1. \tag{44.69}$$

The right hand side term arises from stretching in the presence of rotation, which can be seen by using continuity to express the right hand side as

$$-\widehat{f}_0\, \widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1 = \widehat{f}_0\, \frac{\partial \widehat{w}_1}{\partial \widehat{z}}. \tag{44.70}$$

Evidently, to this order in Rossby number, stretching arises just from the planetary vorticity, with stretching due to relative vorticity appearing at a higher order. Since $\widehat{\beta}\, \widehat{y}$ is time independent, we can write the vorticity equation (44.69) using the geostrophic material time derivative

$$\frac{\mathrm{D}_0\, (\widehat{\zeta}_0 + \widehat{\beta}\, \widehat{y})}{\mathrm{D}\widehat{t}} = -\widehat{f}_0\, \widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1. \tag{44.71}$$

The quasi-geostrophic potential vorticity equation

We need one more step to close the system since the evolution of zeroth order vorticity in equations (44.69) and (44.71) depends on vortex stretching induced by convergence of the first order velocity. To eliminate $\widehat{\nabla} \cdot \widehat{\boldsymbol{u}}_1$, we substitute from the thickness equation (44.67b), thus leading to a prognostic

equation involving just zeroth order terms

$$\frac{\partial[\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} - \widehat{f}_0\,(\widehat{\eta}_0 - \widehat{\eta}_{\mathrm{b}})]}{\partial \widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}[\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} - \widehat{f}_0\,(\widehat{\eta}_0 - \widehat{\eta}_{\mathrm{b}})] = 0, \tag{44.72}$$

which can be written in the material form

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} - \widehat{f}_0\,(\widehat{\eta}_0 - \widehat{\eta}_{\mathrm{b}})\right] = 0. \tag{44.73}$$

Finally, we introduce the geostrophic streamfunction $\widehat{\psi}_0 = \widehat{\eta}_0/\widehat{f}_0$ (equation (44.65)) to render

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\widehat{\nabla}^2\,\widehat{\psi}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\,\widehat{\eta}_{\mathrm{b}} - \widehat{f}_0^2\,\widehat{\psi}_0\right] = 0. \tag{44.74}$$

Equation (44.74) is a statement of the material conservation of quasi-geostrophic potential vorticity, where material evolution is defined by the horizontal geostrophic currents (equation (44.68)). This equation is the culmination of our quest to derive a prognostic equation for the evolution of geostrophic flow. It enables us to evolve the geostrophic velocity and geostrophic free surface by probing, but not explicitly determining, the leading order ageostrophic motions. Practical use of the quasi-geostrophic method is based on time stepping the quasi-geostrophic potential vorticity, and then inverting the potential vorticity equation to diagnose the streamfunction to then determine the geostrophic velocity and free surface. That inversion requires solving an elliptic boundary value problem.

44.6 Physical elements of shallow water quasi-geostrophy

The asymptotic analysis of Section 44.5 worked with non-dimensional quantities, which are suitable for determining the scales required for organizing the perturbation expansion. Now that we have worked through the details, we can make use of that effort to both further expose the physical content of shallow water quasi-geostrophy theory. For that purpose, it is useful to reintroduce physical dimensions.

44.6.1 Dimensional potential vorticity and streamfunction

To introduce physical dimensions, we invert the relations used in Section 44.3.7

$$\widehat{t} = t/T \qquad (\widehat{x},\widehat{y}) = (x,y)/L \qquad \partial_{\widehat{t}} = T\,\partial_t \qquad \widehat{\nabla} = L\,\nabla \qquad (\widehat{u},\widehat{v}) = (u,v)/U \tag{44.75a}$$

$$\widehat{\eta} = \eta'/\mathcal{H} \qquad \widehat{\eta}_{\mathrm{b}} = \eta'_{\mathrm{b}}/\mathcal{B} \qquad \mathcal{H} = H\,\mathrm{Ro} \qquad \mathcal{B} = H\,\mathrm{Ro} \tag{44.75b}$$

$$\widehat{f}_0 = f_0/f_0 \qquad \widehat{\beta}\,\widehat{y} = \beta\,y/(\mathrm{Ro}\,f_0) = (L/U)\,\beta\,y \qquad \widehat{\zeta} = (L/U)\,\zeta = L^2\,\nabla^2\psi. \tag{44.75c}$$

We generally drop asymptotic subscripts on dimensional terms to help reduce clutter.

For the potential vorticity we start from the non-dimensional quasi-geostrophic potential vor-

ticity (44.73) and find

$$\widehat{q} = \widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\,\widehat{\eta}_{\rm b} - \widehat{f}_0\,\widehat{\eta}_0 \tag{44.76a}$$

$$= \frac{L}{U}\,(\zeta + \beta\,y) + \frac{\eta'_{\rm b}}{\mathcal{B}} - \frac{\eta'}{\mathcal{H}} \tag{44.76b}$$

$$= \frac{L}{U}\,(\zeta + \beta\,y) + \frac{\eta'_{\rm b}}{H\,Ro} - \frac{\eta'}{H\,Ro} \tag{44.76c}$$

$$= \frac{L}{U}\left[\zeta + \beta\,y - \frac{f_0\,(\eta' - \eta'_{\rm b})}{H}\right] \tag{44.76d}$$

$$= \frac{L}{U}\left[\zeta + \beta\,y - \frac{g\,(\eta' - \eta'_{\rm b})}{f_0}\,\frac{1}{L_{\rm d}^2}\right] \tag{44.76e}$$

$$= \frac{L}{U}\left[\zeta + \beta\,y - L_{\rm d}^{-2}\,(\psi - \psi_{\rm b})\right], \tag{44.76f}$$

where $L_{\rm d} = \sqrt{g\,H}/f$ is the shallow water deformation radius (equation (44.31)), and we introduced the geostrophic streamfunction[5]

$$\psi = (g/f_0)\,\eta'. \tag{44.77}$$

We also wrote the contribution from topography as

$$\psi_{\rm b} = (g/f_0)\,\eta'_{\rm b}, \tag{44.78}$$

which is a static field. We are thus led to the dimensionful quasi-geostrophic potential vorticity for a single shallow water layer

$$q = f_0\,(1 + {\rm Ro}\,\widehat{q}) = (\zeta + f) - L_{\rm d}^{-2}\,(\psi - \psi_{\rm b}) = f + \psi_{\rm b}\,L_{\rm d}^{-2} + (\nabla^2 - L_{\rm d}^{-2})\,\psi. \tag{44.79}$$

We took the liberty of adding the constant, f_0, to the QG potential vorticity, which does not alter the dynamics but does allow us to introduce the planetary vorticity, $f = f_0 + \beta\,y$. Evidently, the dynamically relevant portions of q appear at order Ro, as expected since the zeroth order theory is f-plane geostrophy, which provides no prognostic capability.

44.6.2 Contributions to the QG potential vorticity

The quasi-geostrophic potential vorticity (44.79) has three main contributions

$$q = f + \zeta - f_0\,h'/H, \tag{44.80}$$

where we wrote

$$L_{\rm d}^{-2}\,(\psi - \psi_{\rm b}) = f_0^2/(g\,H)\,(g/f_0)\,(\eta' - \eta'_{\rm b}) = f_0\,h'/H, \tag{44.81}$$

with h' the undulations in the layer thickness due to undulations in the free surface and bottom topography. Heuristically, we can connect q to the shallow water $Q = (f + \zeta)/h$ by

$$(f + \zeta)/h \approx (f + \zeta)\,(1 - h'/H) \approx H^{-1}\,(f + \zeta - f_0\,h'/H), \tag{44.82}$$

where we assumed $\beta\,y$, ζ, and h' are order Ro whereas f_0 is order unity. We pursue this expansion more formally in Section 44.6.6. But for present purposes we can use it to summarize the various contributions to potential vorticity.

[5] *Vallis* (2017) defines the geostrophic streamfunction in his equation (5.69) as $\psi_{\rm vallis} = g\,\eta/f_0 = \psi + g\,H/f_0$, which differs by the constant $g\,H/f_0$. However, there is no difference in the dynamics since a streamfunction is specified only up to a constant.

- PLANETARY VORTICITY: The contribution $f = f_0 + \beta\, y$ arises from planetary vorticity, with the dynamically relevant contribution for QG arising just from the $\beta\, y$ term.
- GEOSTROPHIC RELATIVE VORTICITY: $\nabla^2\psi = (g/f_0)\,\nabla^2\eta$ is the relative vorticity of the geostrophic flow. Given the Laplacian operator emphasizes small spatial scales, the relative vorticity is most important at scales at or smaller than the deformation radius.
- EFFECTIVE BETA: The contribution from the gradient of planetary vorticity is given by $\beta\, y = \boldsymbol{x}\cdot\nabla f$. Likewise, the contribution from topography is given by

$$\psi_{\rm b}\, L_{\rm d}^{-2} = f_0\, \eta_{\rm b}'/H = (f_0/H)\,(\eta_{\rm b} - \overline{\eta_{\rm b}}) \approx (f_0/H)\,\boldsymbol{x}\cdot\nabla\eta_{\rm b}, \tag{44.83}$$

  where the approximate expression made use of a Taylor series. These two contributions can be combined into an effective beta

$$\beta\, y + \psi_{\rm b}\, L_{\rm d}^{-2} = \boldsymbol{x}\cdot\nabla(f + f_0\,\eta_{\rm b}/H) \approx \boldsymbol{x}\cdot(H-\eta_{\rm b})\,\nabla[f/(H-\eta_{\rm b})], \tag{44.84}$$

  with the final approximate expression connecting to the effective beta discussed in Section 40.5.1.
- VERTICAL STRETCHING: As discussed in Section 36.2, shallow water fluids move as vertical extensible columns. Hence, the term $(f_0/H)\,h'$ accounts for the contribution to potential vorticity from column stretching and squashing. It is most important for scales at or larger than those where the relative vorticity is important; i.e., at or larger than the deformation radius.
- FLOW REGIMES RELATIVE TO THE DEFORMATION RADIUS: As noted above, the term $(\nabla^2 - L_{\rm d}^{-2})\,\psi$ signals two regimes as determined by the deformation radius. For lateral scales on the order of the deformation radius, both the relative vorticity and vortex stretching make equal contributions to the potential vorticity. For smaller scales relative vorticity is more important whereas for larger scales vortex stretching dominates.

44.6.3 Connecting to rest state potential vorticity

For some purposes, particularly when studying Rossby waves in Section 53.9, we find it useful to unpack the material time derivative,

$$\mathrm{D}q/\mathrm{D}t = \partial_t q + \hat{\boldsymbol{z}}\cdot(\nabla\psi\times\nabla q), \tag{44.85}$$

to expose the role of the potential vorticity contained in a resting fluid. For this purpose, expand the gradient

$$\nabla q = \nabla(\nabla^2\psi) - \nabla\psi/L_{\rm d}^2 + \nabla f + \nabla\psi_{\rm b}/L_{\rm d}^2, \tag{44.86}$$

so that

$$\nabla\psi\times\nabla q = \nabla\psi\times\nabla(\nabla^2\psi) + \nabla\psi\times(\nabla f + \nabla\psi_{\rm b}/L_{\rm d}^2). \tag{44.87}$$

The second term on the right hand side can be written in terms of the resting state potential vorticity

$$\nabla f + \nabla\psi_{\rm b}/L_{\rm d}^2 = \nabla f + (f_0/H)\,\nabla\eta_{\rm b}' = \nabla f - (f_0/H)\,\nabla(H-\eta_{\rm b}') \approx H\,\nabla(f/H_{\rm r}) = H\,\nabla Q_{\rm r}, \tag{44.88}$$

where $H_{\rm r} = H - \eta_{\rm b}'$ is the thickness of the resting fluid, and $Q_{\rm r}$ is the potential vorticity of the resting fluid. The approximation in the penultimate step above follows from assuming $\eta_{\rm b}'/H = \mathcal{O}(\mathrm{Ro})$, as per the quasi-geostrophic scaling in Section 44.5.1.

Bringing the pieces together leads us to write the material time evolution of quasi-geostrophic potential vorticity as

$$(f_0/g)\,\mathrm{D}q/\mathrm{D}t = \partial_t\,[(L_\mathrm{d}^{-2} - \nabla^2)\,\eta'] - H\,\hat{\boldsymbol{z}}\cdot(\nabla\eta'\times\nabla Q_\mathrm{r}) - (g/f_0)\,\hat{\boldsymbol{z}}\cdot[\nabla\eta'\times\nabla(\nabla^2\eta')]. \tag{44.89}$$

The second term on the right hand side arises from the geostrophic advection of the potential vorticity in the resting fluid. This linear term is fundamental to the Rossby wave dispersion relation studied in Section 53.9. The nonlinear term on the right hand side arises from advection by the geostrophic velocity of the geostrophic relative vorticity. This term is generally ignored when studying small amplitude wave fluctuations. It is notable, however, that this term vanishes identically for plane waves. We discuss this point further in Section 53.9.2.

44.6.4 The equations of shallow water quasi-geostrophy

The following fields are the key pieces of the single layer shallow water quasi-geostrophic theory

$$\boldsymbol{u} = \hat{\boldsymbol{z}}\times\nabla\psi \quad\text{and}\quad \zeta = \hat{\boldsymbol{z}}\cdot\nabla\times\boldsymbol{u} = \nabla^2\psi \quad\text{and}\quad q = f + \zeta - L_\mathrm{d}^{-2}\,(\psi - \psi_\mathrm{b}) \tag{44.90a}$$

$$\psi = (g/f_0)\,\eta' \quad\text{and}\quad \psi_\mathrm{b} = (g/f_0)\,\eta'_\mathrm{b} \quad\text{and}\quad L_\mathrm{d} = \sqrt{g\,H}/f_0. \tag{44.90b}$$

Evolution of the geostrophic flow

Evolution of the quasi-geostrophic flow is determined by material time changes to the QG potential vorticity that follows the horizontal geostrophic flow

$$\frac{\mathrm{D}q}{\mathrm{D}t} = (\partial_t + \boldsymbol{u}\cdot\nabla)\,q = \partial_t q + \hat{\boldsymbol{z}}\cdot(\nabla\psi\times\nabla q) = \partial_t q + J(\psi, q), \tag{44.91}$$

where the final equality introduced the Jacobian operator

$$J(\psi, q) = \hat{\boldsymbol{z}}\cdot(\nabla\psi\times\nabla q) = \partial_x\psi\,\partial_y q - \partial_y\psi\,\partial_x q. \tag{44.92}$$

For a perfect fluid, the quasi-geostrophic PV is materially constant, whereas more general flows have forcing and dissipation so that

$$\frac{\mathrm{D}q}{\mathrm{D}t} = \text{forcing} - \text{dissipation}. \tag{44.93}$$

As an algorithm to evolve the quasi-geostrophic state forward in time, we first update the potential vorticity to a new time step, then diagnose the streamfunction, $\psi = g\,\eta/f_0$, by solving the elliptic boundary value problem

$$(\nabla^2 - L_\mathrm{d}^{-2})\,\psi = q - f - \psi_\mathrm{b}/L_\mathrm{d}^2, \tag{44.94}$$

at which point we know the updated free surface and updated velocity. This same algorithm was outlined for time stepping the two-dimensional non-divergent barotropic model in Section 39.2.5.

Velocity and free surface equations

In the above algorithm for time stepping the state, we are not concerned with the velocity and free surface equations, but instead we are concerned with inverting the potential vorticity equation (44.94) to find the streamfunction. Even so, it can be of interest to consider the primitive quasi-

geostrophic equations, which are determined by the order Ro^1 equations in Section 44.5.4

$$\partial_t \boldsymbol{u}_{\mathrm{g}} + (\boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, \boldsymbol{u}_{\mathrm{g}} + (f_0 + \beta\, y)\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} + f_0\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{ag}} = -g\, \nabla(\eta_{\mathrm{g}} + \eta_{\mathrm{ag}}) \tag{44.95a}$$

$$\partial_t(\eta_{\mathrm{g}} - \eta_{\mathrm{b}}) + (\boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, (\eta_{\mathrm{g}} - \eta_{\mathrm{b}}) = -H\, \nabla \cdot \boldsymbol{u}_{\mathrm{ag}}. \tag{44.95b}$$

In these equations we temporarily introduced subscripts to distinguish the geostrophic velocity and corresponding surface height

$$f_0\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -g\, \nabla \eta_{\mathrm{g}} \tag{44.96}$$

from the ageostrophic free surface height, η_{ag}, and ageostrophic velocity, $\boldsymbol{u}_{\mathrm{ag}}$. Since the ageostrophic velocity generally has a nonzero horizontal convergence, but it is three dimensionally non-divergent (since the fluid layer has constant density), then we can identify a corresponding vertical component to the ageostrophic velocity that satisfies

$$\boldsymbol{v}_{\mathrm{ag}} = \boldsymbol{u}_{\mathrm{ag}} + \hat{\boldsymbol{z}}\, w_{\mathrm{ag}} \quad \text{with} \quad \nabla \cdot \boldsymbol{v}_{\mathrm{ag}} = \partial_x u_{\mathrm{ag}} + \partial_y v_{\mathrm{ag}} + \partial_z w_{\mathrm{ag}} = 0. \tag{44.97}$$

44.6.5 Energetics

To derive the energetic balances within an unforced quasi-geostrophic shallow water flow, we start by multiplying the potential vorticity equation by the streamfunction

$$\psi\, \partial_t q + \psi\, \boldsymbol{u} \cdot \nabla q = 0. \tag{44.98}$$

The time tendency term can be written

$$\psi\, \partial_t q = \psi\, (\partial_t \zeta - L_{\mathrm{d}}^{-2}\, \partial_t \psi) \tag{44.99a}$$

$$= \psi\, \nabla \cdot (\nabla \partial_t \psi) - (1/2) L_{\mathrm{d}}^{-2}\, \partial_t (\psi)^2 \tag{44.99b}$$

$$= \nabla \cdot (\psi\, \nabla \partial_t \psi) - \nabla \psi \cdot \nabla (\partial_t \psi) - (1/2) L_{\mathrm{d}}^{-2}\, \partial_t (\psi)^2 \tag{44.99c}$$

$$= \nabla \cdot (\psi\, \nabla \partial_t \psi) - \partial_t (\boldsymbol{u} \cdot \boldsymbol{u} + L_{\mathrm{d}}^{-2}\, \psi^2)/2, \tag{44.99d}$$

whereas the advection term can be written

$$\psi\, \boldsymbol{u} \cdot \nabla q = \psi\, \nabla \cdot (\boldsymbol{u}\, q) = \nabla \cdot (\psi\, \boldsymbol{u}\, q) - \nabla \psi \cdot \boldsymbol{u}\, q = \nabla \cdot (\psi\, \boldsymbol{u}\, q), \tag{44.100}$$

where we used

$$\nabla \psi \cdot \boldsymbol{u} = \nabla \psi \cdot (\hat{\boldsymbol{z}} \times \nabla \psi) = 0. \tag{44.101}$$

We are thus led to the energy equation for shallow water quasi-geostrophy

$$\partial_t (\boldsymbol{u} \cdot \boldsymbol{u} + L_{\mathrm{d}}^{-2}\, \psi^2)/2 = \nabla \cdot (\psi\, \nabla \partial_t \psi + \boldsymbol{u}\, q\, \psi). \tag{44.102}$$

The first term on the left hand side is the kinetic energy per mass. The second term is the available potential energy per mass, where the available potential energy is proportional to the free surface height undulation (Section 37.5.6)

$$L_{\mathrm{d}}^{-2}\, \psi^2 = f_0^2/(g\, H)\, (g^2/f_0^2)\, (\eta')^2 = (g/H)\, (\eta')^2 = c_{\mathrm{grav}}^2\, (\eta'/H)^2, \tag{44.103}$$

where the final step introduced the shallow water gravity wave speed

$$c_{\mathrm{grav}} = \sqrt{g\, H}, \tag{44.104}$$

with shallow water gravity waves studied in Section 53.5.

44.6.6 Connecting quasi-geostrophic PV to shallow water PV

We here determine how potential vorticity for shallow water quasi-geostrophy relates to the full shallow water potential vorticity studied in Chapter 40. For that purpose, recall that the potential vorticity for a single layer of shallow water fluid is (Section 40.3)

$$Q = \frac{f + \zeta}{h}, \tag{44.105}$$

where $h = H + \eta' - \eta'_{\mathrm{b}}$ (equation (44.4)) is the layer thickness.

To connect to the quasi-geostrophic potential vorticity, we non-dimensionalize the potential vorticity prior to performing an asymptotic expansion to order Ro^1. For this purpose, use the scaling relations from Section 44.3.7 to write the geostrophic relative vorticity as

$$\zeta = \nabla^2 \psi = (g/f_0)\, \nabla^2 \eta' = (g\, \mathscr{H})/(f_0\, L^2)\, \widehat{\nabla}^2 \widehat{\eta} = (g\, H\, \mathrm{Ro})/(f_0\, L^2)\, \widehat{\zeta}_0 = f_0\, \mathrm{Ro}\, (L_{\mathrm{d}}/L)^2\, \widehat{\zeta}_0, \tag{44.106}$$

as well as

$$h = H + H\, \mathrm{Ro}\, (\widehat{\eta} - \widehat{\eta}_{\mathrm{b}}) \tag{44.107a}$$

$$f = f_0\, (\widehat{f}_0 + \mathrm{Ro}\, \widehat{\beta}\, \widehat{y}). \tag{44.107b}$$

Taking the ratio and expanding to order Ro^1 leads to

$$\frac{f + \zeta}{h} = \frac{f_0}{H} \left[\frac{\widehat{f}_0 + \mathrm{Ro}\, (L_{\mathrm{d}}/L)^2\, \widehat{\zeta}_0 + \mathrm{Ro}\, \widehat{\beta}\, \widehat{y}}{1 + \mathrm{Ro}\, (\widehat{\eta} - \widehat{\eta}_{\mathrm{b}})} \right] \tag{44.108a}$$

$$\approx \frac{f_0}{H} + \frac{f_0\, \mathrm{Ro}}{H} \left[-\widehat{f}_0\, (\widehat{\eta} - \widehat{\eta}_{\mathrm{b}}) + (L_{\mathrm{d}}/L)^2\, \widehat{\zeta}_0 + \widehat{\beta}\, \widehat{y} \right] \tag{44.108b}$$

$$= \frac{f_0}{H} + \frac{f_0\, \mathrm{Ro}}{H} \left[(L_{\mathrm{d}}/L)^2\, \widehat{\zeta}_0 + \widehat{\beta}\, \widehat{y} - \widehat{f}_0\, (\widehat{\eta} - \widehat{\eta}_{\mathrm{b}}) \right] \tag{44.108c}$$

$$= \frac{f_0}{H} + \frac{f_0\, \mathrm{Ro}}{H} \left[\frac{\zeta}{f_0\, \mathrm{Ro}} + \frac{\beta\, y}{f_0\, \mathrm{Ro}} - \frac{\eta'}{\mathscr{H}} + \frac{\eta'_{\mathrm{b}}}{\mathscr{B}} \right] \tag{44.108d}$$

$$= \frac{1}{H} \left[\zeta + f_0 + \beta\, y - \frac{f_0\, (\eta' - \eta'_{\mathrm{b}})}{H} \right] \tag{44.108e}$$

$$= \widehat{q}\, U/(H\, L) \tag{44.108f}$$

$$= q/H. \tag{44.108g}$$

We are thus led to the relation between the shallow water potential vorticity and the quasi-geostrophic shallow water potential vorticity

$$\frac{f + \zeta}{h} = \frac{q}{H} \left[1 + \mathcal{O}(\mathrm{Ro}^2) \right]. \tag{44.109}$$

As noted in Section 44.5.1, this connection between the potential vorticities only holds when assuming deviations in *both* the bottom topography and free surface scale according to the Rossby number, $\eta' = \mathscr{H}\, \mathrm{Ro}$ and $\eta'_{\mathrm{b}} = \mathscr{B}\, \mathrm{Ro}$, thus allowing us to combine $\widehat{\eta}$ and $\widehat{\eta}_{\mathrm{b}}$ in the thickness equation (44.107a).

The identity (44.109) is a consequence of the asymptotic expansion of the velocity and thickness equations. We could alternatively invert our development of quasi-geostrophy by using the quasi-geostrophic potential vorticity as the basis for deriving the governing equations. We pursue that approach to derive the layered quasi-geostrophic equations in Section 44.6.8.

44.6.7 Considering topography to be $\mathcal{O}(\mathrm{Ro}^0)$

In our treatment of quasi-geostrophy, we assumed the topographic undulations to be on the order of Ro. Doing so ensured asymptotic consistency by combining η' and η'_{b} into an order Rossby number fluctuation of the layer thickness. We just encountered this need in Section 44.6.6 when connecting quasi-geostrophic potential vorticity to Ertel potential vorticity (see also Section 44.5.1). What happens if we allow for arbitrarily large topographic undulations? It is not uncommon to examine how an asymptotic theory performs when outside of its formal regime of validity, particularly with the advent of numerical codes to facilitate such studies. In many cases the theories continue to provide provocative, and sometimes physically relevant, information.

To see what happens, consider the quasi-geostrophic PV equation

$$(\partial_t + \boldsymbol{u} \cdot \nabla)\left[\zeta + \beta\, y + L_{\mathrm{d}}^{-2}\,(\psi_{\mathrm{b}} - \psi)\right] = 0. \tag{44.110}$$

If ψ_{b} order Ro^0, whereas the other terms are order Ro, then to leading order the potential vorticity is given by the static term, $L_{\mathrm{d}}^{-2}\,\psi_{\mathrm{b}}$, so that material conservation of potential vorticity reduces to

$$\boldsymbol{u} \cdot \nabla \psi_{\mathrm{b}} = 0 \Longrightarrow \boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} = 0. \tag{44.111}$$

This constraint means that the f-plane geostrophic flow is constrained to flow along lines of constant topography (isobaths), in which case the geostrophic streamfunction satisfies

$$(f/g)\,\boldsymbol{u} \cdot \nabla \eta_{\mathrm{b}} = \hat{\boldsymbol{z}} \cdot (\nabla \eta \times \nabla \eta_{\mathrm{b}}) \equiv J(\eta, \eta_{\mathrm{b}}) = 0. \tag{44.112}$$

Evidently, the order unity bottom topography undulations provide a constraint on the f-geostrophic flow, making the flow align with the bottom topography and in turn aligning surface height undulations with bottom undulations. We uncovered this constraint in our analysis of topographic form stress in Section 40.7.5. We also discussed this flow as a particular realization of the two-dimensional non-divergent barotropic flow in Section 39.1.4.

44.6.8 Two layer quasi-geostrophy

In Section 36.4 we developed the equations for an adiabatic stacked shallow water model. We here specialize those equations to a two-layer quasi-geostrophic model, with extensions to multiple layers following straightforwardly. Rather than pursue the formal asymptotic methods used previously, we here make use of our observation in Section 44.6.6 concerning the connection between shallow water and quasi-geostrophic potential vorticities.

To get started, recall from Section 40.3.6 that the shallow water potential vorticity for an arbitrary layer, labelled by the index k, is given by

$$Q_{\mathrm{k}} = \frac{f + \zeta_{\mathrm{k}}}{h_{\mathrm{k}}}, \tag{44.113}$$

As in Section 44.6.2, we assume $\beta\, y$, ζ_{k}, and h'_{k} scale as Ro, in which case we have the quasi-geostrophic potential vorticity for each layer

$$q_{\mathrm{k}} = f + \zeta_{\mathrm{k}} - f_0\, h'_{\mathrm{k}}/H, \tag{44.114}$$

where ζ_{k} is here the geostrophic relative vorticity for layer k.

From our asymptotic analysis earlier in this section, the toughest part of that analysis concerned the derivation of the quasi-geostrophic potential vorticity equation. In the present approach, we already have the potential vorticity for each layer via equation (44.114). What we

need is the velocity field to advect it. Again, we know what that velocity is: it is the f-plane geostrophic velocity for each layer. The 2-layer velocity equations are given by equations (36.74a) and (36.74b), with their geostrophic components determined by

$$f_0\,\hat{\boldsymbol{z}}\times\boldsymbol{u}_1 = -g\,\nabla(\eta'_{\mathrm{b}} + h'_1 + h'_2) \tag{44.115a}$$

$$f_0\,\hat{\boldsymbol{z}}\times\boldsymbol{u}_2 = -\nabla\left[g^{\mathrm{r}}_{1/2}\,(\eta'_{\mathrm{b}} + h'_1 + h'_2) + g^{\mathrm{r}}_{3/2}\,(\eta'_{\mathrm{b}} + h'_2)\right]. \tag{44.115b}$$

In these equations we set the applied atmospheric pressure to a constant, and made use of the reduced gravities at the layer interfaces are

$$g^{\mathrm{r}}_{1/2} = g\,(\rho_1 - \rho_{\mathrm{a}})/\rho_{\mathrm{ref}} \approx g \quad \text{and} \quad g^{\mathrm{r}}_{3/2} = g\,(\rho_2 - \rho_1)/\rho_{\mathrm{ref}}, \tag{44.116}$$

with the Boussinesq reference density taken as $\rho_{\mathrm{ref}} = \rho_1$. Furthermore, we assume $\rho_{\mathrm{a}} \ll \rho_{\mathrm{ref}}$ so that the top interface reduced gravity is well approximated by the full gravity. From equations (44.115a) and (44.115b) we can identify the geostrophic streamfunctions

$$\psi_1 = (g/f_0)\,(\eta'_{\mathrm{b}} + h'_1 + h'_2) \tag{44.117a}$$

$$\psi_2 = (1/f_0)\,\left[g^{\mathrm{r}}_{1/2}\,(\eta'_{\mathrm{b}} + h'_1 + h'_2) + g^{\mathrm{r}}_{3/2}\,(\eta'_{\mathrm{b}} + h'_2)\right], \tag{44.117b}$$

so that the layer geostrophic velocities are given by

$$\boldsymbol{u}_1 = \hat{\boldsymbol{z}}\times\nabla\psi_1 \quad \text{and} \quad \boldsymbol{u}_2 = \hat{\boldsymbol{z}}\times\nabla\psi_2. \tag{44.118}$$

We thus proceed with the usual quasi-geostrophic algorithm, whereby evolution is determined by the material time changes of the potential vorticity with advection given by the layer geostrophic flow

$$(\partial_t + \boldsymbol{u}_{\mathrm{k}}\cdot\nabla)q_{\mathrm{k}} = 0. \tag{44.119}$$

44.6.9 Rigid lid shallow water quasi-geostrophy

We studied the horizontally non-divergent barotropic model in Chapter 39, whereby the full velocity field has zero horizontal divergence, thus leading to a rigid surface boundary. Gradients in the lid pressure drive the flow, with the lid pressure arising from the non-divergence constraint on the horizontal flow. For a single layer of quasi-geostrophic shallow water fluid, the rigid lid approximation means that the external deformation radius goes to infinity, in which case the quasi-geostrophic potential vorticity reduces to just the absolute geostrophic vorticity

$$L_{\mathrm{d}} \to \infty \Longrightarrow q = \zeta + f. \tag{44.120}$$

The multi-layer shallow water case is more interesting. Here, the depth integrated ageostrophic velocity is constrained to be horizontally non-divergent, so that the vertical velocity in the upper layer (both geostrophic and ageostrophic) vanishes.

MORE TBD ....

44.7 Non-dimensional Boussinesq ocean equations

In this section we non-dimensionalize the continuously stratified Boussinesq ocean equations. As part of this process we identify a variety of non-dimensional numbers that characterize the flow. As for the shallow water system in Section 44.4, continuously stratified planetary geostrophy is rather

simple to derive, so that the detailed work in this section is arguably not necessary. However, the details here are essential for systematically deriving the continuously stratified quasi-geostrophic theory pursued in Chapter 46.

Our starting point is the perfect fluid stratified hydrostatic Boussinesq equations (Section 30.1.6)

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_z \varphi \tag{44.121a}$$

$$\frac{\partial \varphi}{\partial z} = b \tag{44.121b}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \tag{44.121c}$$

$$\nabla \cdot \boldsymbol{v} = 0, \tag{44.121d}$$

where $\boldsymbol{v} = (\boldsymbol{u}, w)$ is the three-dimensional velocity written using Cartesian coordinates, $b = -g\,(\rho - \rho_0)/\rho_0$ is the Archimedian buoyancy relative to a constant reference density, ρ_0, with ρ the density. We also write $\varphi = \delta p/\rho_0$ for the dynamic pressure (dimensions of $\mathrm{L}^2\ \mathrm{T}^{-2}$), and $\nabla_z = (\partial_x, \partial_y, 0)$ for the horizontal gradient operator. We separate a background vertical buoyancy profile from a space-time fluctuating buoyancy

$$b = \tilde{b}(z) + b'(x, y, z, t), \tag{44.122}$$

and introduce the corresponding background squared buoyancy frequency

$$N^2(z) = \frac{\mathrm{d}\tilde{b}(z)}{\mathrm{d}z}. \tag{44.123}$$

The background stratification is not determined by the quasi-geostrophic theory; rather, it is assumed known. We are thus examining flow relative to this prescribed background.

With the above decomposition, the buoyancy equation (44.121c) takes the form

$$\frac{\mathrm{D}b'}{\mathrm{D}t} + w\,N^2 = 0. \tag{44.124}$$

We also introduce an associated decomposition of the hydrostatic pressure

$$\varphi = \tilde{\varphi}(z) + \varphi'(x, y, z, t) \tag{44.125}$$

where $\tilde{\varphi}$ is hydrostatically balanced by $\tilde{b}$

$$\frac{\mathrm{d}\tilde{\varphi}}{\mathrm{d}z} = \tilde{b}, \tag{44.126}$$

and the fluctuating pressure, φ', is hydrostatically balanced by b'

$$\frac{\partial \varphi'}{\partial z} = b'. \tag{44.127}$$

44.7.1 Dimensional parameters

Following the shallow water discussion in Section 44.3.1, we have the following dimensional parameters for the perfect Boussinesq fluid.

- LENGTH SCALES

- ⋆ H = length scale of a typical vertical structure in the fluid (e.g., the depth of the ocean pycnocline or height of the atmospheric tropopause).
- ⋆ L = horizontal/lateral length scale of motions under consideration (e.g., Gulf Stream rings, atmospheric synoptic weather pattern, ocean gyre).
- ⋆ R_e = radius of the planet.

- VELOCITY SCALES
  - ⋆ U = horizontal velocity scale for fluid motion.
  - ⋆ W = vertical velocity scale for fluid motion.
- PRESSURE AND BUOYANCY SCALES: Pressure is a contact force, acting on the boundary of an arbitrary fluid region, and buoyancy arises from the gravitational force that acts to raise or lower a fluid element depending on its density relative to the environment. They have scales given by the following.
  - ⋆ Φ = scale for pressure fluctuations φ' (dimensions of pressure divided by density = length scale × acceleration).
  - ⋆ B = scale of buoyancy fluctuations b' (dimensions of acceleration).
- BODY FORCES: There are two body forces acting on the fluid, one from gravity and one from Coriolis.
  - ⋆ g = gravitational acceleration
  - ⋆ f = Coriolis frequency.

Contrary to the shallow water discussion in Section 44.3.1, we do not introduce a wave speed since it does not affect the asymptotics considered here. Also, we do not introduce a scale for the bottom topography undulations, since for planetary geostrophy there is no constraint on topographic undulations. However, for quasi-geostrophy in Chapter 46 we follow the approach used for shallow water in Section 44.3.5 by assuming topographic undulations scale like the Rossby number. Further details of the bottom boundary conditions and their scaling are detailed in Section 46.5.

44.7.2 Physical dimensions and non-dimensional parameters

There are two physical dimensions in the Boussinesq system: length, L, and time, T. As for the shallow water system, there no mass since mass is determined by the density (buoyancy) and volume. The Buckingham-Π theorem then says there are

$$N_{\text{dimensionless}} = 9 - 2 = 7 \tag{44.128}$$

non-dimensional parameters.

44.7.3 Choosing the non-dimensional parameters

Following the shallow water discussion in Section 44.3.4, we choose the following non-dimensional parameters.

1. VERTICAL TO HORIZONTAL ASPECT RATIO: The ratio of the vertical length scale to the horizontal length scale defines the aspect ratio

$$\delta_{\text{verical/horizontal}} = \frac{\text{vertical length scale}}{\text{horizontal length scale}} = \frac{H}{L}. \tag{44.129}$$

2. RATIO OF HORIZONTAL SCALE TO PLANETARY SCALE: The ratio of the horizontal length scale to the planet radius is given by

$$\delta_{\text{horizontal/planet}} = \frac{\text{horizontal length scale}}{\text{planetary length scale}} = \frac{L}{R_{\text{e}}}. \tag{44.130}$$

3. RATIO VERTICAL TO HORIZONTAL VELOCITY SCALES: The ratio of the vertical to horizontal velocity scales is given by

$$\frac{\text{vertical velocity scale}}{\text{horizontal velocity scale}} = \frac{W}{U}. \tag{44.131}$$

4. HYDROSTATIC NUMBER: The hydrostatic number is the ratio of the pressure fluctuation scale to the buoyancy fluctuation scale,

$$\frac{\text{pressure fluctuations}}{\text{buoyancy fluctuations}} = \frac{\Phi/H}{B}. \tag{44.132}$$

5. ROSSBY NUMBER: The Rossby number is the ratio of the fluid particle acceleration scale to the Coriolis acceleration

$$\text{Ro} = \frac{\text{particle acceleration}}{\text{Coriolis acceleration}} = \frac{U}{f\,L}. \tag{44.133}$$

As in Section 44.3.4, we assume that the time scale is advective

$$T \sim L/U \Longrightarrow \text{Ro} = U/(f\,L) = (f\,T)^{-1}. \tag{44.134}$$

6. GEOSTROPHIC NUMBER: The ratio of the Coriolis acceleration to the pressure gradient acceleration defines the geostrophic number

$$\text{Ge} = \frac{\text{Coriolis acceleration}}{\text{pressure gradient acceleration}}. \tag{44.135}$$

The Coriolis acceleration scales as

$$\text{Coriolis acceleration} \sim f\,U \tag{44.136}$$

whereas the pressure gradient acceleration from the fluctuating pressure, φ', scales as

$$\text{pressure gradient acceleration} \sim \Phi/L, \tag{44.137}$$

so that

$$\text{Ge} = \frac{\text{Coriolis acceleration}}{\text{pressure gradient acceleration}} = \frac{f\,U}{(\Phi/L)}. \tag{44.138}$$

7. RATIO OF FLUCTUATING STRATIFICATION TO BACKGROUND STRATIFICATION: The ratio of the buoyancy frequency arising from the fluctuating buoyancy, B/H, to the background squared buoyancy frequency, $N^2(z)$, is given by

$$\frac{\text{fluctuating squared buoyancy frequency}}{\text{background squared buoyancy frequency}} = \frac{B/H}{N^2(z)}. \tag{44.139}$$

44.7.4 Relating the buoyancy scale to the Coriolis acceleration scale

The fluctuating buoyancy, b', and fluctuating pressure, φ', have scales related through the hydrostatic balance. Hence, taking a unit hydrostatic number from equation (44.132) renders

$$B = \Phi/H. \tag{44.140}$$

Additionally, assuming geostrophic scaling, equation (44.138) means that the fluctuating pressure has a scale related to the Coriolis acceleration scale according to

$$\Phi = f\,U\,L. \tag{44.141}$$

Evidently, the scale for the fluctuating buoyancy is given by

$$B = f\,U\,(L/H). \tag{44.142}$$

We emphasize that the scale for pressure fluctuation, $\Phi = f\,U\,L$, is distinct from the non-rotating case considered in Section 30.2.3, where $\Phi = U^2$.

44.7.5 Richardson number and QG/PG flow regimes

The *Richardson number* provides a measure of the stabilizing effects from vertical stratification versus the destabilizing effects from vertical shear

$$\mathrm{Ri} = \frac{\text{vertical stratification}}{\text{vertical shear}} \tag{44.143}$$

Mathematically, the Richardson number is given by the ratio of the squared buoyancy frequency to the squared vertical shear of the horizontal velocity

$$\mathrm{Ri} = \frac{N^2}{|\partial_z \mathbf{u}|^2}. \tag{44.144}$$

In regions where $\mathrm{Ri} < 1$, the vertical shear is stronger than the stabilizing effects from vertical stratification. In regions with small Richardson numbers, there is enough kinetic energy in the vertical shear to extract potential energy from the stratification, and this extraction process occurs via a vertical shear instability as studied in Chapter 57. In contrast, for large-scale highly stratified flow, the Richardson number is quite large, with $\mathrm{Ri} \sim 100$ common. Large Richardson number flow regimes are where quasi-geostrophy is relevant (Chapter 46).

Given the fundamental role of the Richardson number for stratified fluid motions, it is useful to introduce it as one of our dimensionless parameters. Namely, we define the vertically dependent Richardson number scale as

$$\mathrm{Ri}(z) = \frac{N^2(z)}{(U/H)^2}, \tag{44.145}$$

where we set the vertical length scale to H, the horizontal velocity scale to U, and the squared

buoyancy frequency to the background value, $N^2(z)$, introduced by equation (44.123). Retaining vertical dependence to the background buoyancy frequency means that the Richardson number scale is also vertically dependent.

The Richardson number scale can be related to the Rossby and Burger numbers through

$$\mathrm{Bu}(z) = \left[\frac{L_{\mathrm{d}}(z)}{L}\right]^2 = \left[\frac{N(z)\,H}{f\,L}\right]^2 = \frac{U^2\,\mathrm{Ri}(z)}{U^2/(\mathrm{Ro})^2} = (\mathrm{Ro})^2\,\mathrm{Ri}(z). \tag{44.146}$$

Evidently, vertical dependence to the prescribed background buoyancy frequency makes the Burger number and Richardson number vertically dependent, as well as the deformation radius.

One further way to write the Burger number is by introducing the angle φ defined by the vertical and horizontal length scales

$$\tan\varphi \equiv H/L \tag{44.147}$$

in which case

$$\mathrm{Bu} = \left[\frac{L_{\mathrm{d}}}{L}\right]^2 = \left[\frac{N\,H}{f\,L}\right]^2 = (\mathrm{Ro})^2\,\mathrm{Ri} = [(N/f)\,\tan\varphi]^2. \tag{44.148}$$

When $\tan^2\varphi$ is set according to the slope of the ocean bottom, then $[(N/f)\,\tan\varphi]^2$ is known as the *slope Burger number* (*MacCready and Rhines*, 1993; *Peterson and Callies*, 2022).

For quasi-geostrophic flows, the horizontal length scales, L, are assumed to be on the order of the deformation radius, L_{d}, in which case the Burger number is close to unity. The relation (44.146) means that the Richardson number scales as

$$\mathrm{Ri} \sim (\mathrm{Ro})^{-2} \qquad \text{QG flow regime.} \tag{44.149}$$

For atmospheric flows with a Rossby number order 1/10, quasi-geostrophic flow regimes are realized with a Richardson number ~ 100. For the ocean, the Rossby number can be even smaller, in which case quasi-geostrophic flows are characeterized by an even larger Richardson number. For planetary geostrophy, the Burger number is small. Hence, planetary geostrophic flows are characterized by somewhat smaller Richardson numbers than quasi-geostrophic flows.

44.7.6 The Rossby deformation radius

The combined effects of buoyancy and rotation yield the richness of continuously stratified planetary geostrophic and quasi-geostrophic motions. Hence, the buoyancy frequency and the Coriolis parameter play central role in characterizing these flow regimes. The ratio of these two frequencies, N/f, in regions of nontrivial vertical stratification is typically around 100. Hence, rotational inertial oscillations (usually just called *inertial oscillations*; Section 14.5) have about 100 times longer period, $2\pi/f$, than buoyancy oscillations with period $2\pi/N$.

Letting the squared buoyancy frequency, N^2, refer to a value typical of a particular flow regime, one can define the Rossby deformation radius

$$L_{\mathrm{d}} = H\,(N/f). \tag{44.150}$$

As defined, the deformation radius is the vertical length scale multiplied by the ratio of the buoyancy frequency to the Coriolis frequency. The ratio, f/N, appears frequently in rotating/stratified fluids, and is sometimes called the *Prandtl ratio*

$$\text{Prandtl ratio} = f/N. \tag{44.151}$$

With $H \approx 1$ km and $N/f \approx 100$, the Rossby deformation radius is roughly 100 km. This

length scale measures the relative importance of stratification and rotation. Depending on the ratio L/L_{d}, we can have large or small stratification fluctuations relative to the background stratification. Furthermore, as studied in Chapter 58, the deformation radius sets the scale for unstable baroclinic waves leading to baroclinically unstable flow.

For some context, recall the shallow water deformation radius is given by equation (44.31), $L_{\mathrm{d}} = \sqrt{g\,H}/f$, which is the ratio of the gravity wave speed to Coriolis frequency. With $N = 100\,f = 10^{-2}\ \mathrm{s}^{-1}$ and $H = 10^3$ m, the shallow water deformation radius is about an order of magnitude larger than the internal deformation radius. This scale difference means that the characteristic length scales, as set by L_{d}, are much larger in a single layer of shallow water fluid than in a stratified fluid.

44.7.7 Assumed values for the non-dimensional parameters

We now enumerate the assumed values for the non-dimensional parameters, again largely following the choices made for the shallow water layer in Section 44.3.5. These assumptions are guided by the regimes of interest to our analysis.

1. SMALL VERTICAL TO HORIZONTAL ASPECT RATIO: The aspect ratio is generally small for large-scale atmospheric and oceanic fluid systems

$$\delta_{\mathrm{vertical/horizontal}} \ll 1. \tag{44.152}$$

   This assumption is part of the hydrostatic approximation (Section 28.2), and as such it is a necessary scaling for any asymptotic theory based on a hydrostatic starting point.

2. SMALL OR ORDER ONE RATIO OF HORIZONTAL TO PLANETARY SCALES: The ratio of the horizontal length scale to the planet radius is small for quasi-geostrophic systems, and order unity for planetary geostrophy

$$\delta_{\mathrm{horizontal/planet}} \ll 1 \qquad \text{quasi-geostrophy} \tag{44.153a}$$
$$\delta_{\mathrm{horizontal/planet}} \sim 1 \qquad \text{planetary geostrophy.} \tag{44.153b}$$

   For example, the vertical length scale could be determined by the averaged depth of the pycnocline in the ocean, or the averaged height of the tropopause in the atmosphere. For the horizontal length scale in quasi-geostrophic theory, we might choose the scale of a Gulf Stream ring in the ocean or synoptic weather pattern in the atmosphere. Alternatively, we might choose the laterial scale of an ocean gyre for planetary geostrophy.

3. SMALL RATIO VERTICAL TO HORIZONTAL VELOCITY SCALE: The continuity equation implies

$$W/H = U/L, \tag{44.154}$$

   so that

$$W = U\,(H/L). \tag{44.155}$$

   As noted above, for a hydrostatic fluid the vertical to horizontal aspect ratio H/L is small, so that the vertical velocity scale is smaller than the horizontal velocity scale. Furthermore, when the fluid is close to geostrophically balanced, the vertical velocity scale is even smaller, by a factor of Ro. We see that factor emerge in the following scale analysis.

4. UNIT HYDROSTATIC NUMBER: As already noted, the hydrostatic balance (44.121b) means that the scales for a buoyancy fluctuation and pressure fluctuation are related by (see equa-

tion (44.132))

$$\Phi = H\,B. \tag{44.156}$$

5. Small Rossby number: The Rossby number is assumed small

$$\mathrm{Ro} = U/(f\,L) = (f\,T)^{-1} \ll 1, \tag{44.157}$$

where we set the time scale according to advection, $T = L/U$.

6. Unit geostrophic number: The geostrophic number is assumed to be order unity

$$\mathrm{Ge} \sim 1, \tag{44.158}$$

which means that the Coriolis acceleration and pressure gradient acceleration scale together

$$f\,U \sim \Phi/L. \tag{44.159}$$

This scaling is consistent with the momentum equation (44.121a) so long as the Rossby number is small, $\mathrm{Ro} \ll 1$.

7. stratification fluctuations compared to background stratification: Making use of the assumed unit geostrophic number, the ratio of the buoyancy frequency arising from the fluctuating buoyancy to the background buoyancy frequency is given by

$$\frac{B/H}{N^2} = \frac{\Phi}{H^2\,N^2} = \frac{f\,U\,L}{H^2\,N^2} = \frac{U}{f\,L}\,\frac{L^2\,f^2}{H^2\,N^2} = \mathrm{Ro}\,\frac{L^2}{L_{\mathrm{d}}^2}, \tag{44.160}$$

where we introduced the deformation radius (44.150) $L_{\mathrm{d}} = H\,N/f$, which is a function of vertical position through the prescribed background $N^2(z)$. Note that it is important to keep the depth dependence of N^2 when returning to dimensional fields, particularly for the quasi-geostrophic equations derived in Section 46.3.7.

44.7.8 Non-dimensional Boussinesq equations

Following the shallow water approach in Section 44.3.7, we introduce non-dimensional variables according to

$$t = T\,\widehat{t} \qquad (x,y) = L\,(\widehat{x},\widehat{y}) \qquad \partial_t = \partial_{\widehat{t}}/T \qquad \nabla_z = \widehat{\nabla}_z/L \qquad \partial_z = \partial_{\widehat{z}}/H \qquad f = f_0\,\widehat{f} \tag{44.161a}$$

$$(u,v) = U\,(\widehat{u},\widehat{v}) \qquad w = W\,\widehat{w} \qquad \varphi' = f_0\,U\,L\,\widehat{\varphi} \qquad b' = B\,\widehat{b} = (f_0\,U\,L/H)\,\widehat{b}. \tag{44.161b}$$

For the second equality in the buoyancy scale, we made use of equation (44.142) to connect the buoyancy fluctuation scale to the Coriolis acceleration scale. We also make use of the following relations between scales

$$T = L/U \qquad \text{advective scaling for } T \tag{44.162}$$

$$W = U\,(H/L) \qquad \text{continuity scaling for } W \tag{44.163}$$

$$\mathrm{Ro} = U/(f_0\,L) = (T\,f_0)^{-1} \qquad \text{advective scaling for } T. \tag{44.164}$$

The first relation assumes the time scale is determined by the advection time, $T = L/U$, which then means that the Rossby number is the ratio of the advective frequency, $1/T$, to the Coriolis

frequency, f_0. Furthermore, we assume a vertical velocity scale according to the continuity equation, $W = U\,(H/L)$. This continuity scaling for W is actually an over-estimate, where we find below that W instead scales like $W = \mathrm{Ro}\,U\,(H/L)$.

Non-dimensional momentum equation

Introducing the dimensionless variables and dimensionful scales into the Boussinesq momentum equation (44.121a) renders

$$\frac{U}{T}\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + \frac{U^2}{L}\,(\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}_z)\,\widehat{\boldsymbol{u}} + \frac{W\,U}{H}\,\widehat{\boldsymbol{w}}\,\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{z}} + f_0\,U\,(\widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}}) = -f_0\,U\,\widehat{\nabla}_z\,\widehat{\varphi}, \tag{44.165}$$

and dividing by $f_0\,U$ leads to

$$\mathrm{Ro}\left[\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}_{\widehat{z}})\,\widehat{\boldsymbol{u}} + \widehat{w}\,\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{z}}\right] + (\widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}}) = -\widehat{\nabla}_z\,\widehat{\varphi}. \tag{44.166}$$

The non-dimensional hydrostatic balance is given by

$$\frac{\partial \widehat{\varphi}}{\partial \widehat{z}} = \widehat{b}, \tag{44.167}$$

and the non-dimensional continuity equation is

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{v}} = 0. \tag{44.168}$$

Non-dimensional buoyancy equation

The buoyancy equation (44.124) requires a bit more work to non-dimensionalize. The material time derivative takes the form

$$\frac{\mathrm{D}b'}{\mathrm{D}t} = \frac{B}{T}\,\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}} = \frac{U}{L}\,\frac{f_0\,U\,L}{H}\,\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}} = \frac{f_0\,U^2}{H}\,\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}}, \tag{44.169}$$

where we made use of the advective scaling $T = L/U$ and continuity scaling $W = U\,(H/L)$. The vertical advection of background stratification is given by

$$N^2\,w = N^2\,W\,\widehat{w} = N^2\,U\,(H/L)\,\widehat{w} = L_{\mathrm{d}}^2\,\frac{U\,f_0^2}{H\,L}\,\widehat{w}, \tag{44.170}$$

where we introduced the deformation radius, $L_{\mathrm{d}} = H(N/f)$, from equation (44.150). Bringing these two pieces together leads to

$$\mathrm{Ro}\,\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}} + \mathrm{Bu}\,\widehat{w} = 0, \tag{44.171}$$

where we introduced the Burger number, $\mathrm{Bu} = (L_{\mathrm{d}}/L)^2$.

44.7.9 Comments

As stated earlier, the material in this section serves as the starting point for a systematic derivation of the continuously stratified planetary geostrophic equations in Chapter 45, and the continuously stratified quasi-geostrophic equations in Chapter 46. Particularly for the quasi-geostrophic equations, we make use of asymptotic methods as for the shallow water quasi-geostrophic equations in Section 44.5.

44.8 Exercises

EXERCISE 44.1: PV CONSERVATION FOR PLANETARY GEOSTROPHY
Show that the planetary geostrophic equations

$$\boldsymbol{f} \times \boldsymbol{u} = -g\,\nabla\eta \qquad \text{and} \qquad \frac{\mathrm{D}h}{\mathrm{D}t} = -h\nabla\cdot\boldsymbol{u} \qquad \text{with} \qquad \eta = \eta_{\mathrm{b}} + h \tag{44.172}$$

are equivalent to

$$\boldsymbol{f} \times \boldsymbol{u} = -g\,\nabla\eta \qquad \text{and} \qquad \frac{\mathrm{D}Q}{\mathrm{D}t} = 0 \qquad \text{with} \qquad Q = \frac{f}{h}. \tag{44.173}$$

This result shows that the shallow water PG equations may be written as an evolution equation for an approximated version of the shallow water potential vorticity, $(f+\zeta)/h \approx f/h$. This limit holds when the Rossby number is small.

EXERCISE 44.2: CONSTRAINTS ON STEADY STATE PLANETARY GEOSTROPHIC FLOW
Consider a shallow water fluid satisfying the planetary geostrophic equations developed in Section 44.4. Assume the flow is in steady state.

(a) In what manner does potential vorticity conservation constrain the velocity field?

(b) Consider an initially zonal geostrophic flow. In what direction (poleward or equatorward) will a fluid parcel deviate when encountering a seamount (i.e., a region of relatively shallow depth)?

(c) Describe the geostrophic contours (i.e., path of fluid particles following the geostrophic flow) for the case where the ocean sea surface height undulations, η', are far smaller than undulations in the bottom topography, η'_{b} (see Figure 36.1 for notation).

(d) For the special case of an f-plane, show that the velocity is aligned with isolines of bottom topography.

(e) For the special case of a flat bottom and latitudinally dependent Coriolis parameter, $f(y)$, show that there is no meridional geostrophic velocity. That is, the flow is zonally aligned.

Chapter 45

Planetary geostrophic vorticity analysis

The planetary geostrophic equations consist of steady and linear frictional geostrophic flow coupled to the non-steady and nonlinear buoyancy evolution. Consequently, the fluid state evolves through the buoyancy equation, whereas the flow is diagnosed from frictional geostrophy and continuity. Furthermore, there is no turbulence in planetary geostrophy since the momentum equation is linear and steady. Evidently, planetary geostrophy is focused on large-scale flow of a stably stratified laminar fluid whose vorticity is dominated by planetary rotation in the presence of planetary beta and topographic beta.

We already studied various physical properties of planetary geostrophy in Chapter 32, such as geostrophy, vorticity, thermal wind, and Taylor-Proudman. We also made use of planetary geostrophy to study western boundary current intensification for a shallow water layer in Section 40.7. We were able to present those studies earlier in the book since, as seen in Section 44.4 for the shallow water, derivation of the planetary geostrophic equations is a very simple task, thus allowing the equations to be plausibly written down without needing any formal asymptotics.

The stratified planetary geostrophic equations form the foundation for theories of the large-scale ocean circulation, with vorticity constraints providing a key reason for the central role of planetary geostrophy. The central role for vorticity motivates a focus in this chapter on the mathematical and physical basis for planetary geostrophic vorticity analysis. It is notable that in a planetary geostrophic flow, we are only concerned with planetary vorticity, and thus ignore relative vorticity. Consequently, we ignore vorticity sources from baroclinicity and tilting. Instead, we focus on how vertical stretching modifies a fluid's planetary vorticity, and how the fluid responds by moving meridionally to adjust its planetary vorticity in response to stretching.

After summarizing the planetary geostrophic equation set, we derive the planetary geostrophic potential vorticity budget and determine how the impermeability theorem from Section 43.2 appears in planetary geostrophy. We then study a suite of vorticity budgets arrived at through vertical integration the fluid from its bottom to top, with particular focus on ocean applications. Each of the resulting two-dimensional vorticity budgets offers insights into how large-scale ocean flow is constrained by rotation and the beta effect. In particular, these budgets render insights into how forces and the curl of forces generate vertical flow next to the boundaries as well as meridional flow for the full fluid column.

CHAPTER GUIDE

We here extend the shallow water discussions from Chapter 44 to develop an understanding of the continuously stratified planetary geostrophic equations. We make use of stratified geophysical fluid dynamics from Chapters 25 and 32, vorticity and the planetary beta effect from Chapter 41, and potential vorticity from Chapter 42. Physical properties of stratified geostrophic mechanics were considered in Chapter 32, with an understanding of that material assumed here.

45.1 Loose threads

- Need to distinguish $\nabla_z p$ evaluated at the bottom, from ∇p_{b}. They differ. It is $\nabla_z p$ evaluated at the bottom that is associated with bottom geostrophic flows. I am not accounting for this difference so need to correct that error. See *Bingham and Hughes* (2012).

45.2 Equations for planetary geostrophy

Just like for the shallow water model in Section 44.4, the planetary geostrophic model for the stratified Boussinesq ocean is a rather simple asymptotic theory. For this case, we assume the horizontal scales are large compared to the deformation radius, so that

$$\mathrm{Ro}/\mathrm{Bu} \sim 1 \Longrightarrow \mathrm{Ro}\, L^2 \sim L_{\mathrm{d}}^2. \tag{45.1}$$

With this scaling, and with a small Rossby number, the momentum equation (44.166) reduces to geostrophic balance. However, the continuity and buoyancy equations retain their unapproximated Boussinesq form. Hence, in dimensional form, the perfect (adiabatic and inviscid) planetary geostrophic equations for a stratified Boussinesq ocean are

$$\frac{\mathrm{D}b'}{\mathrm{D}t} + w\,N^2 = 0 \quad \text{and} \quad f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla_z \varphi' \quad \text{and} \quad \frac{\partial \varphi'}{\partial z} = b' \quad \text{and} \quad \nabla \cdot \boldsymbol{v} = 0. \tag{45.2}$$

45.2.1 Common form of the equations

We could just as well write the planetary geostrophic equations (45.2) in terms of the full buoyancy

$$b = \tilde{b}(z) + b', \tag{45.3}$$

and full pressure,

$$p = p_0(z) + \rho_0\,\varphi. \tag{45.4}$$

Additionally, it is quite useful to include non-conservative terms such as buoyancy mixing, $\dot{b}$, to allow for the study of how stratification evolves, as well as horizontal frictional accelerations and/or boundary accelerations, $\boldsymbol{F}$, to include boundary stress driven circulations through Ekman layers (Chapter 34). For these reasons, we take the frictional and diabatic planetary geostrophic equations as the basis for discussions in this chapter

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\rho_0^{-1}\,\nabla_z p + \boldsymbol{F} \qquad \text{frictional geostrophy} \tag{45.5a}$$

$$\partial_t b + \boldsymbol{u} \cdot \nabla_z b + N^2\,w = \dot{b} \qquad \text{diabatic buoyancy equation} \tag{45.5b}$$

$$\partial_z p = -\rho\,g \qquad \text{hydrostatic balance} \tag{45.5c}$$

$$\nabla \cdot \boldsymbol{v} = \nabla_z \cdot \boldsymbol{u} + \frac{\partial w}{\partial z} = 0 \qquad \text{non-divergent flow} \tag{45.5d}$$

$$N^2 = \partial_z b \qquad \text{squared buoyancy frequency} \tag{45.5e}$$

$$b = -g\,(\rho - \rho_0)/\rho_0 \qquad \text{Archimedean buoyancy.} \tag{45.5f}$$

Note that the material time derivative in planetary geostrophy makes use of advection by the three velocity components, $\boldsymbol{v} = (\boldsymbol{u}, w)$, as seen in the buoyancy equation (45.5b), with the horizontal velocity components determined by the frictional geostrophic balance (45.5a). This situation contrasts to quasi-geostrophy, where it is only the horizontal advection by the geostrophic flow that contributes to material time evolution (Section 46.2).

As for the Boussinesq ocean equations discussed in Section 30.1.6, we sometimes find it convenient to combine the horizontal velocity equation with the hydrostatic balance to write

$$f\,\hat{\boldsymbol{z}} \times \boldsymbol{u} = -\nabla\varphi + b\,\hat{\boldsymbol{z}} + \boldsymbol{F}. \tag{45.6}$$

Furthermore, it is common to assume an equation of state that is independent of pressure, so that material time changes in buoyancy arise only from changes in Conservative Temperature and/or salinity

$$\dot{b} = \frac{\partial b}{\partial S}\,\dot{S} + \frac{\partial b}{\partial \Theta}\,\dot{\Theta}. \tag{45.7}$$

The partial derivatives, $\partial b/\partial\Theta$ and $\partial b/\partial S$, are commonly assumed constant in idealized studies.

45.2.2 Planetary geostrophic energetics

Since the velocity is diagnostic in planetary geostrophy, it is determined by the buoyancy field. In turn, there is a prognostic equation for potential energy that arises from the buoyancy equation, whereas kinetic energy is diagnostic. The energetics are thus a special case of the Boussinesq energetics studied in Section 30.6. We here consider just the basics.

General considerations

Multiplying the buoyancy equation (45.5b) by z leads to the potential energy equation

$$\partial_t P + \nabla \cdot (\boldsymbol{v}\, P) + w\, b = -z\, \dot{b}, \tag{45.8}$$

where we introduced the potential energy per mass relative to the reference density[1]

$$P = -z\, b = z\, g\, (\rho - \rho_0)/\rho_0. \tag{45.9}$$

Equation (45.8) says that the potential energy at a point in the planetary geostrophic fluid is affected by advective transport, buoyancy work, and diabatic processes. As we will see, diabatic processes such as diffusion provide a local source for potential energy, whereas buoyancy work transfers potential energy to kinetic energy.

Projecting the geostrophic/hydrostatic balance equation (45.6) onto the velocity leads to the diagnostic balance between pressure work, buoyancy work, and friction

$$\boldsymbol{v} \cdot \nabla \varphi - w\, b = \boldsymbol{u} \cdot \boldsymbol{F}. \tag{45.10}$$

We can add this balance to the potential energy equation (45.8) to eliminate the buoyancy work term, $w\, b$, thus yielding

$$\partial_t P + \nabla \cdot (\boldsymbol{v}\, P + \boldsymbol{v}\, \varphi) = \boldsymbol{u} \cdot \boldsymbol{F} - z\, \dot{b}, \tag{45.11}$$

where we used $\nabla \cdot \boldsymbol{v} = 0$ to bring $\boldsymbol{v}\, \varphi$ inside the divergence. We thus see that potential energy at a point in the planetary geostrophic fluid is affected by reversible transport processes from advection and pressure work, along with irreversible processes from friction and material buoyancy changes.

Diffusively driven flow

It is revealing to consider the special case of a constant volume domain with static and rigid boundaries and with no boundary fluxes. We also assume that buoyancy is irreversibly modified through diffusion

$$\dot{b} = \nabla \cdot (\kappa\, \nabla b), \tag{45.12}$$

with $\kappa > 0$ an isotropic kinematic diffusivity that can be a function of space and time. Integrating the potential energy equation (45.11) over the domain leads to

$$\partial_t \langle P \rangle = \langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle + \langle \kappa\, N^2 \rangle, \tag{45.13}$$

where the angle brackets signify volume means. To reach this identity we made use of

$$z\, \dot{b} = z\, \nabla \cdot (\kappa\, \nabla b) = \nabla \cdot (z\, \kappa\, \nabla b) - \kappa\, \partial_z b = \nabla \cdot (z\, \kappa\, \nabla b) - \kappa\, N^2, \tag{45.14}$$

[1] We considered this same form for the potential energy in Section 30.7 as well as Exercise 30.5 as part of the Boussinesq ocean chapter.

with $\nabla \cdot (z\,\kappa\,\nabla b)$ integrating to zero in the absence of boundary fluxes. The global mean potential energy equation (45.13) indicates that diffusion increases volume mean potential energy for a stably stratified fluid ($N^2 > 0$), whereas friction generally dissipates potential energy since $\langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle < 0$ (Section 27.3.3). So diffusion is the only source for potential energy, with spatial variations in potential energy leading to motion through the geostrophic balance. In the steady state this *diffusively driven flow* leads to the global mean balance between diffusion and friction

$$\langle \kappa\, N^2 \rangle = -\langle \boldsymbol{u} \cdot \boldsymbol{F} \rangle \qquad \text{steady state.} \tag{45.15}$$

45.3 Planetary geostrophic potential vorticity

In Section 42.5 we developed the potential vorticity equation for the hydrostatic Boussinesq ocean in the presence of horizontal friction in the momentum equation and diabatic terms in the buoyancy equation. Here we specialize that result to the case of planetary geostrophic system written in the form of equations (45.5a)-(45.5e).

45.3.1 Derivation

Derivation of the potential vorticity equation proceeds much like that for the hydrostatic Boussinesq ocean. The first step requires the planetary geostrophic vorticity equation as determined by taking the curl of the momentum equation (45.5a). The vertical component of this vorticity equation is given by (see also Section 32.5.2)

$$\beta\, v = f\, \partial_z w + \hat{\boldsymbol{z}} \cdot (\nabla_z \times \boldsymbol{F}) \qquad \text{with} \qquad \beta = \partial_y f. \tag{45.16}$$

Next, make use of frictional thermal wind balance

$$f\, \partial_z \boldsymbol{u} = \hat{\boldsymbol{z}} \times \nabla_z b - \partial_z (\hat{\boldsymbol{z}} \times \boldsymbol{F}) \tag{45.17}$$

as well as the identities

$$N^2 \frac{\mathrm{D} f}{\mathrm{D} t} = N^2\, \beta\, v \tag{45.18a}$$

$$f\, \frac{\mathrm{D} N^2}{\mathrm{D} t} = f\, \frac{\partial \dot{b}}{\partial z} - f\, \nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} \tag{45.18b}$$

$$f\, \nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} = f\, N^2\, \frac{\partial w}{\partial z} - \frac{\partial (\hat{\boldsymbol{z}} \times \boldsymbol{F})}{\partial z} \cdot \nabla_z b, \tag{45.18c}$$

to render

$$\frac{\mathrm{D}(f\, N^2)}{\mathrm{D} t} = N^2\, \beta\, v + f\, \frac{\partial \dot{b}}{\partial z} - f\, \nabla b \cdot \frac{\partial \boldsymbol{v}}{\partial z} \tag{45.19a}$$

$$= N^2 \left[f\, \frac{\partial w}{\partial z} + \hat{\boldsymbol{z}} \cdot (\nabla_z \times \boldsymbol{F}) \right] + f\, \frac{\partial \dot{b}}{\partial z} - f\, N^2\, \frac{\partial w}{\partial z} + \frac{\partial (\hat{\boldsymbol{z}} \times \boldsymbol{F})}{\partial z} \cdot \nabla_z b \tag{45.19b}$$

$$= f\, \frac{\partial \dot{b}}{\partial z} + \nabla b \cdot (\nabla \times \boldsymbol{F}) \tag{45.19c}$$

$$= \nabla \cdot (f\, \dot{b}\, \hat{\boldsymbol{z}} + \boldsymbol{F} \times \nabla b). \tag{45.19d}$$

We thus identify the planetary geostrophic potential vorticity

$$Q_{\mathrm{PG}} = f\, N^2, \tag{45.20}$$

which is materially invariant in the absence of diabatic processes and friction

$$\frac{\mathrm{D}Q_{\mathrm{PG}}}{\mathrm{D}t} = 0 \qquad \text{if } \dot{b} = 0 \text{ and } \boldsymbol{F} = 0. \tag{45.21}$$

We can write the general budget equation in the form of an Eulerian flux-form expression

$$\partial_t Q_{\mathrm{PG}} + \nabla \cdot \boldsymbol{J}_{\mathrm{PG}} = 0, \tag{45.22}$$

where the planetary geostrophic potential vorticity flux is given by

$$\boldsymbol{J}_{\mathrm{PG}} = \boldsymbol{v}\, Q_{\mathrm{PG}} - \dot{b}\, f\, \hat{\boldsymbol{z}} + \nabla b \times \boldsymbol{F} + \nabla \times \boldsymbol{A}. \tag{45.23}$$

The vector $\boldsymbol{A}$ is an arbitrary gauge function that has no impact on the potential vorticity evolution. Comparing to the hydrostatic Boussinesq ocean expression (42.73), we see that the planetary geostrophic result follows by approximating the absolute vorticity by just the planetary vorticity.

45.3.2 Impermeability theorem

Following the discussion in Section 43.2.2, we verify that the potential vorticity flux vector (45.23) satisfies the impermeability theorem for buoyancy isosurfaces. We do so for the particular case of a zero gauge function ($\boldsymbol{A} = 0$), in which case

$$\boldsymbol{v}_{\mathrm{PG}} \cdot \nabla b = (\boldsymbol{J}_{\mathrm{PG}}/Q) \cdot \nabla b = \boldsymbol{v} \cdot \nabla b - \dot{b} = -\partial_t b, \tag{45.24}$$

so that

$$(\partial_t + \boldsymbol{v}_{\mathrm{PG}} \cdot \nabla) b = 0. \tag{45.25}$$

Evidently, there is zero flux of PV-substance crossing buoyancy isosurfaces, even in the presence of irreversible processes that allow matter and buoyancy to cross those surfaces. As shown in the next subsection, we identify two more forms of the PV-substance flux vector that also satisfy impermeability, with these alternative forms differing by gauge transformations.

45.3.3 A kinematic PV flux satisfying impermeability

Following the discussion of impermeability for the Ertel potential vorticity in Section 43.2.2, we expose a purely kinematic means to derive the impermeability theorem for the planetary geostrophic potential vorticity. This derivation follows by computing the time tendency of the potential vorticity

$$\frac{\partial Q}{\partial t} = \frac{\partial}{\partial t} \nabla \cdot (f\, b\, \hat{\boldsymbol{z}}) = \nabla \cdot \left[f\, \frac{\partial b}{\partial t}\, \hat{\boldsymbol{z}} \right] \equiv -\nabla \cdot \tilde{\boldsymbol{J}}_{\mathrm{PG}}, \tag{45.26}$$

where

$$\tilde{\boldsymbol{J}}_{\mathrm{PG}} = -f\, \partial_t b\, \hat{\boldsymbol{z}}. \tag{45.27}$$

This form of the PV-substance flux also satisfies impermeability since

$$\tilde{\boldsymbol{v}}_{\mathrm{PG}} \cdot \nabla b = (\tilde{\boldsymbol{J}}_{\mathrm{PG}}/Q) \cdot \nabla b = -\partial_t b, \tag{45.28}$$

so that

$$(\partial_t + \tilde{\boldsymbol{v}}_{\mathrm{PG}} \cdot \nabla) b = 0. \tag{45.29}$$

The PV-substance flux, $\tilde{\boldsymbol{J}}_{\mathrm{PG}}$, vanishes in the steady state, whereas the steady state form of the alternative flux, $\boldsymbol{J}_{\mathrm{PG}}$, is nonzero. Following the discussion in Section 43.3.2, we may choose

to introduce a gauge transformation to the kinematic flux, $\tilde{\boldsymbol{J}}_{\rm PG}$, so that it does not vanish in the steady state. Taking the small Rossby number limit of the flux (43.32) renders

$$\boldsymbol{J}_{\rm Q}^{\rm marshall\ PG} = -\nabla(g\,z + \varphi) \times \nabla b - f\,\partial_t b\,\hat{\boldsymbol{z}}. \tag{45.30}$$

This flux differs from $\tilde{\boldsymbol{J}}_{\rm PG}$ by a curl

$$\nabla(g\,z + \varphi) \times \nabla b = \nabla \times [(g\,z + \varphi)\,\nabla b], \tag{45.31}$$

and it also satisfies the impermeability theorem. As discussed in Section 43.5.6, there are a variety of motivations for using one form of the PV-substance flux versus another. Some applications prefer a nonzero steady flux that also does not expose any irreversible processes, with $\boldsymbol{J}_{\rm Q}^{\rm marshall\ PG}$ satisfying these desires.

45.4 Depth integrated vorticity budget

In a planetary geostrophic flow, vorticity arises just from planetary vorticity since relative vorticity is negligible by comparison. With planetary vorticity a function just of latitude, a budget for the planetary geostrophic vorticity reveals how the curl of forces imparted to the fluid cause meridional motion as the fluid meets the constraints imposed by the vorticity equation. As per our discussion in Section 41.3.6, we refer to a force curl as a "torque" in our study of vorticity sources. However, one must keep in mind that more common usage in physics refers to a torque as affecting changes to angular momentum, with angular momentum generally distinct from vorticity (see Section 38.9 for a discussion of the distinction).

In this section we study the depth integrated vorticity budget for the planetary geostrophic fluid and derive implications for the meridional flow. For this purpose we focus on frictional and boundary accelerations that take the form of a vertical divergence of horizontal turbulent stress vector

$$\boldsymbol{F} = \partial_z \boldsymbol{\tau}. \tag{45.32}$$

The curl of this stress, as well as pressure forces, provide torques that generate meridional motion as revealed by the planetary geostrophic vorticity budget.

45.4.1 The β-effect, stretching, and meridional transport

In Section 32.5.2 we derived the vorticity equation for planetary geostrophy. We also encountered this equation when deriving the potential vorticity budget in Section 45.3.1. With friction written as a vertical divergence of horizontal turbulent stresses (equation (45.32)), the vertical component of the planetary geostrophic vorticity equation takes the form

$$\rho_0\,\beta\,v = \partial_z\left[\rho_0\,f\,w + \hat{\boldsymbol{z}}\cdot(\nabla\times\boldsymbol{\tau})\right]. \tag{45.33}$$

Vertical integration from the ocean bottom at $z = \eta_{\rm b}(x,y)$ to sea surface at $z = \eta(x,y,t)$ leads to[2]

$$\rho_0\,\beta\,V = \underbrace{\rho_0\,f\,[w(\eta) - w(\eta_{\rm b})]}_{\text{column stretching}} + \underbrace{\hat{\boldsymbol{z}}\cdot(\nabla\times\Delta\boldsymbol{\tau})}_{\text{boundary stresses}}, \tag{45.34}$$

[2] As a means to unclutter notation, we write ∇, rather than ∇_z, whenever acting on a field that is just a function of horizontal position, such as $p_{\rm a}, p_{\rm b}, \eta_{\rm b}$ and $\Delta\boldsymbol{\tau}$. We can do so since, for example, $\nabla p_{\rm b} = \nabla_z p_{\rm b}$, since $\partial_z p_{\rm b} = 0$.

where

$$V = \int_{\eta_b}^{\eta} v \, dz \tag{45.35}$$

is the depth-integrated meridional flow, and

$$\Delta \boldsymbol{\tau} = \boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_b) \tag{45.36}$$

is the difference in boundary stresses applied at the ocean surface and ocean bottom. Note that $\Delta \boldsymbol{\tau}$ is just a function of horizontal position and time.

For a planetary geostrophic flow, absolute vorticity is approximated by just the planetary vorticity

$$\zeta_a = \zeta + f \approx f. \tag{45.37}$$

As revealed by the vorticity equation (45.34), vorticity sources in a planetary geostrophic fluid lead to meridional motion, with meridional motion the only way a planetary geostrophic fluid can modify its vorticity in response to vorticity sources.

The first term on the right hand side of the vorticity equation (45.34) arises from vertical stretching of the depth integrated column, as measured by differences in the vertical velocity at the ocean surface and bottom. For example, vertical stretching caused by positive surface velocity, $w(\eta) > 0$, or a negative bottom velocity, $w(\eta_b) < 0$, lead to poleward motion of the fluid column. Conversely, vertical squashing leads to equatorward motion. We emphasize that when studying the motion of the depth integrated flow, we are only concerned with vertical stretching from differences in the boundary vertical velocity rather than the vertical velocity within the fluid interior.

The second term in the vorticity equation (45.34) arises from differences in the vorticity imparted by surface and bottom boundary stresses. Positive vorticity is imparted to the fluid through a positive curl of wind stresses, $\hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)] > 0$, or by a negative curl of bottom stresses, $\hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta_b)] < 0$, with such stress curls leading to poleward motion of the fluid column. The opposite motion occurs from the converse curls.

The β-effect (Section 41.6.2) is a fundamental element of the depth integrated vorticity equation (45.34). Namely, as fluid columns are stretched or squashed, they must move meridionally to maintain vorticity balance for a planetary geostrophic fluid on a rotating spherical earth. The planetary geostrophic vorticity equation restricts attention to vertical stretching through vertical motion (the w terms) and through the vorticity imparted by the curl of boundary stresses. Notably, the curl of boundary stresses also imparts vertical motion through surface and bottom Ekman layer dynamics (see Chapter 34). Hence, the right hand side of the vorticity equation (45.34) is fundamentally related to vortex stretching.

Equation (45.34) is central to mechanical descriptions of large-scale ocean circulation. For many flow regimes, the curl of the surface wind stress dominates, thus allowing us to ignore the vertical velocity terms as well as bottom frictional stresses. Formally, we isolate the wind stress when studying a flat bottom rigid lid model, whereby $w(\eta) = w(\eta_b) = 0$. However, there can be nontrivial impacts from bottom pressure torques when flow interacts with sloping topography, with the North Atlantic and Southern Ocean providing important case studies. Other processes can be important in various flow regimes, thus prompting us to derive a full diagnostic framework to identify where these processes are important. To pursue that framework, we make use of the kinematic boundary conditions and the horizontal momentum equation to unpack the vertical velocity terms. Doing so reveals the forces and their curls that drive vertical motion at the boundaries for a planetary geostrophic flow.

45.4.2 Bottom kinematics and dynamics

The bottom kinematic boundary condition applied at $z = \eta_{\rm b}(x, y)$ (Section 20.4.1) is given by

$$w = \boldsymbol{u} \cdot \nabla \eta_{\rm b} \qquad \text{at } z = \eta_{\rm b}(x, y). \tag{45.38}$$

This relation expresses the no-normal flow condition, $\hat{\boldsymbol{n}} \cdot \boldsymbol{v} = 0$, at the ocean bottom, with

$$\hat{\boldsymbol{n}} = -\frac{\nabla(z - \eta_{\rm b})}{|\nabla(z - \eta_{\rm b})|} = -\left[\frac{\hat{\boldsymbol{z}} - \nabla \eta_{\rm b}}{\sqrt{1 + \nabla \eta_{\rm b} \cdot \nabla \eta_{\rm b}}}\right] \tag{45.39}$$

the outward unit normal to the bottom. The boundary condition constrains the flow so that any horizontal motion next to a sloping bottom that is oriented either up or down the slope must have an associated vertical motion. As we see in this section, such vertical motion next to the bottom boundary arises from force curls acting to stretch or squash a fluid column. In turn, through the vorticity equation (45.34), vertical motion at the bottom leads to meridional motion of the full fluid column.

Expressions for bottom vertical velocity

The bottom kinematic boundary condition holds for all dynamical flow regimes. For the particular case of planetary geostrophy, we garner insight into the forces that drive vertical flow near the bottom by making use of the planetary geostrophic momentum equation (45.5a). Evaluating the horizontal components of this equation at the ocean bottom yields[3]

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -(\nabla p)_{z=\eta_{\rm b}} + \boldsymbol{F}_{\rm b}, \tag{45.40}$$

where $(\nabla p)_{z=\eta_{\rm b}}$ is the horizontal pressure gradient evaluated at the ocean bottom and $\boldsymbol{F}_{\rm b}(x, y, t)$ is the bottom friction. For the special case of a no-slip bottom, all velocity components vanish at $z = \eta_{\rm b}$. In that case, we consider $\boldsymbol{u}$ in equation (45.40) to be the horizontal velocity averaged within the bottom boundary layer, and w the corresponding vertical velocity leaving the boundary layer.

It is convenient to decompose the bottom horizontal velocity into its geostrophic and Ekman[4] components via

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm g} = -(\nabla p)_{z=\eta_{\rm b}} \qquad \text{and} \qquad \rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm e} = \boldsymbol{F}_{\rm b}, \tag{45.41}$$

so that

$$\boldsymbol{u}_{\rm g} = \frac{\hat{\boldsymbol{z}} \times (\nabla p)_{z=\eta_{\rm b}}}{\rho_0 \, f} \qquad \text{and} \qquad \boldsymbol{u}_{\rm e} = -\frac{\hat{\boldsymbol{z}} \times \boldsymbol{F}_{\rm b}}{\rho_0 \, f}. \tag{45.42}$$

For the horizontal horizontal pressure gradient at the ocean bottom, we make use of equation (28.60b) to write

$$(\nabla_z p)_{z=\eta_{\rm b}} = \nabla_z p_{\rm b} + g \, \rho(\eta_{\rm b}) \, \nabla_z \eta_{\rm b}. \tag{45.43}$$

The corresponding bottom vertical velocity components are determined by inserting equations (45.42) and (45.43) into the bottom kinematic boundary condition (45.38)

$$w_{\rm g} = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_{\rm b} \times \nabla p_{\rm b})}{\rho_0 \, f} \qquad \text{and} \qquad w_{\rm e} = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \eta_{\rm b} \times \boldsymbol{F}_{\rm b})}{\rho_0 \, f}. \tag{45.44}$$

These equations reveal how the curl of pressure forces and boundary frictional forces drive a

[3] Recall that since $p_{\rm b} = p_{\rm b}(x, y, t)$, we have $\nabla p_{\rm b} = \nabla_z p_{\rm b}$. As noted in the footnote on page 1243, we drop the z script to reduce notational clutter.

[4] Recall our discussion of Ekman mechanics in Chapter 34.

nonzero vertical motion next to the bottom, while maintaining the bottom kinematic boundary condition (45.38). As seen by these equations, is only the projection of $\nabla p_{\rm b}$ and $\boldsymbol{F}_b$ onto the isobath direction that contributes to a nonzero vertical velocity. These along-isobath forces are needed to render a horizontal velocity that is itself misaligned with isobaths, thus satisfying the kinematic requirement for vertical motion.[5]

To further understand the bottom pressure term, we write it as

$$w_{\rm g} = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_{\rm b} \times \nabla p_{\rm b})}{\rho_0 \, f} = \frac{\hat{\boldsymbol{z}} \cdot [\nabla \times p_{\rm b} \nabla \eta_{\rm b}]}{\rho_0 \, f}. \tag{45.45}$$

The numerator is the curl of the horizontal projection of the pressure contact force along the bottom, $p_{\rm b} \nabla \eta_{\rm b}$. This term is the topographic form stress discussed in Section 29.2 for a general fluid and in Section 40.7.5 for the shallow water. We thus conclude that vertical geostrophic motion next to the bottom arises from the curl of the topographic form stress. This is an important result that will appear again within this section as well as in Sections 45.6 and 45.7.

Comments on the bottom vertical geostrophic velocity

A large part of the bottom pressure gradient driving the horizontal geostrophic flow in equation (45.42) arises from changes in bottom depth. However, that portion of the bottom pressure gradient has no impact on $w_{\rm g}$, since it only drives horizontal flow along isobaths. We see this property by writing

$$p_{\rm b} = -\rho_0 \, g \, \eta_{\rm b} + p'_{\rm b} \Longrightarrow w_{\rm g} = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta_{\rm b} \times \nabla p'_{\rm b})}{\rho_0 \, f}. \tag{45.46}$$

When there is misalignment between isolines of bottom pressure and bottom topography, the geostrophic flow in a fluid column crosses isobaths. Correspondingly, with the pressure force misaligned with topographic gradients, the fluid column experiences a twisting action akin to how baroclinicity spins a fluid element if the pressure force does not act through the fluid element's center of mass (see Section 41.4).

To illustrate the above, consider the topographic bowl in Figure 45.1, with sides steep enough so that the bottom pressure gradient is dominated by the topographic slopes. Along the bottom the pressure increases moving down (increasing depth) towards the bowl center. The corresponding bottom geostrophic flow is anti-cyclonic within the bowl and largely follows isobaths. As already noted, if the geostrophic flow exactly follows isobaths, then there is no corresponding vertical component to the bottom velocity. A vertical velocity arises only in the presence of an anomalous bottom pressure gradient, $\nabla p'_{\rm b}$, that is misaligned with the bottom slope, $\nabla \eta_{\rm b}$. This bottom pressure gradient balances a geostrophic flow that deviates from isobaths thus giving rise to a nonzero $w_{\rm g}$. Similar geometric analysis holds for the bottom friction vector, $\boldsymbol{F}_{\rm b}$, and how it gives rise to a nonzero vertical Ekman velocity, $w_{\rm e}$.

What causes misalignment between p_b and η_b?

As we just discussed, misalignment of $p_{\rm b}$ and $\eta_{\rm b}$ lead to vertical geostrophic motion along the bottom. In Section 45.4.3 we will see a similar relation for vertical geostrophic motion at the ocean surface. But what causes such misalignment? The answer to this question is circular when working within planetary geostrophy since its momentum equation is diagnostic. Even so, we can offer some insight by returning to the depth-integrated vorticity balance (45.34) and rewriting it

[5] Note that we derived the expression (45.44) for $w_{\rm g}$ in equation (41.192) when studying vorticity mechanics.

FIGURE 45.1: Depicting how bottom pressure gradients create vertical motion in planetary geostrophic flow next to a sloping bottom according to equations (45.44) and (45.46). Here we show a bowl or depression (local maximum in the depth) with $-\eta_{\rm b}$ increasing inward toward the bowl center. Only those portions of $\nabla p_{\rm b}$ and $\boldsymbol{F}_b$ that are aligned parallel to the topographic slope contribute to vertical motion. We illustrate here a case where the bottom pressure gradient leads to $-\nabla \eta_{\rm b} \cdot \boldsymbol{u}_{\rm g} > 0$ so that $w_{\rm g} < 0$ in the northern hemisphere and $w_{\rm g} > 0$ in the southern hemisphere.

as an expression for vertical motion

$$\rho_0 \, f \, [w(\eta_{\rm b}) - w(\eta)] = -\rho_0 \, \beta \, V + \hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau}). \tag{45.47}$$

Hence, vertical motion at the surface and bottom balance meridional motion in the presence of planetary beta, plus the curl of surface and bottom stresses. The absence of planetary beta, and the absence of boundary stress curls, realizes $w(\eta_{\rm b}) = w(\eta)$.

45.4.3 Surface kinematics and dynamics

For purposes of large-scale circulation studies using planetary geostrophy, it is generally sufficient to assume a rigid lid upper boundary condition, whereby $w(\eta) = w(0) = 0$. Even so, we find it revealing to present the results for a free surface in which there is the possibility of nonzero surface mass fluxes. This situation is commonly encountered in general circulation models. The surface kinematic boundary condition for a Boussinesq fluid (Section 22.3) is given by

$$w = -Q_{\rm m}/\rho_0 + (\partial_t + \boldsymbol{u} \cdot \nabla)\eta \qquad \text{at } z = \eta(x, y, t). \tag{45.48}$$

We retain the sea surface time tendency, $\partial_t \eta$, even though for transient solutions the time tendency is many orders of magnitude smaller than the typical vertical velocity under the planetary geostrophic regime.[6] Evaluating the horizontal planetary geostrophic momentum equation (32.25a) at the ocean surface renders

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u} = -(\nabla_z p)_{z=\eta} + \boldsymbol{F}_\eta, \tag{45.49}$$

where $\boldsymbol{F}_\eta$ is the horizontal friction vector at the surface, and (see equation (28.60a))

$$(\nabla_z p)_{z=\eta} = \nabla_z p_{\rm a} + g \, \rho(\eta) \, \nabla_z \eta \tag{45.50}$$

[6]See Section 3.3 of *Samelson* (2011) for more details on this scaling of the planetary geostrophic equations.

is the horizontal pressure gradient at the ocean surface. Like the bottom, we decompose the horizontal velocity into a geostrophic component and an Ekman component via

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -(\nabla_z p)_{z=\eta} \qquad \text{and} \qquad \rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{e}} = \boldsymbol{F}_\eta, \tag{45.51}$$

so that

$$\boldsymbol{u}_{\mathrm{g}} = \frac{\hat{\boldsymbol{z}} \times (\nabla_z p)_{z=\eta}}{\rho_0 \, f} \qquad \text{and} \qquad \boldsymbol{u}_{\mathrm{e}} = -\frac{\hat{\boldsymbol{z}} \times \boldsymbol{F}_\eta}{\rho_0 \, f}. \tag{45.52}$$

The corresponding vertical velocity components are determined by inserting into the surface kinematic boundary condition (45.48)

$$w_{\mathrm{Q}\eta} = -\frac{Q_{\mathrm{m}}}{\rho_0} + \frac{\partial \eta}{\partial t} \qquad \text{and} \qquad w_{\mathrm{g}} = \frac{\hat{\boldsymbol{z}} \cdot (-\nabla \eta \times \nabla p_{\mathrm{a}})}{\rho_0 \, f} \qquad \text{and} \qquad w_{\mathrm{e}} = \frac{\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \boldsymbol{F}_\eta)}{\rho_0 \, f}, \tag{45.53}$$

where we introduced a vertical velocity, $w_{\mathrm{Q}\eta}$, associated with the boundary mass flux and transient sea level fluctuations. As for the bottom, the second and third of these equations reveal how the curl of inviscid pressure forces and boundary frictional forces drive a nonzero vertical motion at the ocean surface, all while maintaining the surface kinematic boundary condition (45.48). Furthermore, it is only the projection of ∇p_{a} and $\boldsymbol{F}_\eta$ onto the direction parallel to sea surface height contours that contributes to a nonzero vertical velocity. This orientation of the surface forces is needed to render a horizontal velocity that is itself misaligned with sea surface height contours, thus satisfying the kinematics required to render vertical motion.

45.4.4 Summary of force curls driving depth integrated meridional flow

Plugging expressions (45.44), (45.46), and (45.53) into equation (45.34) renders the depth integrated planetary vorticity balance

$$\rho_0 \, \beta \, V = f \left(-Q_{\mathrm{m}} + \rho_0 \, \partial_t \eta \right) + \hat{\boldsymbol{z}} \cdot \left[\nabla \eta \times (\boldsymbol{F}_\eta - \nabla p_{\mathrm{a}}) - \nabla \eta_{\mathrm{b}} \times (\boldsymbol{F}_{\mathrm{b}} - \nabla p'_{\mathrm{b}}) + \nabla \times \Delta \boldsymbol{\tau} \right]. \tag{45.54}$$

Evidently, the force curls are symmetrically applied at the surface and bottom, which is part of the motivation for exposing the surface terms even though they are generally subdominant. In general, equation (45.54) shows that the depth integrated meridional flow, within the planetary geostrophic regime, is driven by the following processes.

Surface mass transport plus sea surface fluctuations

The term $f \, \rho_0 \, (-Q_{\mathrm{m}}/\rho_0 + \partial_t \eta)$ arises from mass transport across the ocean surface plus fluctuations in the sea surface height. For example, as sea surface height increases or as water leaves the ocean surface, they impart a positive surface vertical velocity, $w(\eta) > 0$, thus causing column stretching and poleward meridional depth integrated flow. In the steady state, where it is just the mass flux term that contributes, the meridional circulation is known as the Goldsbrough-Stommel circulation (see *Huang and Schmitt* (1993) for a review).

Curl of turbulent boundary stresses

The term $\hat{\boldsymbol{z}} \cdot (\nabla \times \Delta \boldsymbol{\tau})$ arises from the curl of the turbulent wind stress and turbulent bottom stress. The wind stress term is generally larger than the bottom turbulent stress, with many theories for ocean circulation, particularly those with a flat bottom, almost exclusively focused on the role of surface stress in forcing planetary geostrophic vorticity. We comment more on this case in Section 45.5 where we discuss the *Sverdrup balance*.

Atmospheric pressure torque

The term

$$\nabla p_{\mathrm{a}} \times \nabla \eta = \nabla \times (p_{\mathrm{a}} \nabla \eta) = -\nabla \times (\eta \nabla p_{\mathrm{a}}) \tag{45.55}$$

arises from differences in lines of constant atmospheric pressure and lines of constant sea surface height. Such misalignments create a torque akin to the baroclinicity detailed in Section 41.4, with these misalignments driving vertical motion and a corresponding depth integrated meridional flow.

Bottom pressure torque

The term

$$\nabla p'_{\mathrm{b}} \times (-\nabla \eta_{\mathrm{b}}) = \nabla \times (-p'_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) = \nabla \times (\eta_{\mathrm{b}} \nabla p'_{\mathrm{b}}) \tag{45.56}$$

arises from differences in lines of constant bottom pressure and lines of constant bottom topography. That is, bottom pressure torque requires a gradient of bottom pressure along isobaths, thus producing a bottom geostrophic flow that deviates from isobaths. As for the atmospheric pressure torques, such misalignments create a torque that drives a depth integrated meridional flow, with this term vanishing when the bottom topography is flat. In many cases with strong flow next to sloping bottoms, this term can contribute more to the vorticity budget than the turbulent bottom stress. Indeed, in some cases it can rival contributions from the surface wind stress. We sketched out such cases for the shallow water when discussing western boundary currents in Section 40.7.5.

Surface frictional acceleration

The term

$$\hat{\boldsymbol{z}} \cdot (\nabla \eta \times \boldsymbol{F}_{\eta}) = \hat{\boldsymbol{z}} \cdot [\nabla \eta \times \partial_z \boldsymbol{\tau}_{\eta}] \tag{45.57}$$

arises from evaluating the vertical divergence of the frictional stress at the sea surface. A finite volume boundary layer treatment of this term prompts us to integrate the stress divergence over the extent of the surface Ekman layer to render the alternative expression

$$\hat{\boldsymbol{z}} \cdot \int_{-h_{\text{e-surf}}}^{\eta} [\nabla \eta \times \partial_z \boldsymbol{\tau}] \, \mathrm{d}z = \hat{\boldsymbol{z}} \cdot [\nabla \eta \times \boldsymbol{\tau}(\eta)], \tag{45.58}$$

where we assumed $\boldsymbol{\tau}$ is negligible at the base of the surface Ekman layer, $z = -h_{\text{e-surf}}(x, y, t)$. The term $\hat{\boldsymbol{z}} \cdot [\nabla \eta \times \boldsymbol{\tau}(\eta)]$ creates a torque from that component of the surface turbulent stress that is aligned with isolines of the sea surface height.

Bottom frictional acceleration

The term

$$\hat{\boldsymbol{z}} \cdot (-\nabla \eta_{\mathrm{b}} \times \boldsymbol{F}_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot \left[-\nabla \eta_{\mathrm{b}} \times \frac{\partial \boldsymbol{\tau}_{\mathrm{b}}}{\partial z} \right] \tag{45.59}$$

arises from evaluating the vertical divergence of the frictional stress at the ocean bottom. As for the analogous term for the surface, we offer a finite volume Ekman boundary layer treatment to render the alternative expression

$$\hat{\boldsymbol{z}} \cdot \int_{\eta_{\mathrm{b}}}^{h_{\text{e-bot}}} \left[-\nabla \eta_{\mathrm{b}} \times \frac{\partial \boldsymbol{\tau}}{\partial z} \right] \mathrm{d}z = \hat{\boldsymbol{z}} \cdot [-\nabla \eta_{\mathrm{b}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}})], \tag{45.60}$$

where we assumed $\boldsymbol{\tau}$ is negligible at the top of the bottom Ekman layer, $z = -\eta_{\mathrm{b}} + h_{\text{e-bot}}$. The term $\hat{\boldsymbol{z}} \cdot [-\nabla \eta_{\mathrm{b}} \times \boldsymbol{\tau}(\eta_{\mathrm{b}})]$ creates a torque from that component of the bottom turbulent stress that

is aligned with isobaths.

45.4.5 Integral constraints

The atmospheric and bottom pressure torques appearing in the depth integrated planetary vorticity balance (45.54) satisfy an integral constraint that follows from Stokes' curl theorem. To illustrate this constraint, consider the bottom pressure torque integrated over an arbitrary area along the bottom

$$\int (\nabla\eta_{\mathrm{b}} \times \nabla p'_{\mathrm{b}}) \cdot \hat{\boldsymbol{z}}\, \mathrm{d}A = \int [\nabla \times (\eta_{\mathrm{b}}\, \nabla p'_{\mathrm{b}})] \cdot \hat{\boldsymbol{z}}\, \mathrm{d}A \tag{45.61a}$$

$$= \oint \eta_{\mathrm{b}}\, \nabla p'_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s \tag{45.61b}$$

$$= -\oint p'_{\mathrm{b}}\, \nabla \eta_{\mathrm{b}} \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s. \tag{45.61c}$$

We see that the bottom pressure torque vanishes when integrated around a closed loop that follows either an isobath or a bottom isobar, since the integrand vanishes identically. A similar constraint holds for the atmospheric pressure torque, whereas there is generally no analogous constraint satisfied by the turbulent boundary stresses.

One exception for the turbulent stresses occurs for f-plane flow ($\beta = 0$) where the depth integrated flow is non-divergent

$$\partial_t \eta - Q_{\mathrm{m}}/\rho_0 = -\nabla \cdot \boldsymbol{U} = 0, \tag{45.62}$$

and where the interior friction vanishes at the surface and bottom boundaries, $\boldsymbol{F}_\eta = \boldsymbol{F}_{\mathrm{b}} = 0$. From equation (45.54), we see that a steady state is realized only if there is a balance between pressure torques and turbulent boundary stresses

$$\hat{\boldsymbol{z}} \cdot (\nabla\eta \times \nabla p_{\mathrm{a}} - \nabla\eta_{\mathrm{b}} \times \nabla p'_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot (\nabla \times \Delta\boldsymbol{\tau}). \tag{45.63}$$

Consider even further specialization in which the atmospheric pressure torque vanishes, and the bottom turbulent stress is negligible, in which case a steady state balance requires a balance between bottom pressure torques and torques from surface turbulent wind stress

$$-\hat{\boldsymbol{z}} \cdot (\nabla\eta_{\mathrm{b}} \times \nabla p'_{\mathrm{b}}) = \hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)]. \tag{45.64}$$

Integration over either an isobath or bottom pressure isobar then requires, for a steady state, the following identity

$$\int [\nabla \times \boldsymbol{\tau}(\eta)] \cdot \hat{\boldsymbol{z}}\, \mathrm{d}A = \oint \boldsymbol{\tau}(\eta) \cdot \hat{\boldsymbol{t}}\, \mathrm{d}s = 0 \quad f\text{-plane closed isobath or closed isobar.} \tag{45.65}$$

Deviation from this identity leads to non-steady flow on the f-plane. In contrast, the β-plane has no such steady state constraint since meridional flow can balance the circulation imparted by turbulent wind stresses.

45.5 Sverdrup balance and geostrophic Sverdrup balance

The balance (45.54) exposes the many processes that affect meridional flow in a planetary geostrophic fluid. However, when confronted with minimal information from ocean measurements, we are mo-

tivated to examine just the main contributors to this balance.

The *Sverdrup balance* is a very simplified form of the balance (45.54), and it was first encountered in Section 32.5.5

$$\rho_0 \, \beta \, V_{\text{Sverdrup}} = \hat{\boldsymbol{z}} \cdot [\nabla \times \boldsymbol{\tau}(\eta)] \qquad \text{Sverdrup balance.} \tag{45.66}$$

This balance arises from dropping the vertical velocity at both the ocean surface and ocean bottom; ignoring horizontal frictional stresses; and assuming $\partial_t \eta = -Q_{\text{m}}/\rho_0 = 0$ as per a rigid lid flow in which $\nabla \cdot \boldsymbol{U} = 0$. The Sverdrup balance offers a null hypothesis for the large-scale and low frequency meridional ocean circulation away from sloping sides; i.e., in regions where bottom pressure torques can be ignored.

To derive the Sverdrup balance (45.66), we performed a depth integral of the planetary geostrophic vorticity equation (45.33) from the ocean bottom to the free surface. This integral encompasses both the geostrophic interior and the ageostrophic Ekman flow in the top and bottom Ekman layers. In some treatments we focus exclusively on contributions from the geostrophic interior, in which case the depth integral extends from the top of the bottom Ekman layer, $z = \eta_{\text{eb}}$, to the bottom of the top Ekman layer, $z = \eta_{\text{et}}$, thus leading to the depth integrated geostrophic transport

$$V_{\text{g}} \equiv \int_{\eta_{\text{eb}}}^{\eta_{\text{et}}} v \, \text{d}z. \tag{45.67}$$

Integrating the planetary geostrophic vorticity balance (45.33) over this depth range, and ignoring contributions from friction since we are concerned just with the geostrophic interior, leads to

$$\rho_0 \, \beta \, V_{\text{g}} = f \, [w(\eta_{\text{et}}) - w(\eta_{\text{eb}})]. \tag{45.68}$$

This equation provides a balance between the depth integrated meridional transport within the geostrophic interior (left hand side), with the vertical vortex stretching within this depth range (right hand side).

We now make use of the Ekman theory from Chapter 34 to approximate the vertical velocities in equation (45.68). For this purpose we neglect both the time tendency for the vertical position of the Ekman layer and the slope of the Ekman layer, in which case the kinematic identity (34.37), applied at the Ekman base, $z = \eta_{\text{e}}(x, y, t)$, is approximated by

$$w^{(\dot{\eta}_{\text{e}})} = w - (\partial_t z + \boldsymbol{u} \cdot \nabla z) \approx w \qquad \text{at} \;\; z = \eta_{\text{e}}(x, y, t), \tag{45.69}$$

where $z = \eta_{\text{e}}$ is ths vertical position of the Ekman layer. We now make use of the Ekman layer mass budgets to determine the entrainment velocity, $w^{(\dot{\eta}_{\text{e}})}$. In particular, equation (34.44) is used for $w(\eta_{\text{et}})$ to give

$$w(\eta_{\text{et}}) \approx w^{(\dot{\eta}_{\text{e}})}_{\text{Ekman-top}} = (1/\rho_0) \, \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}(\eta)/f)]. \tag{45.70}$$

with a similar treatment for the bottom leading to

$$w(\eta_{\text{eb}}) \approx w^{(\dot{\eta}_{\text{e}})}_{\text{Ekman-bot}} = (1/\rho_0) f \, \hat{\boldsymbol{z}} \cdot [\nabla \times (\boldsymbol{\tau}(\eta_{\text{b}})/f)]. \tag{45.71}$$

Bringing these results into equation (45.68) leads to

$$\rho_0 \, \beta \, V_{\text{g}} = f \, \hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}(\eta)/f - \boldsymbol{\tau}(\eta_{\text{b}})/f]. \tag{45.72}$$

Since the bottom turbulent stress is generally much smaller than the surface, it is typically ignored,

in which case we reach the *geostrophic Sverdrup balance*

$$\rho_0 \, \beta \, V_{\mathrm{g}} = f \, \hat{\boldsymbol{z}} \cdot \nabla \times [\boldsymbol{\tau}(\eta)/f] \qquad \text{geostrophic Sverdrup balance.} \tag{45.73}$$

The geostrophic Sverdrup balance relates the meridional geostrophic transport to the curl of $\boldsymbol{\tau}/f$ due to upper ocean mechanical stresses from boundary processes; i.e., wind stress and ice-ocean stresses. It is differs from the full Sverdrup balance in equation (45.66) by the presence of the f outside of the curl and $1/f$ inside the curl. *Gray and Riser* (2014) assess the geostrophic Sverdrup balance based on ocean measurements.

45.6 Vorticity of the depth integrated velocity

In Section 45.4 we studied the depth integrated vorticity budget for planetary geostrophic flow. We were led to see how boundary torques (i.e., the curl of boundary forces) lead to vertical motion and in turn, through the β-effect, lead to meridional motion of the depth integrated flow. In this section we present another analysis of vorticity in the planetary geostrophic regime, here focusing on vorticity of the depth integrated velocity. Elements of this material were discussed in Section 41.9 without making the planetary geostrophic assumption. By assuming planetary geostrophy we can further constrain the flow by focusing just on vortex stretching.

45.6.1 Depth integrated velocity equation

The depth integrated horizontal velocity equation (45.5a) is given by

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{U} = - \int_{\eta_{\mathrm{b}}}^{\eta} \nabla_z p \, \mathrm{d}z + \Delta \boldsymbol{\tau} \tag{45.74}$$

where

$$\boldsymbol{U} = \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \tag{45.75}$$

is the depth integrated horizontal velocity, and we assumed friction in the form of the vertical divergence of a horizontal turbulent stress as in equation (45.32). For the depth integrated pressure gradient, we follow the decomposition in Section 29.4.4 by writing

$$\int_{\eta_{\mathrm{b}}}^{\eta} p \, \mathrm{d}z = \int_{\eta_{\mathrm{b}}}^{\eta} [\mathrm{d}(p \, z) - z \, \mathrm{d}p] = p_{\mathrm{a}} \, \eta - p_{\mathrm{b}} \, \eta_{\mathrm{b}} + \mathscr{P}, \tag{45.76}$$

where we used the hydrostatic balance to write $\mathrm{d}p = -g \, \rho \, \mathrm{d}z$, which is valid for each fluid column. We also introduced the potential energy per horizontal area of a fluid column

$$\mathscr{P} = \int_{\eta_{\mathrm{b}}}^{\eta} g \, \rho \, z \, \mathrm{d}z = (g \, \rho_0/2) \, (\eta^2 - \eta_{\mathrm{b}}^2) + \int_{\eta_{\mathrm{b}}}^{\eta} g \, \rho' \, z \, \mathrm{d}z, \tag{45.77}$$

where

$$\rho' = \rho - \rho_0 \tag{45.78}$$

is the density deviation from the background reference density. These results then lead to the depth integrated horizontal pressure gradient

$$\int_{\eta_b}^{\eta} \nabla_z p \, dz = \nabla_z \left[\int_{\eta_b}^{\eta} p \, dz \right] - p_a \nabla_z \eta + p_b \nabla_z \eta_b \tag{45.79a}$$

$$= \nabla_z \left[p_a \, \eta - p_b \, \eta_b + \mathscr{P} \right] - p_a \nabla_z \eta + p_b \nabla_z \eta_b \tag{45.79b}$$

$$= \eta \nabla_z p_a - \eta_b \nabla_z p_b + \nabla_z \mathscr{P}, \tag{45.79c}$$

$$= \eta \nabla p_a - \eta_b \nabla p_b + \nabla \mathscr{P}, \tag{45.79d}$$

where the final equality follows since p_a, η_b, p_b, and $\mathscr{P}$, are functions just of horizontal position and time. We are thus led to the depth integrated planetary geostrophic momentum balance

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{U} = -\eta \, \nabla p_a + \eta_b \nabla p_b - \nabla \mathscr{P} + \Delta \boldsymbol{\tau}. \tag{45.80}$$

The depth integrated balance is here written in terms of gradients in the surface and bottom pressures, the gradient of the potential energy per area, and the difference in turbulent stresses at the top and bottom boundaries, $\Delta \boldsymbol{\tau} = \boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_b)$.

45.6.2 Vorticity budget

Taking the curl of the depth integrated balance (45.80) annihilates the potential energy term, thus leaving

$$\rho_0 \, \beta \, V = -\rho_0 \, f \, \nabla \cdot \boldsymbol{U} + \hat{\boldsymbol{z}} \cdot \nabla \times [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)]. \tag{45.81}$$

From Section 22.8, we know that the divergence of the depth-integrated flow for a steady Boussinesq fluid is given by

$$\rho_0 \nabla \cdot \boldsymbol{U} = Q_m, \tag{45.82}$$

so that

$$\rho_0 \, \beta \, V = -f \, Q_m + \hat{\boldsymbol{z}} \cdot \nabla \times [p_a \nabla \eta + \boldsymbol{\tau}(\eta) - p_b \nabla \eta_b - \boldsymbol{\tau}(\eta_b)]. \tag{45.83}$$

This is the vorticity equation for the depth integrated planetary geostrophic fluid. It is quite similar to the vorticity balance for a shallow water fluid as given by equation (40.101) (which considered zero atmospheric pressure). In the presence of β, meridional mass transport for the fluid column is balanced by surface mass fluxes, $Q_m \neq 0$; the curl of surface form stresses and surface turbulent stresses; and the curl of topographic form stresses and bottom turbulent stresses. This result follows quite naturally when recognizing that the forces acting on a depth integrated fluid column arise from the depth integrated stresses acting on the column sides plus those acting on the top and bottom boundaries. In the absence of interior friction stresses due to horizontal strains (as assumed here), it is only the depth integrated pressure that acts on the column sides, and this term has zero curl. We are thus left just with the curl of the surface and bottom boundary form stresses and turbulent stresses, along with a contribution from boundary mass transport.

The Sverdrup balance (45.66) is a special case of the more complete vorticity budget (45.81). Furthermore, the *topographic Sverdrup balance* results when meridional transport balances the curl of the wind plus bottom pressure form stress

$$\rho_0 \, \beta \, V_{\text{topo-Sverdrup}} = \hat{\boldsymbol{z}} \cdot \nabla \times (\boldsymbol{\tau}(\eta) - p_b \nabla \eta_b) \qquad \text{topographic Sverdrup balance.} \tag{45.84}$$

In the presence of flows interacting with topography, where bottom pressure torques are sizable, this balance is generally much more accurate than the Sverdrup balance.

45.6.3 Integral balances for steady flows

Following the discussion in Section 41.9.5, we write the vorticity balance (45.81) in the form

$$\rho_0 \, \nabla \cdot (f \, \boldsymbol{U}) = \hat{\boldsymbol{z}} \cdot \nabla \times [p_{\mathrm{a}} \nabla \eta + \boldsymbol{\tau}(\eta) - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} - \boldsymbol{\tau}(\eta_{\mathrm{b}})]. \tag{45.85}$$

Integrating over a horizontal area, $\mathcal{S}$, leads to

$$\rho_0 \oint_{\partial \mathcal{S}} f \, \boldsymbol{U} \cdot \hat{\boldsymbol{n}} \, \mathrm{d}s = \oint_{\partial \mathcal{S}} [p_{\mathrm{a}} \nabla \eta + \boldsymbol{\tau}(\eta) - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} - \boldsymbol{\tau}(\eta_{\mathrm{b}})] \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s. \tag{45.86}$$

To reach this result we used Gauss's divergence theorem for the left hand side and Stokes' curl theorem for the right hand side. The unit vector $\hat{\boldsymbol{n}}$ points horizontally outward from the boundary of the area, whereas the unit vector $\hat{\boldsymbol{t}}$ is the counter-clockwise oriented tangent to the closed contour around the boundary. For the special case of $Q_{\mathrm{m}} = 0$ we are afforded a steady state streamfunction for the depth-integrate flow since $\nabla \cdot \boldsymbol{U} = 0$. Choosing the area, $\mathcal{S}$, to be bounded by a closed streamline allows us to set $\boldsymbol{U} \cdot \hat{\boldsymbol{n}} = 0$ along that streamline. We thus see that for steady planetary geostrophic flow with $\nabla \cdot \boldsymbol{U} = 0$, any closed streamline of the flow must maintain the following work balance around the streamline

$$\oint_{\partial \mathcal{S}} [p_{\mathrm{a}} \nabla \eta + \boldsymbol{\tau}(\eta) - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}} - \boldsymbol{\tau}(\eta_{\mathrm{b}})] \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = 0. \tag{45.87}$$

This equation is a simplified form of equation (41.204) that was formulated for a more general flow. We can rearrange equation (45.87) to display an integrated balance between the work done by boundary pressure form stresses around a closed streamline, and work done by boundary turbulent stresses around the same streamline

$$\oint_{\partial \mathcal{S}} (p_{\mathrm{a}} \nabla \eta - p_{\mathrm{b}} \nabla \eta_{\mathrm{b}}) \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = - \oint_{\partial \mathcal{S}} [\boldsymbol{\tau}(\eta) - \boldsymbol{\tau}(\eta_{\mathrm{b}})] \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s. \tag{45.88}$$

45.6.4 Comments

Yeager (2015) connects torques acting on the depth integrated horizontal flow in the North Atlantic to buoyancy forces affecting the Atlantic meridional overturning circulation, thus illustrating how the formulation in this section can be of use for the analysis of an ocean circulation model.

45.7 Vorticity equation for the depth averaged velocity

In some numerical models, it is more common to have access to the depth averaged velocity

$$\overline{\boldsymbol{u}} = \frac{1}{D} \int_{\eta_{\mathrm{b}}}^{\eta} \boldsymbol{u} \, \mathrm{d}z \qquad \text{with} \qquad D = \eta - \eta_{\mathrm{b}}. \tag{45.89}$$

We thus find it useful to develop a budget for the vorticity of the depth averaged velocity. In this discussion we encounter a distinct means for describing how bottom topography, in the presence of baroclinicity, generates meridional flow.

45.7.1 Relating the depth average velocity to boundary velocities

Before studying the vorticity equation, we here relate the depth averaged velocity, $\overline{\boldsymbol{u}}(x, y, t)$, to the surface velocity, $\boldsymbol{u}(x, y, z = \eta, t)$, and bottom velocity, $\boldsymbol{u}(x, y, z = \eta_{\mathrm{b}}, t)$. This analysis exposes some general features of how the boundary flows are driven away from the depth average.

The starting point is the identity

$$\int_{\eta_\mathrm{b}}^{\eta} \boldsymbol{u}\,\mathrm{d}z = (\eta-\eta_\mathrm{b})\,\boldsymbol{u}(\eta) - \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z}\,(z-\eta_\mathrm{b})\,\mathrm{d}z, \tag{45.90}$$

which, along with the analogous identity for the bottom flow, leads to

$$\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta) = -\int_{\eta_\mathrm{b}}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z}\left[\frac{z-\eta_\mathrm{b}}{\eta-\eta_\mathrm{b}}\right]\mathrm{d}z \qquad \text{and} \qquad \overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_\mathrm{b}) = \int_{\eta_\mathrm{b}}^{\eta} \frac{\partial \boldsymbol{u}}{\partial z}\left[\frac{\eta-z}{\eta-\eta_\mathrm{b}}\right]\mathrm{d}z. \tag{45.91}$$

Note that $\boldsymbol{u}(\eta) - \boldsymbol{u}(\eta_\mathrm{b}) = \int_{\eta_\mathrm{b}}^{\eta} (\partial \boldsymbol{u}/\partial z)\,\mathrm{d}z$ serves as a useful check on the manipulations leading to equation (45.91). We see that the difference between the depth averaged flow and the surface flow, $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)$, is determined by the integral of the weighted vertical shear, with the weight linearly decreasing from unity at the surface to zero at the bottom. The minus sign in front of the integral for $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)$ follows because if the flow increases in the positive direction from the bottom to the surface, then the depth averaged flow will have a smaller magnitude than the surface flow. The converse weighting holds for computing the difference $\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_\mathrm{b})$.

The identities (45.91) hold for arbitrary horizontal velocity fields. Assuming the flow satisfies frictional geostrophy as per equation (45.5a) leads to the frictional thermal wind relation

$$f\,\boldsymbol{u} = \rho_0^{-1}\,\hat{\boldsymbol{z}} \times \nabla p - \hat{\boldsymbol{z}} \times \boldsymbol{F} \Longrightarrow f\,\partial_z \boldsymbol{u} = -(g/\rho_0)\,\hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}, \tag{45.92}$$

so that the velocity differences are given by

$$f\,[\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta)] = \int_{\eta_\mathrm{b}}^{\eta} [(g/\rho_0)\,\hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}]\left[\frac{z-\eta_\mathrm{b}}{\eta-\eta_\mathrm{b}}\right]\mathrm{d}z \tag{45.93a}$$

$$f\,[\overline{\boldsymbol{u}} - \boldsymbol{u}(\eta_\mathrm{b})] = -\int_{\eta_\mathrm{b}}^{\eta} [(g/\rho_0)\,\hat{\boldsymbol{z}} \times \nabla \rho - \hat{\boldsymbol{z}} \times \partial_z \boldsymbol{F}]\left[\frac{\eta-z}{\eta-\eta_\mathrm{b}}\right]\mathrm{d}z. \tag{45.93b}$$

Hence, differences between the depth averaged flow and the boundary flows are determined by weighted integrals of the baroclinicity and vertical friction shears.

45.7.2 Formulation of the vorticity equation

To develop the vorticity equation, we start by deriving the momentum equation for the depth averaged flow. For that purpose, rearrange the depth integrated momentum budget (45.80) according to

$$\rho_0\,f\,\hat{\boldsymbol{z}} \times \boldsymbol{U} = -\eta\,\nabla_z(p_\mathrm{a} - p_\mathrm{b}) - D\,\nabla p_\mathrm{b} - \nabla \mathscr{P} + \Delta \boldsymbol{\tau}, \tag{45.94}$$

and then divide by the column thickness, $D = \eta - \eta_\mathrm{b}$, to render

$$\rho_0\,f\,\hat{\boldsymbol{z}} \times \overline{\boldsymbol{u}} = -(\eta/D)\,\nabla(p_\mathrm{a} - p_\mathrm{b}) - \nabla p_\mathrm{b} + (1/D)\,(-\nabla \mathscr{P} + \Delta \boldsymbol{\tau}). \tag{45.95}$$

Taking the curl then leads to

$$\rho_0\,\nabla \cdot (f\,\overline{\boldsymbol{u}}) = -\hat{\boldsymbol{z}} \cdot \nabla \times [(\eta/D)\,\nabla(p_\mathrm{a} - p_\mathrm{b})] + D^{-2}\,\hat{\boldsymbol{z}} \cdot [\nabla \times (D\,\nabla \mathscr{P})] + \hat{\boldsymbol{z}} \cdot [\nabla \times (D^{-1}\,\Delta \boldsymbol{\tau})] \tag{45.96a}$$

$$= \hat{\boldsymbol{z}} \cdot \nabla \times [(p_\mathrm{a} - p_\mathrm{b})\,\nabla(\eta/D)] - D^{-2}\,\hat{\boldsymbol{z}} \cdot [\nabla \times (\mathscr{P}\,\nabla D)] + \hat{\boldsymbol{z}} \cdot [\nabla \times (D^{-1}\,\Delta \boldsymbol{\tau})]. \tag{45.96b}$$

The vorticity budget (45.96) is a bit less tidy than that for the depth integrated budget (45.83).

Nonetheless, it offers some novel insights concerning the flow, which can be seen by writing the left hand side in the form

$$\nabla \cdot (f\,\overline{\boldsymbol{u}}) = \nabla \cdot [(f/D)\,\boldsymbol{U}], \tag{45.97}$$

with f/D reminiscient of the shallow water potential vorticity for the planetary geostrophic flow (Section 44.4). Motivated by this analog, we write the vorticity equation (45.96) in the form

$$\rho_0\,\boldsymbol{U}\cdot\nabla(f/D) = -\rho_0\,(f/D)\,\nabla\cdot\boldsymbol{U} + \hat{\boldsymbol{z}}\cdot\nabla\times[(p_{\mathrm{a}}-p_{\mathrm{b}})\,\nabla(\eta/D)] \\ - D^{-2}\,\hat{\boldsymbol{z}}\cdot[\nabla\times(\mathscr{P}\,\nabla D)] + \hat{\boldsymbol{z}}\cdot[\nabla\times(D^{-1}\,\Delta\boldsymbol{\tau})]. \tag{45.98}$$

Contrary to the shallow water case, we here see that even for a perfect planetary geostrophic fluid, the depth-integrated flow does not generally follow contours of constant f/D. Even so, it is of interest to examine how the processes on the right hand side contribute to flow deviations from f/D contours. For that purpose we simplify the flow even more by making the rigid lid approximation.

45.7.3 Rigid lid approximation and the role of JEBAR

The rigid lid approximation is commonly made for studies of large-scale circulation. Indeed, it was the basis for many ocean general circulation models following the work of *Bryan* (1969). A fluid satisfying the rigid lid approximation has a vanishing horizontal divergence for the depth integrated flow

$$\text{rigid lid approximation} \Longrightarrow \nabla\cdot\boldsymbol{U} = 0. \tag{45.99}$$

Furthermore, as part of the rigid lid approximation we assume the free surface undulations are much smaller than the resting ocean depth so that

$$|\eta| \ll |\eta_{\mathrm{b}}| \Longrightarrow \eta/D \approx 0 \tag{45.100a}$$

$$1/(\eta-\eta_{\mathrm{b}}) \approx 1/(-\eta_{\mathrm{b}}) = 1/\mathtt{H}. \tag{45.100b}$$

We introduced

$$\mathtt{H} = -\eta_{\mathrm{b}} \tag{45.101}$$

to correspond to the literature for rigid lid models and the JEBAR term.[7] Hence, with the rigid lid approximation the vorticity equation (45.98) takes the simplified form

$$\boldsymbol{U}\cdot\nabla(f/\mathtt{H}) = \rho_0^{-1}\,\hat{\boldsymbol{z}}\cdot[\nabla\times(\mathscr{P}\,\nabla\mathtt{H}^{-1}) + \nabla\times(\mathtt{H}^{-1}\,\Delta\boldsymbol{\tau})]. \tag{45.102}$$

Each term in this equation has dimensions of inverse squared time, T^{-2}.

JEBAR drives deviations from $f/\mathtt{H}$ aligned flow

The first term on the right hand side of the vorticity equation (45.102) is referred to as the Joint Effect of Baroclinicity and Relief (JEBAR)

$$\text{JEBAR} \equiv \rho_0^{-1}\,\hat{\boldsymbol{z}}\cdot[\nabla\times(\mathscr{P}\,\nabla\mathtt{H}^{-1})] = \rho_0^{-1}\,\hat{\boldsymbol{z}}\cdot[\nabla\mathscr{P}\times\nabla\mathtt{H}^{-1}]. \tag{45.103}$$

This name arises since JEBAR is nonzero only in the presence of non-flat topography ("relief") and (as shown below) when density is not a constant (i.e., for baroclinic flow). In addition to contributions from boundary stresses, equation (45.102) says that misalignment of $f/\mathtt{H}$ contours

[7] Note that H is the vertical depth scale, which is a constant, and it is distinct from $\mathtt{H}(x,y) = -\eta_{\mathrm{b}}(x,y)$, which is a function of horizontal position.

with the depth-integrated steady rigid lid flow is driven by misalignments of isobaths and isolines of the depth integrated potential energy.

Contributions to JEBAR arise only from the component of the potential energy that deviates from a constant density reference state. To show that property, note that in the rigid lid approximation, the potential energy in a column, as given by equation (45.77), takes the form

$$\mathscr{P} = (1/2)\, g\, \rho_0\, \mathtt{H}^2 + g \int_{-\mathtt{H}}^{0} \rho'\, z\, \mathrm{d}z, \tag{45.104}$$

where $\rho' = \rho - \rho_0$. With $\nabla \mathtt{H}^2 \times \nabla(1/\mathtt{H}) = 0$, we are left with just the contribution from ρ'

$$\text{JEBAR} = \rho_0^{-1}\, \hat{\boldsymbol{z}} \cdot \left[\nabla \left(g \int_{-\mathtt{H}}^{0} \rho'\, z\, \mathrm{d}z \right) \times \nabla \mathtt{H}^{-1} \right]. \tag{45.105}$$

JEBAR vanishes for a homogeneous density field, where ρ' is a constant, but is nonzero with a nonzero ρ'. In a Boussinesq ocean, a nonzero ρ' is associated with baroclinicity (Figure 41.10).

Relating JEBAR to pressure

JEBAR as given by equation (45.103) has the appearance of the curl of a form stress, and yet it is not. The reason is that $\mathscr{P}$ is the potential energy of the fluid column rather than bottom pressure. We make this point explicit by recalling the decomposition (45.76), here specialized to the rigid lid in which

$$\mathscr{P} = \mathtt{H}\, (\overline{p} - p_{\mathrm{b}}) \qquad \text{with} \qquad \overline{p} = \mathtt{H}^{-1} \int_{-\mathtt{H}}^{0} p\, \mathrm{d}z = (-\eta_{\mathrm{b}})^{-1} \int_{\eta_{\mathrm{b}}}^{0} p\, \mathrm{d}z. \tag{45.106}$$

Plugging into the vorticity equation (45.102) leads to

$$\rho_0\, \boldsymbol{U} \cdot \nabla(f/\mathtt{H}) = \mathtt{H}^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_{\mathrm{b}})] + \hat{\boldsymbol{z}} \cdot \nabla \times (\mathtt{H}^{-1}\, \Delta \boldsymbol{\tau})]. \tag{45.107}$$

Evidently, JEBAR is nonzero where the depth averaged pressure deviates from the bottom pressure

$$\text{JEBAR} = \rho_0^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathscr{P} \times \nabla \mathtt{H}^{-1})] = (\rho_0\, \mathtt{H})^{-1}\, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_{\mathrm{b}})]. \tag{45.108}$$

We can go one more step in exposing the pressure difference through use of equation (45.91), here applied to hydrostatic pressure, in which case (remember that $\mathtt{H} = -\eta_{\mathrm{b}}$)

$$\overline{p} - p_{\mathrm{b}} = \int_{\eta_{\mathrm{b}}}^{0} \frac{\partial p}{\partial z} \frac{z}{\eta_{\mathrm{b}}}\, \mathrm{d}z = (g/\mathtt{H}) \int_{-\mathtt{H}}^{0} z\, \rho\, \mathrm{d}z = \mathtt{H}^{-1}\, \mathscr{P}, \tag{45.109}$$

so that[8]

$$\nabla_z(\overline{p} - p_{\mathrm{b}}) = -g\, \rho(z = -\mathtt{H})\, \nabla_z \mathtt{H} + g \int_{-\mathtt{H}}^{0} \nabla_z(\rho\, z/\mathtt{H})\, \mathrm{d}z. \tag{45.110}$$

The first term arises from slopes in the bottom topography as weighted by the bottom density, whereas the second term arises from the integral of horizontal gradients in the $z/\mathtt{H}$ weighted density.

Alternatively, we can introduce a geostrophic velocity associated with the gradient of the

[8] We reintroduced the notation, ∇_z, given the presence of z and $\rho(z)$ in the integral in equation (45.110).

bottom pressure as well as the vertically averaged pressure

$$\rho_0 \, f \, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{gb}} = -\nabla p_{\mathrm{b}} \quad \text{and} \quad \rho_0 \, f \, \hat{\boldsymbol{z}} \times \overline{\boldsymbol{u}_{\mathrm{g}}} = -\nabla \overline{p} \Longrightarrow \nabla(\overline{p} - p_{\mathrm{b}}) = \rho_0 \, f \, \hat{\boldsymbol{z}} \times (\boldsymbol{u}_{\mathrm{gb}} - \overline{\boldsymbol{u}_{\mathrm{g}}}). \tag{45.111}$$

Doing so brings JEBAR from equation (45.108) into the form

$$\mathrm{JEBAR} = (\rho_0 \, \mathtt{H})^{-1} \, \hat{\boldsymbol{z}} \cdot [\nabla \mathtt{H} \times \nabla(\overline{p} - p_{\mathrm{b}})] = -f \, \mathtt{H}^{-1} \, \nabla \mathtt{H} \cdot (\overline{\boldsymbol{u}_{\mathrm{g}}} - \boldsymbol{u}_{\mathrm{gb}}). \tag{45.112}$$

JEBAR thus arises from a nonzero projection onto the bottom slope of the difference between the geostrophic velocity arising from the bottom pressure and the geostrophic velocity arising from the depth averaged pressure.

Equation (45.83) provides the budget for vorticity of the depth integrated flow, in which we find the curl of the topographic form stress leads to vortex stretching. For the vorticity of the depth averaged flow, we instead encounter the JEBAR term in equation (45.107), which is not a pure vortex stretching term. Instead, it accounts for the fact that it is the horizontal velocity flowing across isobaths, $\boldsymbol{u}(z = \eta_{\mathrm{b}})$, rather than depth averaged horizontal velocity, $\overline{\boldsymbol{u}}$, that leads to vortex stretching. Hence, when studying vorticity of the depth averaged velocity, $\overline{\boldsymbol{u}}$, accounting for the role of vortex stretching requires us to include JEBAR.

Integral balances

Since the depth integrated flow is assumed to be non-divergent in the rigid lid approximation, $\nabla \cdot \boldsymbol{U} = 0$, we know there exists a streamfunction for this flow. Consider a region where there are closed streamlines. Following the steps in Section (45.6.3), we integrate the steady vorticity equation (45.102) around the streamline. Noting that $\boldsymbol{U} \cdot \hat{\boldsymbol{n}} = 0$ along the streamline, where $\hat{\boldsymbol{n}}$ is the horizontal unit normal to the streamline, thus renders the steady balance

$$\oint_{\partial \mathcal{S}_{\mathrm{streamline}}} (\mathscr{P} \, \nabla \mathtt{H}^{-1} + \mathtt{H}^{-1} \, \Delta \boldsymbol{\tau}) \cdot \hat{\boldsymbol{t}} \, \mathrm{d}s = 0. \tag{45.113}$$

45.7.4 Further study

Mertz and Wright (1992) discuss the physics of how JEBAR relates to the curl of the topographic form stress as well as other mathematically equivalent forms. *Cane et al.* (1998) as well as Section 2.5 of *Drijfhout et al.* (2013) discusses how JEBAR can be physically misleading. For this reason, recent studies of vorticity budgets in ocean models generally eschew JEBAR, instead favoring an analysis of vorticity of the depth integrated flow as in Section 45.6 or the depth integrated vorticity from Section 45.4. *Waldman and Giordani* (2023) provide a review of vorticity analysis for the ocean.

Chapter 46

Foundations of quasi-geostrophy

Quasi-geostrophy (QG) is the canonical *balanced model* in geophysical fluid mechanics whereby the quasi-geostrophic potential vorticity is the sole prognostic field. All other fields, such as the velocity and buoyancy, are diagnosed from potential vorticity. The process of diagnosing the allied fields requires solving an elliptic boundary value problem to compute the geostrophic streamfunction with potential vorticity acting as the source. This connection between potential vorticity and streamfunction represents an *invertibility* principle, with the mathematical technology required for inversion shared with many other elliptic problems in mathematical physics.[1]

Quasi-geostrophy is an elegant theory of mathematical physics that offers physical and mathematical insights into the workings of geophysical fluid motions where rotation and stratification play leading roles. Our goal in this chapter is to provide a taste of its continuously stratified realization, offering a detailed derivation that builds from Chapters 44 and 45. We also sample some of its physical and mathematical content.

CHAPTER GUIDE

In this chapter we extend to continuously stratified fluids the shallow water discussion of quasi-geostrophy in Chapter 44. Continuously stratified quasi-geostrophy is not concerned with the processes that affect stratification, but instead with the processes that slightly perturb that stratification. We make use of stratified geophysical fluid dynamics from Chapters 25 and 32, as well as potential vorticity from Chapter 42. This chapter is essential for the study of baroclinic instability in Chapter 58.

46.2 Quasi-geostrophic potential vorticity

In deriving the quasi-geostrophic potential vorticity equation, we proceed much like for the single layer of shallow water fluid in Section 44.5. In particular, quasi-geostrophic scaling from Section 44.5.1 is relevant for both the shallow water and for the continuously stratified fluid. We employ an asymptotic expansion in the Rossby number and stop at the first nontrivial order, which (as for the shallow water) is Ro^1. For this purpose, recall the non-dimensional momentum and continuity equations from Section 44.7.8

$$\mathrm{Ro}\left[\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}\cdot\widehat{\nabla}_{\widehat{z}})\,\widehat{\boldsymbol{u}} + \widehat{w}\frac{\partial \widehat{\boldsymbol{u}}}{\partial \widehat{z}}\right] + \widehat{\boldsymbol{f}}\times\widehat{\boldsymbol{u}} = -\widehat{\nabla}_z\,\widehat{\varphi} \tag{46.1a}$$

$$\frac{\partial \widehat{\varphi}}{\partial \widehat{z}} = \widehat{b} \tag{46.1b}$$

$$\widehat{\nabla}\cdot\widehat{\boldsymbol{v}} = 0 \tag{46.1c}$$

$$\frac{\mathrm{Ro}}{\mathrm{Bu}}\frac{\mathrm{D}\widehat{b}}{\mathrm{D}\widehat{t}} + \widehat{w} = 0. \tag{46.1d}$$

We expand all fields in an asymptotic series in Rossby number

$$\widehat{u} = \widehat{u}_0 + \mathrm{Ro}\,\widehat{u}_1 + \mathrm{Ro}^2\,\widehat{u}_2 + \ldots \tag{46.2a}$$

$$\widehat{v} = \widehat{v}_0 + \mathrm{Ro}\,\widehat{v}_1 + \mathrm{Ro}^2\,\widehat{v}_2 + \ldots \tag{46.2b}$$

$$\widehat{w} = \widehat{w}_0 + \mathrm{Ro}\,\widehat{w}_1 + \mathrm{Ro}^2\,\widehat{w}_2 + \ldots \tag{46.2c}$$

$$\widehat{b} = \widehat{b}_0 + \mathrm{Ro}\,\widehat{b}_1 + \mathrm{Ro}^2\,\widehat{b}_2 + \ldots \tag{46.2d}$$

$$\widehat{\varphi} = \widehat{\varphi}_0 + \mathrm{Ro}\,\widehat{\varphi}_1 + \mathrm{Ro}^2\,\widehat{\varphi}_2 + \ldots \tag{46.2e}$$

along with the expansion (44.55) for the Coriolis parameter

$$\widehat{f} = \widehat{f}_0 + \mathrm{Ro}\,\widehat{\beta}\,\widehat{y}, \tag{46.3}$$

and where (equation (44.56))

$$\widehat{\beta}\,\widehat{y} = \frac{\beta\, y}{\mathrm{Ro}\, f_0} = T\,\beta\, y. \tag{46.4}$$

As noted in Section 44.5.2, the velocity field is non-divergent at each order of Rossby number, so that

$$\nabla \cdot \widehat{\boldsymbol{v}}_n = 0 \quad \forall\, n. \tag{46.5}$$

The Burger number is order unity since the horizontal length scales of the flow considered here are on the order of the deformation radius

$$\mathrm{Bu} \sim 1 \Longrightarrow L \sim L_{\mathrm{d}}, \tag{46.6}$$

where we introduced the *internal deformation radius* from Section 44.7.6

$$L_{\mathrm{d}}(z) = H\,[N(z)/f_0]. \tag{46.7}$$

It is important to retain the depth dependence of the Burger number through its dependence on the background stratification $N^2(z)$

$$\mathrm{Bu}(z) = \left[\frac{L_{\mathrm{d}}}{L}\right]^2 = N^2(z)\left[\frac{H}{L\, f_0}\right]^2, \tag{46.8}$$

which motivates the name *Burger function* for continuously stratified quasi-geostrophy. Importantly, the Burger function does not commute with the vertical derivative operator.

46.2.1 Zeroth order asymptotic equations

The zeroth order asymptotic equations are

$$\widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\, \widehat{\varphi}_0 \tag{46.9a}$$

$$\frac{\partial \widehat{\varphi}_0}{\partial \widehat{z}} = \widehat{b}_0 \tag{46.9b}$$

$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_0 + \frac{\partial \widehat{w}_0}{\partial \widehat{z}} = 0 \tag{46.9c}$$

$$\widehat{w}_0 = 0. \tag{46.9d}$$

The first equation represents f-plane geostrophy, which means that the horizontal velocity has zero divergence

$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_0 = 0. \tag{46.10}$$

Equation (46.9b) means the zeroth order buoyancy determines the zeroth order hydrostatic pressure. Since the horizontal velocity has zero divergence, the continuity equation (46.9c) means that the vertical velocity is depth independent

$$\frac{\partial \widehat{w}_0}{\partial \widehat{z}} = 0. \tag{46.11}$$

If it vanishes somewhere, such as a solid horizontal bottom boundary, then it vanishes everywhere. This is a manifestation of the Taylor-Proudman theorem (see Section 32.5.3). Indeed, a vanishing

$\widehat{w}_0$ is required by the zeroth-order buoyancy equation (46.9d) even if the bottom is not flat. Hence, the non-dimensional velocity has a nonzero contribution only at order Ro^1

$$\widehat{w} = \mathrm{Ro}\,\widehat{w}_1 + \mathrm{Ro}^2\,\widehat{w}_2 + \ldots, \tag{46.12}$$

thus manifesting the vertical stiffening of fluid columns found in rotating fluids. Correspondingly, the dimensionful vertical velocity has the asymptotic expansion

$$w = W\widehat{w} = W\,\mathrm{Ro}\,(\widehat{w}_1 + \mathrm{Ro}\,\widehat{w}_2 + \ldots), \tag{46.13}$$

so that to leading to order Ro^1

$$\widehat{w}_1 = \frac{w}{W\,\mathrm{Ro}}. \tag{46.14}$$

Since the zeroth-order horizontal velocity is non-divergent, we can introduce a geostrophic streamfunction

$$\widehat{u}_0 = -\partial\widehat{\psi}_0/\partial\widehat{y} \qquad \text{and} \qquad \widehat{v}_0 = \partial\widehat{\psi}_0/\partial\widehat{x} \qquad \text{and} \qquad \widehat{\zeta}_0 = \widehat{\nabla}^2\widehat{\psi}_0, \tag{46.15}$$

where the zeroth-order streamfunction is the ratio of the zeroth order pressure to zeroth order Coriolis parameter

$$\widehat{\psi}_0 = \widehat{\varphi}_0/\widehat{f}_0. \tag{46.16}$$

Note also that the zeroth-order system satisfies the thermal wind balance

$$\widehat{\boldsymbol{f}}_0 \times \frac{\partial\widehat{\boldsymbol{u}}_0}{\partial\widehat{z}} = -\widehat{\nabla}_z\,\widehat{b}_0. \tag{46.17}$$

Finally, note that the zeroth order buoyancy is determined by the streamfunction through the hydrostatic balance

$$\widehat{b}_0 = \frac{\partial\widehat{\varphi}_0}{\partial\widehat{z}} = \widehat{f}_0\,\frac{\partial\widehat{\psi}_0}{\partial\widehat{z}}. \tag{46.18}$$

46.2.2 First order asymptotic equations

The zeroth order equations do not render a prognostic equation, for which we need to consider equations at order Ro^1

$$\frac{\mathrm{D}_0\widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + \widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_1 + \widehat{\beta}\,\widehat{y}\,\widehat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\widehat{\varphi}_1 \tag{46.19a}$$

$$\frac{\partial\widehat{\varphi}_1}{\partial\widehat{z}} = \widehat{b}_1 \tag{46.19b}$$

$$\widehat{\nabla}_z \cdot \widehat{\boldsymbol{u}}_1 + \frac{\partial\widehat{w}_1}{\partial\widehat{z}} = 0 \tag{46.19c}$$

$$\frac{1}{\mathrm{Bu}}\frac{\mathrm{D}_0\widehat{b}_0}{\mathrm{D}\widehat{t}} + \widehat{w}_1 = 0. \tag{46.19d}$$

The first order terms are often referred to as the *ageostrophic* components, though note that all contributions higher than zeroth order constitute ageostrophic contributions.

At order Ro^1, the material time derivative makes use *only* of the zeroth order horizontal geostrophic velocity

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}} = \frac{\partial}{\partial\widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}. \tag{46.20}$$

To close this set of equations, we produce the vorticity equation from the momentum equation,

and then combine the vorticity equation and buoyancy equation to produce the quasi-geostrophic potential vorticity equation. In Section 44.5, we performed the same procedure for deriving the shallow water quasi-geostrophic equations.

Taking the curl of the momentum equation (46.19a) eliminates the pressure gradient, $\widehat{\nabla}\widehat{\varphi}_1$, thus producing the vorticity equation

$$\frac{\partial \widehat{\zeta}_0}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = -\widehat{f}_0\,\widehat{\nabla}_z \cdot \boldsymbol{u}_1. \tag{46.21}$$

We make use of the continuity equation (46.19c) to eliminate the horizontal convergence

$$\frac{\partial \widehat{\zeta}_0}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = \widehat{f}_0\,\frac{\partial \widehat{w}_1}{\partial \widehat{z}}. \tag{46.22}$$

The right hand side represents the contribution to vorticity evolution from stretching by the ageostrophic vertical velocity acting in a rotating reference frame. We can eliminate the ageostrophic vertical velocity through use of the buoyancy equation (46.19d). When doing so, it is important to keep the depth dependence of the Burger function, $\mathrm{Bu}(z)$, according to equation (46.8), with this depth dependence arising from the prescribed background stratification, $N^2(z)$. The resulting vorticity equation is

$$\frac{\partial \widehat{\zeta}_0}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla})\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) = -\widehat{f}_0\,\frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\,\frac{\mathrm{D}_0 \widehat{b}_0}{\mathrm{D}\widehat{t}}\right]. \tag{46.23}$$

We now use the identity

$$\frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\,\frac{\mathrm{D}_0 \widehat{b}_0}{\mathrm{D}\widehat{t}}\right] = \frac{\partial}{\partial \widehat{z}}\left[\frac{1}{\mathrm{Bu}}\left(\frac{\partial}{\partial \widehat{t}} + \widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}\right)\widehat{b}_0\right] \tag{46.24a}$$

$$= \frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right] + \frac{1}{\mathrm{Bu}}\,\frac{\partial \widehat{\boldsymbol{u}}_0}{\partial \widehat{z}} \cdot \widehat{\nabla}_z \widehat{b}_0 \tag{46.24b}$$

$$= \frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right], \tag{46.24c}$$

where we set

$$\frac{\partial \widehat{\boldsymbol{u}}_0}{\partial \widehat{z}} \cdot \widehat{\nabla}_z \widehat{b}_0 = 0 \tag{46.25}$$

since the zeroth-order velocity maintains thermal wind balance (46.17). Bringing terms together then leads to the material conservation equation for quasi-geostrophic potential vorticity

$$\frac{\mathrm{D}_0}{\mathrm{D}\widehat{t}}\left[\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\,\frac{\partial}{\partial \widehat{z}}\left(\frac{\widehat{b}_0}{\mathrm{Bu}}\right)\right] = 0. \tag{46.26}$$

46.3 Reintroducing physical dimensions

To expose the physical elements to the quasi-geostrophic theory, we find it useful, if not essential, to reintroduce physical dimensions as we did for shallow water quasi-geostrophy in Section 44.6.

For that purpose, we write

$$\boldsymbol{u} \equiv \boldsymbol{u}_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{ag}} = U\,(\widehat{\boldsymbol{u}}_0 + \mathrm{Ro}\,\widehat{\boldsymbol{u}}_1) \tag{46.27a}$$

$$w \equiv w_{\mathrm{ag}} = \mathrm{Ro}\,W\,\widehat{w}_1 \tag{46.27b}$$

$$b \equiv b_{\mathrm{g}} + b_{\mathrm{ag}} = B\,(\widehat{b}_0 + \mathrm{Ro}\,\widehat{b}_1) \tag{46.27c}$$

$$\varphi \equiv \varphi_{\mathrm{g}} + \varphi_{\mathrm{ag}} = f_0\,U\,L\,(\widehat{\varphi}_0 + \mathrm{Ro}\,\widehat{\varphi}_1). \tag{46.27d}$$

The details of reintroducing dimensions are straightforward but can be tedious. We provide details to help develop experience working with the equtaions of quasi-geostrophy.

46.3.1 Hydrostatic balance

Hydrostatic balance is maintained for terms at each Rossby number order, so that we have the dimensional equations

$$\frac{\partial \varphi_{\mathrm{g}}}{\partial z} = b_{\mathrm{g}} \quad \text{and} \quad \frac{\partial \varphi_{\mathrm{ag}}}{\partial z} = b_{\mathrm{ag}}. \tag{46.28}$$

46.3.2 Geostrophic balance

The non-dimensional geostrophic balance for the zeroth order fields

$$\widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z\,\widehat{\varphi}_0 \tag{46.29}$$

takes on the dimensional form

$$\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}}/U = -L\,\nabla_z\,\varphi_{\mathrm{g}}/(f_0\,U\,L). \tag{46.30}$$

Canceling factors leads to the expected form of f-plane geostrophy

$$f_0\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\nabla_z\,\varphi_{\mathrm{g}}. \tag{46.31}$$

46.3.3 Material time derivative

For the material time derivative operator we write

$$\begin{aligned}
\mathrm{D}/\mathrm{D}t &= \partial_t + \boldsymbol{u}\cdot\nabla + w\,\partial_z && (46.32\mathrm{a})\\
&= (1/T)\,\partial_{\widehat{t}} + (U/L)\,\widehat{\boldsymbol{u}}\cdot\widehat{\nabla} + (W/H)\,\widehat{w}\,\partial_{\widehat{z}} && (46.32\mathrm{b})\\
&= (1/T)\,(\partial_{\widehat{t}} + \widehat{\boldsymbol{u}}\cdot\widehat{\nabla} + \widehat{w}\,\partial_{\widehat{z}}) && (46.32\mathrm{c})\\
&= (1/T)\,(\partial_{\widehat{t}} + \widehat{\boldsymbol{u}}_0\cdot\widehat{\nabla}_z) + (\mathrm{Ro}/T)\,(\widehat{\boldsymbol{u}}_0\cdot\widehat{\nabla}_z + \widehat{w}_1\,\partial_{\widehat{z}}) && (46.32\mathrm{d})\\
&= \partial_t + \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_z + \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_z + w_{\mathrm{ag}}\,\partial_z && (46.32\mathrm{e})\\
&\equiv \mathrm{D}_{\mathrm{g}}/\mathrm{D}t + \boldsymbol{u}_{\mathrm{ag}}\cdot\nabla_z + w_{\mathrm{ag}}\partial_z, && (46.32\mathrm{f})
\end{aligned}$$

where time scales according to advection, $T = L/U$, vertical velocity scales according to continuity, $W = H\,U/L$, and we introduced the geostrophic material time derivative operator

$$\mathrm{D}_{\mathrm{g}}/\mathrm{D}t \equiv \partial_t + \boldsymbol{u}_{\mathrm{g}}\cdot\nabla_z. \tag{46.33}$$

46.3.4 Buoyancy equation

The buoyancy equation requires a bit more work. For that purpose, we split buoyancy into a depth dependent static background and a deviation from the background

$$b = \tilde{b}(z) + b'(x, y, z, t), \tag{46.34}$$

with its vertical derivative

$$\partial_z b = \mathrm{d}\tilde{b}/\mathrm{d}z + \partial_z b' = N^2 + \partial_z b', \tag{46.35}$$

where $N^2(z)$ is the squared buoyancy frequency for the prescribed background buoyancy field. In this manner, we can write the buoyancy equation for an adiabatic fluid as

$$\frac{\partial b'}{\partial t} + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z b') = 0. \tag{46.36}$$

We non-dimensionalize this equation by making use of the following relations between the scales

$$B = f_0\, U\, L/H \qquad W = H\,(U/L) \qquad \mathrm{Ro} = U/(f_o\, L) \qquad \mathrm{Bu} = (N\, H)^2/(f_0\, L)^2, \tag{46.37}$$

in which case the buoyancy equation takes the form

$$\frac{\partial b'}{\partial t} + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z b') = \frac{B}{T}\,\frac{\partial \widehat{b}}{\partial \widehat{t}} + \frac{U\,B}{L}\,\widehat{\boldsymbol{u}} \cdot \widehat{\nabla}_z \widehat{b} + W\,\widehat{w}\,N^2 + \frac{W\,B}{H}\,\widehat{w}\,\partial_{\widehat{z}} \widehat{b} = 0. \tag{46.38}$$

We find it useful to divide by $f_0\, N^2$, so that

$$\frac{1}{f_0\, N^2}\left[\frac{\partial b'}{\partial t} + \boldsymbol{u} \cdot \nabla b' + w\,(N^2 + \partial_z\, b')\right] = \frac{H\,\mathrm{Ro}^2}{\mathrm{Bu}}\left[\frac{\partial \widehat{b}}{\partial \widehat{t}} + \widehat{\boldsymbol{u}} \cdot \widehat{\nabla} \widehat{b} + \widehat{w}\,\partial_{\widehat{z}} \widehat{b}\right] + \mathrm{Ro}\,\widehat{w} = 0. \tag{46.39}$$

The vertical velocity component, $\widehat{w}$, is nonzero only at order Ro^1, so the term $\mathrm{Ro}\,\widehat{w}$ is order Ro^2 (recall equation (46.27b)). For the material time derivative term, we drop the vertical velocity term, $\widehat{w}\,\partial_{\widehat{z}} \widehat{b}$, since it is order Ro^1 smaller than the other terms in the material time operator. We thus retain only the zeroth order buoyancy contribution, $\widehat{b}_0$. Reintroducing physical dimensions then leads to the dimensional form of the quasi-geostrophic buoyancy equation

$$\partial_t b_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z b_{\mathrm{g}} + w_{\mathrm{ag}}\, N^2 = \frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} + w_{\mathrm{ag}}\, N^2 = 0. \tag{46.40}$$

This equation means that the geostrophic transport of the geostrophic buoyancy is affected by a source due to the ageostrophic vertical advection of background buoyancy

$$\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = -w_{\mathrm{ag}}\, N^2 \quad \text{with} \quad b_{\mathrm{g}} = f_0\, \partial_z \psi. \tag{46.41}$$

46.3.5 Vorticity equation

Reintroducing dimensions to the vorticity equation (46.22) yields[2]

$$\frac{\partial \widehat{\zeta}_0}{\partial \widehat{t}} + (\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}_z)\,(\widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y}) - \widehat{f}_0\,\frac{\partial \widehat{w}_1}{\partial \widehat{z}} = T^2\left[\frac{\partial \zeta}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z(\zeta + \beta\, y)\right] - \frac{H}{W\,\mathrm{Ro}}\,\frac{\partial w_{\mathrm{ag}}}{\partial z}. \tag{46.42}$$

[2]Recall from equation (46.27b) that $W\,\widehat{w} = \mathrm{Ro}\,W\,\widehat{w}_1 = w_{\mathrm{ag}}$.

The identity $H/(W\,\mathrm{Ro}) = f_0\,T^2$ leads to the order Ro^1 vorticity equation

$$\frac{\partial \zeta_{\mathrm{a}}}{\partial t} + J(\psi, \zeta_{\mathrm{a}}) = f_0\,\frac{\partial w_{\mathrm{ag}}}{\partial z}, \tag{46.43}$$

with the absolute vorticity given by the sum of the geostrophic relative vorticity plus the planetary beta contribution

$$\zeta_{\mathrm{a}} = \zeta_{\mathrm{g}} + \beta\,y. \tag{46.44}$$

Hence, the absolute geostrophic vorticity is advected by the geostrophic flow, and it has a source (right hand side of equation (46.43)) due to vertical stretching by the ageostrophic flow. Expanding the Jacobian and introducing the geostrophic velocity, $\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla\psi$, leads to the geostrophic relative vorticity equation

$$\frac{\partial \zeta_{\mathrm{g}}}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z \zeta_{\mathrm{g}} = -\beta\,v_{\mathrm{g}} + f_0 \frac{\partial w_{\mathrm{ag}}}{\partial z}. \tag{46.45}$$

We thus see that the beta effect from the geostrophic flow, plus vertical stretching by the ageostrophic flow, provide local sources for geostrophic relative vorticity.

46.3.6 Velocity equation

The prognostic velocity equation arises from the first order asymptotic equation (46.19a)

$$\frac{\mathrm{D}_0 \widehat{\boldsymbol{u}}_0}{\mathrm{D}\widehat{t}} + \widehat{\boldsymbol{f}}_0 \times \widehat{\boldsymbol{u}}_1 + \widehat{\beta}\,\widehat{y}\,\hat{\boldsymbol{z}} \times \widehat{\boldsymbol{u}}_0 = -\widehat{\nabla}_z \widehat{\varphi}_1. \tag{46.46}$$

Our skills with reintroducing dimensional quantities should be sufficient to write down the dimensional velocity equation by inspection[3]

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\,\boldsymbol{u}_{\mathrm{g}} + \beta\,y\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} + f_0\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{ag}} = -\nabla_z\,\varphi_{\mathrm{ag}}. \tag{46.47}$$

We can also choose to add the geostrophic balanced flow that holds at order Ro^0, $f_0\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} = -\nabla_z\,\varphi_{\mathrm{g}}$, so to have the equivalent equation

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\,\boldsymbol{u}_{\mathrm{g}} + \beta\,y\,\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{g}} + f_0\,\hat{\boldsymbol{z}} \times (\boldsymbol{u}_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{ag}}) = -\nabla_z\,(\varphi_{\mathrm{g}} + \varphi_{\mathrm{ag}}). \tag{46.48}$$

46.3.7 Potential vorticity

From equation (46.26), we identify the non-dimensional quasi-geostrophic potential vorticity

$$\widehat{q} = \widehat{\zeta}_0 + \widehat{\beta}\,\widehat{y} + \widehat{f}_0\,\frac{\partial(\widehat{b}_0/\mathrm{Bu})}{\partial \widehat{z}}. \tag{46.49}$$

Introducing dimensional quantities to the right hand side yields[4]

$$\widehat{q} = \frac{L}{U}\,[\zeta_{\mathrm{g}} + \beta\,y] + \frac{\partial}{\partial z}\left[\frac{H\,b_{\mathrm{g}}}{B\,\mathrm{Bu}}\right] \tag{46.50a}$$

$$= (1/(f_0\,\mathrm{Ro})\,(\zeta_{\mathrm{g}} + \beta\,y) + \frac{H}{B}\,\frac{\partial}{\partial z}\left[\frac{b_{\mathrm{g}}}{\mathrm{Bu}}\right]. \tag{46.50b}$$

[3]Recall from equation (46.27d) that $\varphi_{\mathrm{ag}} = f_0\,U\,L\,\mathrm{Ro}\,\widehat{\varphi}_1 = U^2\,\widehat{\varphi}_1$.

[4]Recall $\widehat{f}_0 = 1$ and $\widehat{\beta}\,\widehat{y} = T\,\beta\,y = (L/U)\,\beta\,y$.

The scale for the fluctuating buoyancy is given by equation (44.142), $B = f_0 \, U \, L/H$, and the inverse Burger function is given by equation (46.8), $\mathrm{Bu}^{-1} = [(L \, f_0)/(H \, N)]^2$, so that

$$\widehat{q} = (1/(f_0 \, \mathrm{Ro}) \, (\zeta_{\mathrm{g}} + \beta \, y) + \frac{H^2}{f_0 \, U \, L} \, \frac{L^2 \, f_0^2}{H^2} \, \frac{\partial}{\partial z} \left[\frac{b_{\mathrm{g}}}{N^2} \right] \tag{46.51a}$$

$$= (1/(f_0 \, \mathrm{Ro}) \, (\zeta_{\mathrm{g}} + \beta \, y) + \frac{1}{\mathrm{Ro}} \left[\frac{\partial}{\partial z} \left(\frac{b_{\mathrm{g}}}{N^2} \right) \right]. \tag{46.51b}$$

Introducing the geostrophic streamfunction,

$$\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla_z \psi \quad \text{and} \quad \zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}_{\mathrm{g}}) = \nabla_z^2 \psi \quad \text{and} \quad b_{\mathrm{g}} = f_0 \, \partial_z \psi, \tag{46.52}$$

leads to

$$q \equiv f_0 \, \mathrm{Ro} \, \widehat{q} = \beta \, y + \zeta_{\mathrm{g}} + \frac{\partial}{\partial z} \left[\frac{f_0^2}{N^2} \, \frac{\partial \psi}{\partial z} \right]. \tag{46.53}$$

Just as for the shallow water case in Section 44.6.1, the potential vorticity (46.53) scales as $f_0 \, \mathrm{Ro}$. The order Ro scaling is expected since it is only at this order that we realize a prognostic set of equations. We sometimes choose to add the constant f_0 to q, which has no effect on the dynamics but reveals the beta plane planetary vorticity

$$q = \underbrace{f_0 + \beta \, y}_{\text{planetary vorticity}} + \underbrace{\nabla_z^2 \psi}_{\text{relative vorticity}} + \underbrace{\frac{\partial}{\partial z} \left[\frac{f_0^2}{N^2} \, \frac{\partial \psi}{\partial z} \right]}_{\text{stretching by } f}. \tag{46.54}$$

Evidently, there are three contributions to the quasi-geostrophic potential vorticity.

- PLANETARY VORTICITY: The planetary vorticity contribution, $f_0 + \beta \, y$, arises from rotation of the reference frame. As noted above, the $\beta \, y$ term is the only dynamically relevant contribution, so that we can equally well drop the f_0 contribution.

- GEOSTROPHIC RELATIVE VORTICITY: The vertical component of the geostrophic relative vorticity, $\zeta = \hat{\boldsymbol{z}} \cdot (\nabla \times \boldsymbol{u}) = \nabla_z^2 \psi$, acts to bring out the smaller scale features in the streamfunction.

- VERTICAL STRETCHING: The final contribution arises from the vertical stretching in the presence of a rotating planet. Equation (46.22) helps to remind us why this term arises from vortex stretching.

The material evolution of the quasi-geostrophic PV follows the horizontal geostrophic flow

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z) q = 0. \tag{46.55}$$

The material constancy of q represents a balance, following the geostrophic flow, of time changes for the planetary vorticity, relative vorticity, and vertical stretching. This is a remarkable property of quasi-geostrophic flows.

46.3.8 Comments about doubly-periodic QG models

It is notable that we can consider a doubly periodic quasi-geostrophic β-plane model whereby there is periodicity in flow properties in both the zonal and meridional directions. The basic reason is that the value of the Coriolis parameter does not appear in the potential vorticity equation

(46.55). Rather, it is only $\partial_y f = \beta$ that appears. So even though the Coriolis parameter is not meridionally periodic, its actual value has no relevance to the quasi-geostrophic flow.

Furthermore, we can study quasi-geostrophic flows in doubly periodic domains in the presence of certain idealized background flows. Namely, for a prescribed depth-independent thermal wind flow, the corresponding buoyancy that supports this flow plays no role in the quasi-geostrophic potential vorticity. For example, if the buoyancy has the form

$$b = \underbrace{M^2\, y + N^2\, z}_{\text{prescribed background}} + b'(x, y, z, t), \tag{46.56}$$

with M and N constant frequencies, then the corresponding quasi-geostrophic potential vorticity is independent of M. In this manner, the background buoyancy, though not meridionally periodic, prescribes a background thermal wind shear that is constant and so is trivially periodic.

46.4 Quasi-geostrophic PV and Ertel PV

Following our treatment for the shallow water system in Section 44.6.6, we here determine how quasi-geostrophic potential vorticity relates to the Ertel potential vorticity from Chapter 42. For this purpose, consider the continuously stratified hydrostatic Boussinesq fluid and make use of the Ertel potential vorticity derived in Exercise 42.1

$$Q = (\boldsymbol{\omega} + \hat{\boldsymbol{z}}\, f) \cdot \nabla b = \frac{\partial u}{\partial z}\frac{\partial b}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b}{\partial x} + (\zeta + f)\,\frac{\partial b}{\partial z}. \tag{46.57}$$

In a perfect fluid we have the material conservation

$$(\partial_t + \boldsymbol{u} \cdot \nabla_z + w\,\partial_z)\, Q = 0. \tag{46.58}$$

Our strategy in this section is to non-dimensionalize both Q and the material time operator, and then to organize terms in equation (46.58) according to the Rossby number. We then show that material conservation of Ertel potential vorticity, when expanded asymptotically to order Ro^1, leads to the geostrophic material conservation of quasi-geostrophic potential vorticity. The continuous stratification makes the derivation more involved than for the shallow water potential vorticity in Section 44.6.6, prompting us to expose the details.

46.4.1 Non-dimensionalizing the Ertel potential vorticity

As above for the buoyancy, we are led to write the Ertel potential vorticity in the form

$$\frac{Q - f_0\, N^2}{f_0\, N^2} = \frac{1}{f_0\, N^2}\left[\frac{\partial u}{\partial z}\frac{\partial b'}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b'}{\partial x}\right] + \frac{1}{N^2}\,\frac{\partial b'}{\partial z} + \frac{\beta\, y + \zeta}{f_0}\left[1 + \frac{1}{N^2}\,\frac{\partial b'}{\partial z}\right]. \tag{46.59}$$

with non-dimensionalization leading to

$$\frac{1}{f_0\, N^2}\left[\frac{\partial u}{\partial z}\frac{\partial b'}{\partial y} - \frac{\partial v}{\partial z}\frac{\partial b'}{\partial x}\right] = \frac{B\, U}{f_0\, N^2\, H\, L}\left[\frac{\partial \widehat{u}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{y}} - \frac{\partial \widehat{v}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{x}}\right] = \frac{\mathrm{Ro}^2}{\mathrm{Bu}}\left[\frac{\partial \widehat{u}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{y}} - \frac{\partial \widehat{v}}{\partial \widehat{z}}\frac{\partial \widehat{b}}{\partial \widehat{x}}\right] \tag{46.60a}$$

$$\frac{1}{N^2}\,\frac{\partial b'}{\partial z} = \frac{B}{H\, N^2}\,\frac{\partial \widehat{b}}{\partial \widehat{z}} = \frac{\mathrm{Ro}}{\mathrm{Bu}}\,\frac{\partial \widehat{b}}{\partial \widehat{z}} \tag{46.60b}$$

$$\frac{\beta\, y + \zeta}{f_0} = \mathrm{Ro}\,(\widehat{\beta}\,\widehat{y} + \widehat{\zeta}). \tag{46.60c}$$

The order Ro^2 terms appearing in equation (46.60a) are dropped since they do not contribute to the quasi-geostrophic potential vorticity, which involve terms only up to order Ro^1. For the order Ro^1 term, we only retain the zeroth order buoyancy, $\widehat{b}_0 = b_{\mathrm{g}}/B$, and likewise we just retain the zeroth order vorticity, $\widehat{\zeta}_0 = (L/U)\,\zeta_{\mathrm{g}}$. Hence, the Ertel potential vorticity is given by

$$Q = N^2\,(f_0 + q_*) + \mathcal{O}(\mathrm{Ro}^2) \tag{46.61}$$

where q_* is the order Ro^1 term

$$q_* = \mathrm{Ro}\, f_0 \left[\frac{1}{\mathrm{Bu}}\,\frac{\partial \widehat{b}_0}{\partial \widehat{z}} + \widehat{\beta}\,\widehat{y} + \widehat{\zeta}_0\right] = \frac{f_0}{N^2}\,\frac{\partial b_{\mathrm{g}}}{\partial z} + \beta\, y + \zeta_{\mathrm{g}}. \tag{46.62}$$

46.4.2 Material conservation of Ertel PV to order Ro^1

The material conservation of Ertel PV now takes the form

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z + w_{\mathrm{ag}}\,\partial_z)\,(f_0\,N^2 + q_*\,N^2) = f_0\,w_{\mathrm{ag}}\,\partial_z N^2 + N^2\,\mathrm{D}_{\mathrm{g}} q_*/\mathrm{D}t = 0. \tag{46.63a}$$

We dropped the $w_{\mathrm{ag}}\,\partial_z$ contribution to the advection of q_* since ageostrophic vertical advection of q_* is an order Ro^2 term. To eliminate the vertical ageostrophic velocity we make use of the buoyancy equation (46.40) so that

$$\frac{\mathrm{D}_{\mathrm{g}} q_*}{\mathrm{D}t} + \frac{w_{\mathrm{ag}}}{N^2}\,\frac{\partial N^2}{\partial z} = \frac{\mathrm{D}_{\mathrm{g}} q_*}{\mathrm{D}t} - \frac{f_0}{N^4}\,\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t}\,\frac{\partial N^2}{\partial z} = 0. \tag{46.64}$$

Writing

$$\frac{\partial}{\partial z}\left[\frac{1}{N^2}\right] = -\frac{1}{N^4}\,\frac{\partial N^2}{\partial z} \tag{46.65}$$

leads to

$$\frac{\mathrm{D}_{\mathrm{g}} q_*}{\mathrm{D}t} + f_0\left[\frac{\partial N^{-2}}{\partial z}\right]\,\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = 0. \tag{46.66}$$

Since the geostrophic material time derivative operator only involves horizontal advection, we can merge these two terms to render

$$\begin{aligned}
\frac{\mathrm{D}_{\mathrm{g}} q_*}{\mathrm{D}t} + f_0\left[\frac{\partial N^{-2}}{\partial z}\right]\,\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} &= \frac{\mathrm{D}_{\mathrm{g}}}{\mathrm{D}t}\left[q_* + f_0\,b_{\mathrm{g}}\left(\frac{\partial N^{-2}}{\partial z}\right)\right] && (46.67a)\\
&= \frac{\mathrm{D}_{\mathrm{g}}}{\mathrm{D}t}\left[\beta\,y + \zeta + \frac{f_0}{N^2}\left(\frac{\partial b_{\mathrm{g}}}{\partial z}\right) + f_0\,b_{\mathrm{g}}\left(\frac{\partial N^{-2}}{\partial z}\right)\right] && (46.67b)\\
&= \frac{\mathrm{D}_{\mathrm{g}}}{\mathrm{D}t}\left[\beta\,y + \zeta + f_0\,\frac{\partial}{\partial z}\left(\frac{b_{\mathrm{g}}}{N^2}\right)\right] && (46.67c)\\
&= \frac{\mathrm{D}_{\mathrm{g}} q}{\mathrm{D}t} && (46.67d)\\
&= 0. && (46.67e)
\end{aligned}$$

In the penultimate step we introduced the quasi-geostrophic potential vorticity given by equation (46.54)

$$q = \beta\,y + \zeta + f_0\,\frac{\partial}{\partial z}\left[\frac{b_{\mathrm{g}}}{N^2}\right] = q_* + f_0\,b_{\mathrm{g}}\frac{\partial N^{-2}}{\partial z}. \tag{46.68}$$

We have thus established how material conservation of Ertel potential vorticity, when expanded asymptotically to order Ro^1, leads to the geostrophic material conservation of quasi-geostrophic potential vorticity.

46.5 Boundary conditions

We need boundary conditions on the geostrophic streamfunction, ψ, to invert the elliptic quasi-geostrophic PV equation (46.54). For lateral boundaries, it is common to choose periodicity, whereby the boundaries are absent. Alternatively, we may choose to set the normal component of the flow to zero for the inviscid case, in which case ψ is a constant along material boundaries as discussed in Section 22.4.2. The top and bottom boundaries require fundamental considerations that are discussed in this section.

46.5.1 Buoyancy equation

To develop the vertical boundary conditions on the streamfunction, consider the quasi-geostrophic buoyancy equation (46.40)

$$\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}/\mathrm{D}t + w_{\mathrm{ag}}\, N^2 = (\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, b_{\mathrm{g}} + w_{\mathrm{ag}}\, N^2 = 0, \tag{46.69}$$

where the buoyancy is related to the geostrophic streamfunction via

$$b_{\mathrm{g}} = f_0\, \partial_z \psi, \tag{46.70}$$

which leads to the equivalent form of the buoyancy equation

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z)\, (f_0\, \partial_z \psi) + w_{\mathrm{ag}}\, N^2 = 0. \tag{46.71}$$

We now consider how the buoyancy equation appears at the top and bottom boundaries.

46.5.2 Top boundary condition

Assuming the top boundary is a material surface, we are led to the kinematic boundary condition (20.51)

$$w = (\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z)\, \eta. \tag{46.72}$$

How does this vertical velocity compare to that associated with motion in the fluid interior? To answer that question we assume an advective scaling for time derivatives so that the vertical velocity at the free surface scales as

$$w_{\mathrm{surf}} \sim U\, \eta/L \sim U\, p/(\rho_0\, g\, L) \sim U^2\, f_0/g, \tag{46.73}$$

where L is the horizontal length scale, and we scaled the surface pressure gradient according to the free surface gradient. A point in the fluid interior has a vertical velocity that scales according to the buoyancy equation (46.69),

$$w_{\mathrm{interior}} \sim U\, b/(N^2\, L) \sim f_0\, U^2/(H\, N^2), \tag{46.74}$$

where H is the vertical scale over which the thermal wind shear is sizable, and which scales the buoyancy frequency according to

$$N^2 \sim (g/\rho_0)\, \Delta\rho/H, \tag{46.75}$$

where $\Delta\rho \ll \rho_0$ is the scale for the density difference setting the size of the buoyancy frequency. The ratio of the two vertical velocities is thus given by

$$w_{\text{surf}}/w_{\text{interior}} = H\,N^2/g = \Delta\rho/\rho_0 \ll 1. \tag{46.76}$$

Evidently, we can set the surface boundary condition to that of a rigid lid, in which $w_{\text{ag}} = 0$. In this case, the top boundary condition reduces to geostrophic advection of boundary buoyancy

$$(\partial_t + \boldsymbol{u}_{\text{g}} \cdot \nabla_z)\,(f_0\,\partial_z\psi) = (\partial_t + \boldsymbol{u}_{\text{g}} \cdot \nabla_z)\,b_{\text{g}} = 0 \quad \text{at top boundary where } w_{\text{ag}} = 0. \tag{46.77}$$

That is, the geostrophic buoyancy at the surface is a material constant when advected by the surface geostrophic flow.

46.5.3 Bottom boundary condition

With a nonzero slope in the bottom topography, $\nabla\eta_{\text{b}} \neq 0$, the bottom kinematic boundary condition (Section 20.4.1) says that velocity is constrained so that

$$\boldsymbol{v} \cdot \hat{\boldsymbol{n}} = 0 \Longrightarrow w = \boldsymbol{u} \cdot \nabla\eta_{\text{b}}, \tag{46.78}$$

where $\hat{\boldsymbol{n}} = -\nabla(z - \eta_{\text{b}})/|\nabla(z - \eta_{\text{b}})|$ is the boundary's outward normal. Expanding this kinematic boundary condition leads to

$$w_{\text{ag}} = (\boldsymbol{u}_{\text{g}} + \boldsymbol{u}_{\text{ag}}) \cdot \nabla\eta_{\text{b}}, \tag{46.79}$$

which means there is vertical ageostrophic motion at the bottom so long as the horizontal motion is not aligned with isobaths. To be clear on the implications of this boundary condition, it is useful to examine the asymptotics by non-dimensionalizing[5]

$$\boldsymbol{u}_{\text{g}} = U\,\widehat{\boldsymbol{u}}_0 \tag{46.80a}$$

$$w_{\text{ag}} = W\,\text{Ro}\,\widehat{w}_1 \tag{46.80b}$$

$$\boldsymbol{u}_{\text{ag}} = U\,\text{Ro}\,\widehat{\boldsymbol{u}}_1 \tag{46.80c}$$

$$\nabla\eta_{\text{b}} = (\mathcal{B}/L)\,\widehat{\nabla}\widehat{\eta}_{\text{b}} = (H\,\text{Ro}/L)\,\widehat{\nabla}\widehat{\eta}_{\text{b}}, \tag{46.80d}$$

which brings the kinematic boundary condition (46.79) to

$$f_0\,H\,\text{Ro}^2\,(\widehat{\boldsymbol{u}}_0 + \text{Ro}\,\widehat{\boldsymbol{u}}_1) \cdot \widehat{\nabla}\widehat{\eta}_{\text{b}} = W\,\text{Ro}\,\widehat{w}_1 \Longrightarrow (\widehat{\boldsymbol{u}}_0 + \text{Ro}\,\widehat{\boldsymbol{u}}_1) \cdot \widehat{\nabla}\widehat{\eta}_{\text{b}} = \widehat{w}_1. \tag{46.81}$$

Asymptotic consistency implies that

$$\widehat{\boldsymbol{u}}_0 \cdot \widehat{\nabla}\widehat{\eta}_{\text{b}} = \widehat{w}_1 \Longrightarrow \boldsymbol{u}_{\text{g}} \cdot \nabla\eta_{\text{b}} = w_{\text{ag}}. \tag{46.82}$$

Hence, for quasi-geostrophic flow, any projection of the horizontal geostrophic velocity in a direction not aligned with isobaths leads to an ageostrophic vertical velocity at the bottom.

Use of the bottom kinematic boundary condition (46.82) in the buoyancy equation (46.71) leads to the bottom boundary evolution of buoyancy

$$\partial_t(f_0\,\partial_z\psi) + \boldsymbol{u}_{\text{g}} \cdot \nabla_z\left[f_0\,\partial_z\psi + N^2\,\eta_{\text{b}}\right] = 0 \quad \text{at } z = \overline{\eta_{\text{b}}}, \tag{46.83}$$

[5]The bottom topography slope is non-dimensionalized according to the shallow water discussion in Section 44.3.4.

which can be written in terms of the geostrophic buoyancy

$$\partial_t b_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z (b_{\mathrm{g}} + N^2 \, \eta_{\mathrm{b}}) = 0 \quad \text{at } z = \overline{\eta_{\mathrm{b}}}, \tag{46.84}$$

The boundary condition is evaluated at the horizontally averaged bottom positin, $z = \overline{\eta_{\mathrm{b}}}$, since the more precise boundary location, $z = \eta_{\mathrm{b}}(x, y)$, is higher order in Rossby number. Since $N^2 \, \eta_{\mathrm{b}}$ is time independent, the boundary condition (46.84) can be written as a material conservation statement for buoyancy at the bottom

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z)(b_{\mathrm{g}} + N^2 \, \eta_{\mathrm{b}}) = \frac{\mathrm{D}_{\mathrm{g}}(b_{\mathrm{g}} + N^2 \, \eta_{\mathrm{b}})}{\mathrm{D}t} = 0 \quad \text{at } z = \overline{\eta_{\mathrm{b}}}. \tag{46.85}$$

When η_{b} is a constant, and since N^2 is just a function of z, then the bottom boundary condition becomes a statement about the material conservation of buoyancy along the bottom boundary

$$\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = 0 \quad \text{at } z = \overline{\eta_{\mathrm{b}}} = 0, \tag{46.86}$$

which is the bottom analog of the top boundary condition (46.77) that holds when making the rigid lid approximation. The more general case of a nonzero bottom slope renders a source for bottom buoyancy

$$\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = -N^2 \, \boldsymbol{u}_{\mathrm{g}} \cdot \nabla \eta_{\mathrm{b}} = -N^2 \, w_{\mathrm{ag}} \quad \text{at } z = \overline{\eta_{\mathrm{b}}}. \tag{46.87}$$

In this manner we see that a material evolution of bottom buoyancy is associated with vertical ageostrophic flow at the bottom, and correspondingly to horizontal geostrophic flow that deviates from the contours of constant topography.

Finally, since N^2 is a function only of z, this boundary condition can be written in terms of the stretching term appearing in the potential vorticity

$$\frac{\mathrm{D}_{\mathrm{g}}}{\mathrm{D}t} \left[\frac{f_0 \, b_{\mathrm{g}}}{N^2} \right] = -f_0 \, \boldsymbol{u}_{\mathrm{g}} \cdot \nabla \eta_{\mathrm{b}} \quad \text{at } z = \overline{\eta_{\mathrm{b}}}. \tag{46.88}$$

Evidently, material evolution of vertical stretching is coupled to bottom geostrophic flow that crosses lines of constant topography.

46.6 Potential vorticity with Dirac delta sheets

Based on the boundary conditions derived in Section 46.5, we know that quasi-geostrophic theory is comprised of the material conservation of potential vorticity in the interior, along with material evolution of buoyancy at the boundaries, with the material evolution determined by the horizontal geostrophic velocity

$$\frac{\mathrm{D}_{\mathrm{g}} q}{\mathrm{D}t} = 0 \qquad \text{for } \overline{\eta_{\mathrm{b}}} < z < 0 \tag{46.89a}$$

$$\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = 0 \qquad \text{for } z = 0 \tag{46.89b}$$

$$\frac{\mathrm{D}_{\mathrm{g}} b_{\mathrm{g}}}{\mathrm{D}t} = -N^2 \, \boldsymbol{u}_{\mathrm{g}} \cdot \nabla \eta_{\mathrm{b}} \quad \text{for } z = \overline{\eta_{\mathrm{b}}}, \tag{46.89c}$$

FIGURE 46.1: Geometry for the transition layers associated with the Dirac delta sheets at the upper and lower boundaries of the domain.

where the geostrophic velocity, buoyancy, material time derivative, and quasi-geostrophic potential vorticity are written in terms of the geostrophic streamfunction

$$\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla\psi \tag{46.90a}$$

$$b_{\mathrm{g}} = f_0\, \partial_z \psi \tag{46.90b}$$

$$\mathrm{D}_{\mathrm{g}}/\mathrm{D}t = \partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla \tag{46.90c}$$

$$q = f_0 + \beta\, y + \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0^2}{N^2}\frac{\partial \psi}{\partial z}\right] = f_0 + \beta\, y + \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0\, b_{\mathrm{g}}}{N^2}\right]. \tag{46.90d}$$

Studying the dynamics of boundary buoyancy constitutes the focus of *surface quasi-geostrophy*, as exemplified by *Held et al.* (1995) and whose mathematical foundations were examined by *Yassin and Griffies* (2022). In this section we focus on how to understand the transition from the interior to the boundaries. We follow the method of *Bretherton* (1966), where he noted that it can be conceptually convenient to bring the boundary conditions into the potential vorticity, much like when studying Green's functions for elliptic operators as in Chapter 5. In this manner, the boundary and interior terms can be placed on equal footing and thus their contribution to the potential vorticity directly compared.[6]

46.6.1 Transition between the interior and the boundaries

The transition from the interior to the boundary occurs over an infinitesimal region surrounding each boundary. There is a corresponding jump in the buoyancy as it moves from the domain interior to the boundaries. To help understand the nature of the jump it is useful to expand the infinitesimal thickness into a tiny but finite layer whose thickness, $\Delta z = \epsilon$, is later taken to vanish. For notational brevity introduce

$$S = b_{\mathrm{g}}/N^2, \tag{46.91}$$

and, with reference to the geometry in Figure 46.1, the full domain extent of this function is written

$$S^{\mathrm{ext}}(z) = \underbrace{S(\overline{\eta_b} - \epsilon)\, \mathcal{H}(\overline{\eta_b} - \epsilon - z)}_{\text{lower region}} + \underbrace{S(z)\left[\mathcal{H}(z - \overline{\eta_b} - \epsilon) - \mathcal{H}(z + \epsilon)\right]}_{\text{interior region}} + \underbrace{S(\epsilon)\, \mathcal{H}(z - \epsilon)}_{\text{upper region}}, \tag{46.92}$$

[6] See also Section 5.4.3 of *Vallis* (2017) for general comments on this approach.

where $\mathcal{H}$ is the Heaviside step function detailed in Section 5.3.5. Values within the outer edge of the transition regions (i.e., $S(\epsilon)$ and $S(\overline{\eta_\mathrm{b}}-\epsilon)$) are constructs whose values must be set consistent with the boundary conditions (46.89b) and (46.89c). We furthermore choose these values to be static, since we have no way to determine their evolution since they are outside the domain. The upper boundary satisfies the homogeneous boundary condition

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla)b_\mathrm{g} = 0, \tag{46.93}$$

which allows us to set

$$b_\mathrm{g}(\epsilon) = 0. \tag{46.94}$$

Likewise, the lower boundary condition

$$(\partial_t + \boldsymbol{u}_\mathrm{g}\cdot\nabla)b_\mathrm{g} = -N^2\,\boldsymbol{u}_\mathrm{g}\cdot\nabla\eta_\mathrm{b}, \tag{46.95}$$

is consistent with the choice

$$S(\overline{\eta_\mathrm{b}}-\epsilon) = -\eta_\mathrm{b}. \tag{46.96}$$

46.6.2 Calculating the stretching term over the extended domain

Since the derivative of a Heaviside step function yields a Dirac delta (Section 5.3.5), we have

$$\begin{aligned}\partial_z S^\mathrm{ext}(z) = \partial_z S(z)\,[\mathcal{H}(z-\overline{\eta_\mathrm{b}}-\epsilon)-\mathcal{H}(z+\epsilon)] + S(z)\,\delta(z-\overline{\eta_\mathrm{b}}-\epsilon)\\ - S(\overline{\eta_\mathrm{b}}-\epsilon)\,\delta(\overline{\eta_\mathrm{b}}-\epsilon-z) + S(\epsilon)\,\delta(z-\epsilon) - S(z)\,\delta(z+\epsilon),\end{aligned} \tag{46.97}$$

whose $\epsilon\to 0$ limit is

$$\partial_z S^\mathrm{ext}(z) = \partial_z S(z)\,[\mathcal{H}(z-\overline{\eta_\mathrm{b}})-\mathcal{H}(z)] + [S(z)-S(\overline{\eta_\mathrm{b}}-\epsilon)]\,\delta(z-\overline{\eta_\mathrm{b}}) + [S(\epsilon)-S(z)]\,\delta(z). \tag{46.98}$$

Reintroducing the definition of S as per equation (46.91) yields the stretching term contribution to the potential vorticity, nowe defined over the full vertical extent of the domain (i.e., the domain interior and its boundaries)

$$\begin{aligned}\partial_z(f_0\,b_\mathrm{g}/N^2)^\mathrm{ext} = \partial_z(f_0\,b_\mathrm{g}/N^2)\,[\mathcal{H}(z-\overline{\eta_\mathrm{b}})-\mathcal{H}(z)]\\ + \delta(z-\overline{\eta_\mathrm{b}})\left[\frac{f_0\,b_\mathrm{g}}{N^2}\right]_{z=\overline{\eta_\mathrm{b}}^-}^{z=\overline{\eta_\mathrm{b}}^+} + \delta(z)\left[\frac{f_0\,b_\mathrm{g}}{N^2}\right]_{z=0^-}^{z=0^+},\end{aligned} \tag{46.99}$$

where the square bracket terms measure the jump in the stretching term taking place across the respective boundaries. The Heaviside term is nonzero only within the interior of the domain, whereas the two Dirac delta terms fire at their respective boundaries.

46.6.3 The extended potential vorticity

Making use of the extended stretching term (46.99) for the potential vorticity allows us to collapse the three equations (46.89a)-(46.89c) into the single equation valid over the domain interior as well as the domain boundaries

$$\frac{\mathrm{D_g}q^\mathrm{ext}}{\mathrm{D}t} = 0 \quad \text{for } \overline{\eta_\mathrm{b}} \le z \le 0. \tag{46.100}$$

Bringing the above results together leads to the extended potential vorticity[7]

$$q^{\text{ext}} = \underbrace{f_0 + \beta\, y + \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]}_{\text{interior}} + \underbrace{\delta(z)\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=0^-}^{z=0^+} + \delta(z-\overline{\eta_{\text{b}}})\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=\overline{\eta_{\text{b}}}^-}^{z=\overline{\eta_{\text{b}}}^+}}_{\text{boundary contributions}}. \tag{46.101}$$

Note that the Dirac deltas have dimensions of inverse length (see Section 5.3.9), thus making this equation dimensionally consistent. We can make use of the transition region values (46.94) and (46.96) to evaluate the jump conditions

$$\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=0^-}^{z=0^+} = \left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=0} \tag{46.102a}$$

$$\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=\overline{\eta_{\text{b}}}^-}^{z=\overline{\eta_{\text{b}}}^+} = \left[\frac{f_0\, b_{\text{g}}}{N^2}\right]_{z=\overline{\eta_{\text{b}}}} + f_0\, \eta_{\text{b}}, \tag{46.102b}$$

in which case the extended potential vorticity is

$$q^{\text{ext}} = \underbrace{f_0 + \beta\, y + \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]}_{\text{interior}} + \underbrace{\delta(z)\,(f_0\, b_{\text{g}}/N^2) + f_0\, \delta(z-\overline{\eta_{\text{b}}})\,(b_{\text{g}}/N^2 + \eta_{\text{b}})}_{\text{boundary contributions}}. \tag{46.103}$$

For some studies it is useful to ignore the buoyancy contribution at the two boundaries by setting them to zero, in which case the potential vorticity is

$$q^{\text{ext}} = \underbrace{f_0 + \beta\, y + \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0\, b_{\text{g}}}{N^2}\right]}_{\text{interior}} + \underbrace{f_0\, \eta_{\text{b}}\, \delta(z-\overline{\eta_{\text{b}}})}_{\text{bottom topog}}. \tag{46.104}$$

Dropping the boundary buoyancy contributions allows one to focus on contributions from the bottom topography and interior processes, in isolation from the boundary buoyancy.

46.7 Mathematical expressions of the theory

In this section we sample various mathematical expressions of quasi-geostrophic theory.

46.7.1 The Jacobian form of geostropic advection

The geostrophic velocity, as a horizontally non-divergent field, can be written in terms of the quasi-geostrophic streamfunction

$$\boldsymbol{u}_{\text{g}} = \hat{\boldsymbol{z}} \times \nabla \psi. \tag{46.105}$$

[7] We drop the Heaviside terms in equation (46.101) for brevity.

We can thus write the following equivalent forms for the material time derivative of quasi-geostrophic PV

$$\frac{\mathrm{D}q}{\mathrm{D}t} = \frac{\partial q}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla q \tag{46.106a}$$

$$= \frac{\partial q}{\partial t} + (\hat{\boldsymbol{z}} \times \nabla \psi) \cdot \nabla q \tag{46.106b}$$

$$= \frac{\partial q}{\partial t} + (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}} \tag{46.106c}$$

$$= \frac{\partial q}{\partial t} + J(\psi, q). \tag{46.106d}$$

The final equality introduced the Jacobian operator

$$J(\psi, q) = (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}}, \tag{46.107}$$

which is a notation commonly used in the geophysical fluids literature.[8]

For a perfect fluid, in which $\mathrm{D}q/\mathrm{D}t = 0$, a steady state (zero Eulerian time derivative) is realized when

$$\boldsymbol{u}_{\mathrm{g}} \cdot \nabla\, q = (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}} = J(\psi, q) = 0, \tag{46.108}$$

which means that the steady velocity is parallel to surfaces of constant q. We are ensured that these equalities hold if the streamfunction is a function only of the potential vorticity

$$\psi = \psi(q) \Longrightarrow (\nabla \psi \times \nabla q) \cdot \hat{\boldsymbol{z}} = J(\psi, q) = 0. \tag{46.109}$$

As the steady state is of physical interest, this functional relation between streamfunction and potential vorticity commonly arises in applications.

46.7.2 The case of constant background buoyancy frequency

Consider the quasi-geostrophic potential vorticity for the special case of a constant background buoyancy frequency, $N^2 =$ constant, in which the relative potential vorticity (46.53) takes on the form

$$q - \beta\, y = \nabla_z^2 \psi + \frac{\partial}{\partial z}\left[\frac{f_0^2}{N^2}\frac{\partial \psi}{\partial z}\right] \tag{46.110a}$$

$$= \frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{f_0^2}{N^2}\frac{\partial^2 \psi}{\partial z^2} \tag{46.110b}$$

$$= [\partial_{xx} + \partial_{yy} + \partial_{\tilde{z}\tilde{z}}]\psi. \tag{46.110c}$$

For the final equality we introduced the vertical coordinate

$$z = (f/N)\, \tilde{z} \Longleftrightarrow \tilde{z} = (N/f)\, z, \tag{46.111}$$

where f/N is the Prandtl ratio introduced by equation 44.151. Since $|N/f| >> 1$ the stably stratified flows considered in QG, $\tilde{z}$ is a *stretched* vertical coordinate so that the Laplacian operator acting on ψ is anisotropic. The linear operator acting on ψ remains elliptic even in the more general case of a depth dependent stratification, thus warranting the use of elliptical solvers when performing the inversion numerically.

[8] Recall that we also encountered the Jacobian form for horizontally non-divergent two-dimensional advection in Section 39.2.3 when studying the non-divergent barotropic flows.

46.7.3 Potential vorticity induction and impermeability

Outside of boundaries, the potential vorticity equation is the sole prognostic equation required to evolve the quasi-geostrophic flow. Consequently, one often ignores the quasi-geostrophic velocity and buoyancy equations. Even so, we found it useful to use the buoyancy equation in Section 46.3.4 as part of connecting quasi-geostrophic potential vorticity to Ertel potential vorticity. Likewise, there are occasions when it is useful to examine the velocity equation, with a similar discussion provided in Section 44.6.4. In this section we directly connect the velocity and buoyancy equations and then reveal their connection to the potential vorticity equation.

Combining the velocity and buoyancy equations

Consider the quasi-geostrophic velocity and buoyancy equations derived in Section 46.3

$$(\partial_t + \boldsymbol{u}_{\rm g} \cdot \nabla)\boldsymbol{u}_{\rm g} + \hat{\boldsymbol{z}} \times (\beta\, y\, \boldsymbol{u}_{\rm g} + f_0\, \boldsymbol{u}_{\rm ag}) = -\nabla_z\, \varphi_{\rm ag} + \boldsymbol{F} \tag{46.112a}$$

$$(\partial_t + \boldsymbol{u}_{\rm g} \cdot \nabla_z) b_{\rm g} + w_{\rm ag}\, N^2 = \dot{b} \tag{46.112b}$$

$$f_0\, \hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm g} + \nabla_z \varphi_{\rm g} = 0 \tag{46.112c}$$

$$\nabla \cdot \boldsymbol{u}_{\rm g} = \partial_x u_{\rm g} + \partial_y v_{\rm g} = 0 \tag{46.112d}$$

$$\nabla \cdot \boldsymbol{v}_{\rm ag} = \nabla \cdot \boldsymbol{u}_{\rm ag} + \partial_z w_{\rm ag} = 0, \tag{46.112e}$$

where we added a non-conservative force per mass, $\boldsymbol{F}$ (e.g., friction, wind stress), and irreversible buoyancy source, $\dot{b}$ (e.g., diffusion, boundary fluxes). Taking $-\hat{\boldsymbol{z}} \times$ on the velocity equation and multiplying the buoyancy equation by f_0/N^2 leads to

$$(\partial_t + \boldsymbol{u}_{\rm g} \cdot \nabla)(-\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm g}) + \beta\, y\, \boldsymbol{u}_{\rm g} + f_0\, \boldsymbol{u}_{\rm ag} = \hat{\boldsymbol{z}} \times \nabla_z\, \varphi_{\rm ag} - \hat{\boldsymbol{z}} \times \boldsymbol{F} \tag{46.113a}$$

$$(\partial_t + \boldsymbol{u}_{\rm g} \cdot \nabla_z)(f_0\, b_{\rm g}/N^2) + f_0\, w_{\rm ag} = f_0\, \dot{b}/N^2. \tag{46.113b}$$

Introduce the following vector fields

$$\boldsymbol{D} \equiv -\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\rm g} + (f_0/N^2)\, b_{\rm g}\, \hat{\boldsymbol{z}} = \nabla_z \psi + (f_0/N)^2\, \partial_z \psi\, \hat{\boldsymbol{z}} \tag{46.114a}$$

$$\boldsymbol{R} \equiv -\hat{\boldsymbol{z}} \times \boldsymbol{F} + (f_0/N^2)\, \dot{b}\, \hat{\boldsymbol{z}}, \tag{46.114b}$$

with $\boldsymbol{D}$ built from both the velocity and buoyancy fields and $\boldsymbol{R}$ built from the corresponding non-conservative tendencies. These vectors allow us to combine the velocity and buoyancy equations into a single vector equation

$$(\partial_t + \boldsymbol{u}_{\rm g} \cdot \nabla)\, \boldsymbol{D} + \beta\, y\, \boldsymbol{u}_{\rm g} + f_0\, \boldsymbol{v}_{\rm ag} = \hat{\boldsymbol{z}} \times \nabla_z\, \varphi_{\rm ag} + \boldsymbol{R}. \tag{46.115}$$

Potential vorticity induction

The divergence of $\boldsymbol{D}$ yields the relative quasi-geostrophic potential vorticity

$$\nabla \cdot \boldsymbol{D} = q - (f_0 + \beta\, y), \tag{46.116}$$

where we made use of the expression (46.54) for the potential vorticity. In analogy to Gauss's law of electromagnetism, we refer to $\boldsymbol{D}$ as the quasi-geostrophic potential vorticity *induction vector*.[9]

[9] This connection between potential vorticity dynamics and electromagnetism was pointed out by *Schneider et al.* (2003) and further examined by *Maddison and Marshall* (2013).

Additionally, the potential vorticity equation can be written (see Exercise 46.5)

$$(\partial_t + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla)\, q = \nabla \cdot \boldsymbol{R}, \tag{46.117}$$

so that the quasi-geostrophic potential vorticity flux vector

$$\boldsymbol{J}_{\mathrm{q}} = \boldsymbol{u}_{\mathrm{g}}\, q - \boldsymbol{R} \tag{46.118}$$

allows us to write the potential vorticity equation in the Eulerian flux-form

$$\partial_t q = -\nabla \cdot \boldsymbol{J}_{\mathrm{q}}. \tag{46.119}$$

Kinematic PV flux and impermeability

Taking the Eulerian time derivative of the potential vorticity induction equation (46.116) renders

$$\partial_t q = \partial_t(\nabla \cdot \boldsymbol{D}) = \nabla \cdot (\partial_t \boldsymbol{D}) \equiv -\nabla \cdot \boldsymbol{J}_q^{\mathrm{kin}}, \tag{46.120}$$

where we introduced the kinematic form of the potential vorticity flux

$$\boldsymbol{J}_q^{\mathrm{kin}} \equiv -\partial_t \boldsymbol{D} = \boldsymbol{J}_q + \nabla \times \boldsymbol{A}, \tag{46.121}$$

with $\boldsymbol{A}$ a gauge function. This equation is analogous to the kinematic Ertel PV flux discussed in Section 43.2.2. We determine the explicit expression for the gauge function in Exercise 46.6.

46.8 Energetics for quasi-geostrophic flow

Consider a quasi-geostrophic fluid configured with flat upper (rigid lid) and lower boundaries, and assume the lateral boundaries are periodic or material solid boundaries. These restrictive assumptions allow us to more readily study energetics within the fluid, sans the impacts from nontrivial boundary effects. To study energetics we make use of the quasi-geostrophic buoyancy equation (46.40) and relative vorticity equation (46.45)

$$\frac{\partial b}{\partial t} + \boldsymbol{u} \cdot \nabla b = -w\, N^2 \tag{46.122a}$$

$$\frac{\partial \zeta}{\partial t} + \boldsymbol{u} \cdot \nabla \zeta = -\beta\, v + f_0\, \frac{\partial w}{\partial z}, \tag{46.122b}$$

where all labels are dropped from the variables to reduce clutter, and where

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla \qquad b = f_0\, \frac{\partial \psi}{\partial z} \qquad u = -\frac{\partial \psi}{\partial y} \qquad v = \frac{\partial \psi}{\partial x} \qquad \zeta = \nabla_z^2 \psi. \tag{46.123}$$

46.8.1 Kinetic energy

The kinetic energy per mass for the total fluid domain is given by the integral

$$\mathcal{K} = \frac{1}{2} \int \boldsymbol{u} \cdot \boldsymbol{u}\, \mathrm{d}V = \frac{1}{2} \int \nabla_z \psi \cdot \nabla_z \psi\, \mathrm{d}V, \tag{46.124}$$

and its time derivative is

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int \nabla_z \psi \cdot \nabla_z (\partial \psi / \partial t)\, \mathrm{d}V. \tag{46.125}$$

For the kinetic energy time derivative we noted that the fluid domain has a constant volume to allow the time derivative to move inside the integral without introducing boundary terms. Manipulation renders

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int \nabla_z \psi \cdot \nabla_z (\partial \psi / \partial t) \, \mathrm{d}V \tag{46.126a}$$

$$= \int \left[\nabla_z \cdot [\psi \, \nabla_z (\partial \psi / \partial t)] - \psi \, \partial (\nabla_z^2 \psi) / \partial t \right] \mathrm{d}V \tag{46.126b}$$

$$= - \int \psi \, (\partial \zeta / \partial t) \, \mathrm{d}V, \tag{46.126c}$$

where we dropped the lateral boundary term and introduced relative vorticity. Use of the vorticity equation (46.122b) yields

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = - \int \psi \, (\partial \zeta / \partial t) \, \mathrm{d}V = \int \psi \, [\boldsymbol{u} \cdot \nabla_z \zeta + \beta \, v - f_0 \, \partial_z w] \, \mathrm{d}V. \tag{46.127}$$

The first and second terms vanish since

$$\int \psi \, (\boldsymbol{u} \cdot \nabla_z \zeta + \beta \, v) \, \mathrm{d}V = \int \psi \, \boldsymbol{u} \cdot \nabla_z (\zeta + f) \, \mathrm{d}V \tag{46.128a}$$

$$= \int \psi \, \nabla_z \cdot (\boldsymbol{u} \, \zeta_{\mathrm{a}}) \, \mathrm{d}V \tag{46.128b}$$

$$= \int [\nabla_z \cdot (\psi \, \boldsymbol{u} \, \zeta_{\mathrm{a}}) - \nabla_z \psi \cdot \boldsymbol{u} \, \zeta_{\mathrm{a}}] \, \mathrm{d}V = 0. \tag{46.128c}$$

The final equality holds since the boundary term vanishes, and $\boldsymbol{u} \cdot \nabla_z \psi = 0$ since ψ is the streamfunction for the horizontal geostrophic flow. We are thus left with the expression for the kinetic energy evolution

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = - f_0 \int \psi \, \frac{\partial w}{\partial z} \, \mathrm{d}V. \tag{46.129}$$

Since the top and bottom are assumed flat and rigid, the vertical velocity vanishes on these boundaries so that

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = - f_0 \int \psi \, \frac{\partial w}{\partial z} \, \mathrm{d}V = - f_0 \int \left[\frac{\partial (w \, \psi)}{\partial z} - w \, \frac{\partial \psi}{\partial z} \right] \mathrm{d}V = f_0 \int w \, \frac{\partial \psi}{\partial z} \, \mathrm{d}V. \tag{46.130}$$

Introducing the quasi-geostrophic buoyancy through $b = f_0 \, \partial \psi / \partial z$ leads to

$$\frac{\mathrm{d}\mathcal{K}}{\mathrm{d}t} = \int w \, b \, \mathrm{d}V. \tag{46.131}$$

Kinetic energy thus increases when vertical motion is positively correlated with buoyancy. For example, upward motion ($w > 0$) of a positive buoyancy anomaly (relatively light water has $b > 0$) increases kinetic energy, as does downward motion of a negative buoyancy anomaly. This behavior is also reflected in the full fluid system discussed in Section 27.4.

46.8.2 Available potential energy

Available potential energy was introduced in Section 30.9 within the context of the Boussinesq ocean. An approximate form of the APE is given by equation (30.224), which we here write as

$$\mathcal{A}_{\text{bouss}} \approx \frac{1}{2} \int \left[\frac{b}{N} \right]^2 \mathrm{d}V = \frac{1}{2} \int \left[\frac{f_0}{N} \frac{\partial \psi}{\partial z} \right]^2 \mathrm{d}V, \tag{46.132}$$

where we set $b = f_0 \, \partial \psi / \partial z$ for the second equality. Taking a time derivative leads to

$$\frac{\mathrm{d}\mathcal{A}}{\mathrm{d}t} = \int \left[\frac{f_0}{N} \right]^2 \frac{\partial \psi}{\partial z} \frac{\partial}{\partial t} \frac{\partial \psi}{\partial z} \, \mathrm{d}V = \int \frac{f_0}{N^2} \frac{\partial \psi}{\partial z} \left[-w \, N^2 - \nabla_z \cdot (\boldsymbol{u} \, b) \right] \mathrm{d}V, \tag{46.133}$$

where we used the buoyancy equation (46.122a) for the second equality. The second term vanishes since

$$\int \frac{f_0}{N^2} \frac{\partial \psi}{\partial z} \left[\nabla_z \cdot (\boldsymbol{u} \, b) \right] \mathrm{d}V = \int \left[\frac{f_0^2}{N^2} \frac{\partial \psi}{\partial z} \right] \boldsymbol{u} \cdot \nabla_z \left[\frac{\partial \psi}{\partial z} \right] \mathrm{d}V \tag{46.134a}$$

$$= \frac{1}{2} \int \nabla_z \cdot \left[\boldsymbol{u} \left(\frac{f_0}{N} \frac{\partial \psi}{\partial z} \right)^2 \right] \mathrm{d}V \tag{46.134b}$$

$$= 0. \tag{46.134c}$$

Consequently, the quasi-geostrophic APE has a time derivative given by

$$\frac{\mathrm{d}\mathcal{A}}{\mathrm{d}t} = - \int w \, f_0 \frac{\partial \psi}{\partial z} \, \mathrm{d}V = - \int w \, b \, \mathrm{d}V, \tag{46.135}$$

so that the APE evolves oppositely to the kinetic energy.

46.8.3 Exchange of mechanical energy

We refer to the term

$$\text{buoyancy work} = \int w \, f_0 \frac{\partial \psi}{\partial z} \, \mathrm{d}V = \int w \, b \, \mathrm{d}V, \tag{46.136}$$

as the buoyancy work conversion term. It has the same form as that encountered for the conversion between potential energy and kinetic energy in the unapproximated equations studied in Section 27.4.

The evolution of kinetic energy involves the relative vorticity equation, whereas evolution of the APE involves the buoyancy equation. However, their sum remains constant in time. The reason for the exact exchange of energy is that, when the kinetic energy increases through buoyancy work, the available potential energy decreases

$$\frac{\mathrm{d}(\mathcal{K} + \mathcal{A})}{\mathrm{d}t} = 0. \tag{46.137}$$

This is a relatively simple mechanical energy budget equation reminscent of a classical point particle discussed in Section 14.8. In particular, note the absence of a pressure work term that appears in the mechanical energy budget for other fluids such as for the Euler equations (Section 27.4) and Boussinesq ocean (Sections 30.6 and 30.8). We anticipate the absence of pressure work since knowledge of potential vorticity is sufficient to know all quasi-geostrophic dynamical fields, and yet pressure plays no explicit role in potential vorticity evolution.

46.8.4 Scaling APE and KE

The scale for kinetic energy in a quasi-geostrophic flow is given by

$$\mathcal{K} = \frac{1}{2}\int (\nabla_z \psi \cdot \nabla_z \psi)\,\mathrm{d}V \sim L^{-2}\,\Psi^2\,V \tag{46.138}$$

and the scale for the APE is

$$\mathcal{A} = \frac{1}{2}\int \left[\frac{f_0}{N}\frac{\partial \psi}{\partial z}\right]^2 \mathrm{d}V \sim H^{-2}\,(f_0/N)^2 \Psi^2\,V = L_{\mathrm{d}}^{-2}\,\Psi^2\,V, \tag{46.139}$$

where we wrote Ψ for the streamfunction scale, V for the domain volume, and $L_{\mathrm{d}} = H\,(N/f_0)$ is the deformation radius (see equation (46.7)). Taking the ratio yields

$$\frac{\mathcal{K}}{\mathcal{A}} \sim \left[\frac{L_{\mathrm{d}}}{L}\right]^2 = \left[\frac{H}{L}\right]^2 \left[\frac{N}{f_0}\right]^2 = \mathrm{Bu}. \tag{46.140}$$

Hence, the Burger number is the ratio of the scale for quasi-geostrophic kinetic energy to the scale for quasi-geostrophic available potential energy. A large Burger number means that the horizontal scales of the flow are smaller than the deformation radius, in which case the quasi-geostrophic dynamics is dominated by its kinetic energy. In contrast, for scales larger than the deformation radius (not much larger, as then the flow would not satisfy quasi-geostrophic scaling), the Burger number is less than unity, in which case the quasi-geostrophic dynamics is dominated by available potential energy.

46.9 Exercises

EXERCISE 46.1: A VARIETY OF POTENTIAL VORTICITIES

Give the mathematical expressions for dimensionful potential vorticity in the following fluid models. Define all terms in the respective expressions. Give the physical dimensions and/or SI units for the potential vorticity. Hint: the answers can be found somewhere in this book.

(a) Ertel potential vorticity for compressible fluid in a rotating reference frame using potential temperature as the tracer.

(b) Ertel potential vorticity for a Boussinesq ocean in a rotating reference frame using Archimedean buoyancy as the tracer.

(c) Single shallow water layer on a beta plane

(d) Continuously stratified planetary geostrophy

(e) Continously stratified quasi-geostrophy on a beta plane

EXERCISE 46.2: QUASI-GEOSTROPHIC PV EVOLUTION WITH VERTICAL FRICTION

The first part of this exercise involves elements of the asymptotic method used for deriving the quasi-geostrophic equations, only now with the advent of a non-zero friction. Use is made to incorporate the non-dimensionalization detailed in Section 34.1, which provides a detailed discussion of the Ekman number and Ekman layers. The second part of this exercise makes use of

the thermal wind balance to connect horizontal buoyancy transfer to the vertical viscous transfer of horizontal momentum.

(a) Derive the material evolution equation for quasi-geostrophic potential vorticity in a continuously stratified Boussinesq fluid in the presence of friction, $\boldsymbol{F}$. Assume the Ekman number is on the order of the Rossby number, so that the zeroth order asymptotic solution satisfies the usual inviscid f-plane geostrophic balance. Friction only appears in the first order equations.

(b) Assume friction arises just from vertical shears in the horizontal velocity, so that

$$\boldsymbol{F} = \frac{\partial}{\partial z}\left[\nu \frac{\partial \boldsymbol{u}}{\partial z}\right], \tag{46.141}$$

where $\nu = \nu(z)$ is a vertical eddy viscosity that is a function of depth (dimensions of squared length per time). Also assume an approximate form of quasi-geostrophic potential vorticity in which we drop relative vorticity (i.e., quasi-geostrophic potential vorticity is dominated by planetary vorticity and stretching). Determine the form for the vertical eddy viscosity so that the approximate form of quasi-geostrophic PV is laterally diffused via

$$\frac{\mathrm{D}q^{\mathrm{approx}}}{\mathrm{D}t} = A\,\nabla_z^2 q^{\mathrm{approx}}, \tag{46.142}$$

where A is a constant eddy diffusivity for the potential vorticity.

Hint: to leading order, the friction operator is a function just of the geostrophic velocity.

EXERCISE 46.3: QUASI-GEOSTROPHIC ω-EQUATION

As we discovered in this chapter, for quasi-geostrophy the vertical component to the velocity is non-zero only at first order in Rossby number, whereas the zeroth order flow is horizontal and geostrophic. To time step the horizontal geostrophic flow it is not necessary to explicitly compute the ageostrophic vertical velocity component. However, the there are cases where vertical velocity component is of interest. In this exercise we derive the ω-equation for quasi-geostrophic flow, thus providing a diagnostic expression for the ageostrophic vertical velocity. The name for this equation originates from the atmospheric community where ω is the common symbol for transport across pressure surfaces. Here, we make use of the Boussinesq system so that the vertical velocity component is across depth surfaces.

An outline for the derivation of the traditional form for the ω-equation is given in Section 5.4 of *Vallis* (2017) for the anelastic version of quasi-geostrophy and for the f-plane. Here we work with the Boussinesq system and consider a β-plane. Nonetheless, the solution is nearly the same as in *Vallis* (2017). Hence, the aim for this exercise is to fully explain the derivation and show each of the relevant steps.

(a) Cross-multiply the dimensional buoyancy and vorticity equations from Section 46.3 to eliminate the time derivative, thus deriving a diagnostic equation for the ageostrophic vertical velocity that is valid to order Ro^1.

(b) The diagnostic equation you should have derived takes the form

$$\mathcal{L} w = \sigma, \tag{46.143}$$

where

$$\mathcal{L} = N^2 \nabla_z^2 + f_0^2 \frac{\partial^2}{\partial z^2} \tag{46.144}$$

is a linear partial differential operator and

$$\sigma = f_0\, \partial_z[J(\psi, \zeta + \beta\, y)] - \nabla_z^2 J(\psi, b) \tag{46.145}$$

is a source term. The source is a function of the geostrophic flow and the buoyancy field. For vertically stable stratification, $N^2 > 0$, characterize the differential operator, $\mathcal{L}$, according to the elliptic, hyperbolic, or parabolic classes discussed in Section 3.3. What about when $N^2 < 0$? What new physical phenomena do you expect when $N^2 < 0$?

EXERCISE 46.4: HOSKINS' FORM OF THE QUASI-GEOSTROPHIC ω-EQUATION

We here rederive the ω-equation from Exercise 46.3 using methods introduced by *Hoskins et al.* (1978). It is not necessary to have solved Exercise 46.3 to solve the present exercise. Hoskins' approach reveals an insightful form for the source function contributing to vertical motion. As in Exercise 46.3, we work with the adiabatic and hydrostatic Boussinesq system (see Section 44.7)

$$\frac{\mathrm{D}u}{\mathrm{D}t} - fv = -\frac{\partial \varphi}{\partial x} \tag{46.146a}$$

$$\frac{\mathrm{D}v}{\mathrm{D}t} + fu = -\frac{\partial \varphi}{\partial y} \tag{46.146b}$$

$$\frac{\partial \varphi}{\partial z} = b \tag{46.146c}$$

$$\frac{\mathrm{D}b}{\mathrm{D}t} = 0 \tag{46.146d}$$

$$\nabla \cdot \boldsymbol{v} = \nabla_z \cdot \boldsymbol{u} + \frac{\partial w}{\partial z} = 0 \tag{46.146e}$$

$$\frac{\mathrm{D}}{\mathrm{D}t} = \frac{\partial}{\partial t} + \boldsymbol{v} \cdot \nabla. \tag{46.146f}$$

In Exercise 46.3, we derived the ω-equation making use of the buoyancy equation and vorticity equation. *Hoskins et al.* (1978) worked with the momentum equation rather than the vorticity equation. For this purpose, rather than consider an asymptotic expansion, Hoskins decomposed the horizontal velocity into its geostrophic and ageostrophic components

$$\boldsymbol{u} = \boldsymbol{u}_{\mathrm{g}} + \boldsymbol{u}_{\mathrm{ag}}, \tag{46.147}$$

with the geostrophic velocity balancing the horizontal gradient of the <u>full</u> pressure field

$$f\boldsymbol{u}_{\mathrm{g}} = \hat{\boldsymbol{z}} \times \nabla \varphi. \tag{46.148}$$

This definition for $\boldsymbol{u}_{\mathrm{g}}$ is distinct from that arising from an asymptotic expansion, whereby the geostrophic velocity is the zeroth order term balancing the zeroth order pressure gradient (see Section 46.2.1 or Exercise 46.3). We are generally able to access the full hydrostatic pressure field through knowledge of the buoyancy field, in which case there is no need to make an asymptotic expansion of pressure.

Hoskins' definition for the geostrophic velocity brings the horizontal momentum equations into the rather elegant form

$$\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + f\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{ag}} = 0, \tag{46.149}$$

with the pressure gradient annihilated since it exactly balances the geostrophic velocity. There has been no approximation made thus far. Rather, we have only introduced a strategic decomposition of the velocity field as per Hoskins.

At this point we make the quasi-geostrophic approximation by setting the momentum equation equal to

$$\frac{\partial \boldsymbol{u}_{\mathrm{g}}}{\partial t} + (\boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z)\boldsymbol{u}_{\mathrm{g}} + f\hat{\boldsymbol{z}} \times \boldsymbol{u}_{\mathrm{ag}} = 0 \tag{46.150}$$

and the buoyancy equation equal to

$$\frac{\partial b}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z b + N^2 w = 0, \tag{46.151}$$

where $N^2(z)$ is a prescribed static background stratification. That is, both the horizontal geostrophic velocity and the buoyancy are advected just by the geostrophic velocity. The buoyancy equation is the same as derived to order Ro^1 using asymptotic methods (Section 46.2.2). However, Hoskins' momentum equation (46.150) has no pressure gradient on the right hand side, whereas an asymptotic approach has contributions from higher order pressure gradients (Section 46.2.2). Hoskins' approach dispenses with such pressure terms by defining the geostrophic velocity using the full pressure field.

(a) Show that the evolution of horizontal buoyancy gradients by the horizontal geostrophic currents can be written

$$\left[\frac{\partial}{\partial t} + \boldsymbol{u}_{\mathrm{g}} \cdot \nabla_z\right] |\nabla_z b|^2 = \boldsymbol{Q} \cdot \nabla_z b. \tag{46.152}$$

Hence, horizontal buoyancy gradients grow in magnitude in regions where the horizontal buoyancy gradient projects positively onto the $\boldsymbol{Q}$-vector. Write the expression for the vector $\boldsymbol{Q}$. Hint: A general version of this result is derived in Exercise 18.3.

(b) Show that the quasi-geostrophic ω-equation on an f-plane can be written

$$N^2 \nabla_z^2 w + f_0^2 \frac{\partial^2 w}{\partial z^2} = 2\nabla_z \cdot \boldsymbol{Q}. \tag{46.153}$$

We see that the source for vertical motion is the divergence of the $\boldsymbol{Q}$-vector. This formula offers useful insight into the origin of vertical motion, with *Hoskins et al.* (1978) offering examples. For this part of the exercise, you are to fully explain the derivation of equation (46.153) and show each of the relevant steps.

(c) The equation (46.153) for the vertical velocity takes the form

$$\mathcal{L} w = \sigma, \tag{46.154}$$

where

$$\mathcal{L} = N^2 \nabla_z^2 + f_0^2 \frac{\partial^2}{\partial z^2} \tag{46.155}$$

is a linear partial differential operator and

$$\sigma = 2\nabla_z \cdot \boldsymbol{Q} \tag{46.156}$$

is a source term. The source term is a function of the geostrophic flow and the buoyancy field. For vertically stable stratification, $N^2 > 0$, characterize the differential operator $\mathcal{L}$ according to the elliptic, hyperbolic, or parabolic classes discussed in Section 3.3. What about when $N^2 < 0$? What new physical phenomena do you expect when $N^2 < 0$?

EXERCISE 46.5: QGPV FLUX-FORM EQUATION WITH NON-CONSERVATIVE PROCESSES

Derive the quasi-geostrophic potential vorticity equation (46.117). Show all the relevant steps.

Hint: the key step requires showing that

$$\nabla \cdot [(\boldsymbol{u}_{\mathrm{g}} \cdot)\, \boldsymbol{D}] = (\boldsymbol{u}_{\mathrm{g}} \cdot) \nabla \cdot \boldsymbol{D}. \tag{46.157}$$

To do so, it is useful to express $\boldsymbol{u}_{\mathrm{g}}$ and b_{g} in terms of the geostrophic streamfunction.

EXERCISE 46.6: QGPV GAUGE FUNCTION

Derive the gauge function, $\boldsymbol{A}$, that connects the two forms of the quasi-geostrophic flux vector as per equation (46.121).

Part IX

Linear wave mechanics

Waves and the central role of a dispersion relation

Waves in fluids manifest as fluctuations of fluid particles and associated fluid properties, with the fluctuations possessing coherency in both space and time. Dynamically, linear waves exist when there is a restoring force that provides the means for fluid particles to undergo simple harmonic oscillations. Kinematically, waves arise when a symmetry is mildly broken whereby coherent fluctuations are a response to symmetry breaking. In this part of the book we study the mechanics of non-dissipative linear waves as they occur in fluids. This *wave mechanics* forms a key part of observed geophysical fluid phenomena.[10]

Linear waves have spatial and temporal properties that are closely linked. This linkage relates the angular frequency, ω, which measures the temporal structure of a wave, to the wavevector, $\boldsymbol{k}$, which measures the spatial structure of a wave. The *dispersion relation* is the mathematical equation that quantifies this linkage. Details of the dispersion relation are determined by the physical forces that give rise to the wave, such as compressibility for acoustic waves (Chapter 49), surface tension for capillary waves (Chapter 50), gravitational acceleration for gravity waves (Chapters 50, 53, and 54), the Coriolis acceleration for inertial waves (Chapters 51 and 53) and differential rotation (beta effect) for planetary Rossby waves (Chapters 52 and 53).

Linear waves satisfy the *superposition principle* that holds for linear physical phenomena. As a result, interactions between linear waves are reversible, and consist of constructive and destructive *interferences*.[11] The superposition principle allows for the solution of a linear wave equation to be constructed from constituent elementary pieces. Linear superposition is the fundamental reason we can usefully examine properties of waves by examining the behavior of a single traveling wave. We use this property of linearity when deriving the dispersion relation for waves, and, in Part X of this book, for determining stability properties.

Linearization to derive the wave equations

Derivation of the wave equation(s) and corresponding dispersion relation requires us to linearize the nonlinear governing equations of fluid motion. We approach the linearization process in a mostly heuristic manner, though are careful to expose assumptions about what terms are small for the purpose of reducing ambiguity. After deriving the linearized equations, we study their salient properties to help understand the kinematics and dynamics of the corresponding wave solutions and dispersion relations. Each wave system offers unique facets depending on the underlying dynamical forces. Even so, the kinematical features of wave mechanics typically transcends details of the dynamics.

Wave energy transport versus matter transport

The movement of fluid particles within a fluid constitutes the movement of matter, along with properties carried by matter such as tracers, enthalpy, entropy, etc. Although waves can lead to a net transfer of matter, through a process known as *Stokes drift*, the transfer of energy by waves generally occurs without any net movement of fluid particles, where "net movement" refers to a time average over a wave period (i.e., the *phase average* from Section 4.2.2). As such, wave energy propagates at speeds that are unconstrained by fluid particle speeds. Indeed, wave energy in linear waves is generally trasmitted many times faster than matter. We thus conceive of waves as organized disturbances on a background fluid state (sometimes called the base state

[10] "Wave mechanics" sometimes refers to that part of quantum mechanics based on Schrödinger's equation. We are instead here concerned with waves that occur in classical geophysical fluids.

[11] Some authors prefer to consider reversible interactions as the absence of any interaction, since one can exactly distinguish individual linear waves through the Fourier decomposition of a wave field comprised of multiple waves.

or equilibrium state) that transmit energy from one part of the media to another. The speed and direction of wave energy is determined by the dispersion relation, thus making the dispersion relation a central feature of wave dynamics.

Scope for our study of wave mechanics

The study of wave phenomena forms a central part of physics, engineering, and applied mathematics. Indeed, waves can be studied by a variety of observational and mathematical means, from the insights of a poet to the analysis of a mathematician. We target the reader aiming to learn wave mechanics for the first time, while also providing selected material for the experienced physicist interested in geophysical fluid wave mechanics. For these purposes, we survey a suite of geophysical fluid waves and dive deep into particular special topics that support understanding and develop mathematical methods. To help simplify the maths, we restrict attention to Cartesian waves (i.e., plane waves), leaving the geophysically relevant topic of spherical waves for more specialized treatments.

Our presentation is not comprehensive. Instead, we aim to offer an intellectual platform for further study and research. Insights and skills working with waves requires practice, and we get plenty from the wide variety of geophysical fluid waves. It is notable that we generally leave for other books the important, and difficult, topic of providing a wave interpretation for observed phenomena in the atmosphere and ocean. Here, we instead focus on the physical and mathematical foundations of wave mechanics.

Chapter 47

Plane waves and wave packets

Forces acting in a fluid determine the *dispersion relation* satisfied by linear waves, with the dispersion relation connecting the wave angular frequency, ω, to the *wavevector*, $\boldsymbol{k}$. We write this relation in the functional form[1]

$$\omega = \varpi(\boldsymbol{k}), \tag{47.1}$$

where ϖ is a generally nonlinear function of the wavevector. The dispersion relation couples the space and time structure of a wave: once a wavevector is chosen then the angular frequency is specified. A key purpose of this chapter is to develop the foundations for *wave kinematics*, which focuses on wave properties arising from the existence of a dispersion relation yet is unconcerned with the forces that determine this relation.

The *wave function* plays a fundamental role in describing waves. Example wave functions include the velocity potential (acoustic and surface waves), the streamfunction (Rossby waves), and free surface height (shallow water waves). All other dynamical fields can be generated from the wave function, thus allowing us to focus on characterizing how the wave appears through study of the wave function. The wave function has both an $\boldsymbol{x}$-space (geographic/height space) representation as well as a $\boldsymbol{k}$-space (wavevector space) representation. These two representations offer complementary characterizations of wave properties, with the transformation between these representations provided by Fourier's integral theorem from Section 4.4.1. One of the more remarkable aspects of this complementarity arises through the *uncertainty relation*, which states that it is not possible to simultaneously specify the position of a wave packet with arbitrary precision in both $\boldsymbol{x}$-space and $\boldsymbol{k}$-space. That is, precision in one space corresponds to imprecision in the other. We derive this uncertainty relation through the study of Gaussian wave packets.

READER'S GUIDE TO THIS CHAPTER

We focus on plane waves in this chapter and so make use of Cartesian coordinates and Cartesian tensors (Chapters 1 and 2). Furthermore, we assume familiarity with the use of complex variables as well as Fourier transforms, both reviewed in Chapter 4. We restrict attention to a homogeneous background/base state upon which waves are supported. A homogeneous base state is rarely realized in geophysics, and yet it serves our pedagogical needs prior to moving onto the more realistic, and mathematically complex, case of an inhomogeneous base state as studied in Chapter 48.

The presentation shares much with books and reviews covering topics in linear wave mechanics, such as *Bretherton* (1971), chapter 3 of *Acheson* (1990), chapters 1 and 2 of *Pedlosky* (2003), chapter 6 of *Olbers et al.* (2012), chapter 1 of *Sutherland* (2010), chapter 7 of *Thorne and Blandford* (2017), and chapter 6 of *Vallis* (2017). However, be mindful that not all authors

[1] For waves moving on a space and time dependent background, the dispersion relation picks up space and time dependence. This topic is the focus of Chapter 48.

47.1 Loose threads

- Figures

- More on wave packets and Green's functions. Derive the Green's function equation from the packet equation plus the dispersion relation.

47.2 Nomenclature and conventions

Many readers have encountered wave kinematics in prior studies. Yet some of the conventions are not universal, so that it is useful to summarize salient points to expose the choices made in this book.

47.2.1 Types of waves

Table 47.1 summarizes the various types of waves considered in this book. We mostly encounter plane traveling waves, though also make use of standing waves (as for waves within a bounded domain) and stationary waves (when a wave has only spatial periodicity and no time dependence). The wave patterns in Table 47.1 can arise from any conceivable context, physical or otherwise (e.g., the wave produced by spectators in a large sporting event). The specifics of a physical system arises when enforcing that a wave function, Φ, satisfies a linear partial differential equation, and it is through this equation that we derive the dispersion relation.

We wish to emphasize the above points in a bit more mundane manner. Namely, there are many mathematical functions that give rise to oscillating patterns. However, these patterns correspond to particular solutions to a physical system only when they satisfy a partial differential equation such as equation (3.63). That is, there are more mathematial wave-like patterns than there are physical waves. For example, consider the function

$$\Phi(x, y, t) = A\cos(k_x\, x - \omega\, t)\cos(\omega\, t) = (A/2)\,[\cos(k_x\, x - 2\,\omega\, t) + \cos(k_x x)], \tag{47.2}$$

where A is a constant amplitude. The second expression reveals the sum of a traveling plane wave plus a stationary wave. It is notable that this function is *not* in the form of a Fourier component that constitutes the wave patterns in Table 47.1. Rather, it is simply the sum of two trigonometric functions having a particular space and time structure. Is this function a particular solution to the classic wave equation with operator $\partial_{tt} - c^2\,\partial_{xx}$? A quick calculation reveals that it is *not* a solution since

$$\partial_{tt}\Phi = -2\,A\,\omega^2\cos(k_x\, x - 2\,\omega\, t) \tag{47.3a}$$

$$\partial_{xx}\Phi = -k_x^2\,\Phi = -(k_x^2\,A/2)[\cos(k_x\, x - 2\,\omega\, t) + \cos(k_x x)], \tag{47.3b}$$

revealing that there is no way to relate $\partial_{tt}\Phi$ and $c^2\,\partial_{xx}\Phi$ at arbitrary space and time points. In turn, this function is *not* a suitable wave function ansatz for deriving a dispersion relation.[2] We conclude that the mere presence of oscillating and/or traveling patterns is insufficient for a function to be a particular solution to a physical wave equation.

47.2.2 Types of dispersion relations

The dispersion relation (47.1) is the root of all wave properties since it links the space and time structure of the wave. Some waves encountered in this book have a dispersion relation in the slightly more restricted form

$$\omega = \varpi(|\boldsymbol{k}|), \tag{47.4}$$

[2]See Section 47.5.5 for a discussion of wave *ansatz*.

NAME	SPACE-TIME STRUCTURE
monochromatic	$\mathrm{Re}[\Phi_0\, \mathrm{e}^{-\mathrm{i}\,\omega\, t}]$
traveling	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)}]$
standing	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}]\cos(\omega t)$
stationary	$\mathrm{Re}[\mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}]$

TABLE 47.1: Summarizing the variety of waves encountered in this book, with distinctions based on their space-time structure. The operator, Re, extracts the real part of its argument, so that, for example, $\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)}] = \cos(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\, t)$. The first three patterns are monochromatic, which means they oscillate coherently with a single period, $2\pi/\omega$, where $\omega \geq 0$ is the angular frequency. However, note that $\mathrm{Re}[\Phi_0\, \mathrm{e}^{-\mathrm{i}\,\omega\, t}]$ is monochromatic and yet we cannot conclude whether it is a wave without further information about its spatial structure. Spatial dependence is introduced in the form $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}$, where $\boldsymbol{k}$ is the wavevector that determines the direction of the wave and its wavelength. For a plane wave in three-dimensional space, $\boldsymbol{k}\cdot\boldsymbol{x} = k_x\, x + k_y\, y + k_z\, z$, whereas a plane wave in two dimensions has wavevector $\boldsymbol{k}\cdot\boldsymbol{x} = k_x\, x + k_y\, y$. Standing waves do not travel in space but oscillate in place. A stationary wave has an oscillatory spatial pattern but has no time dependence and so is static. The final three waves are *harmonic* since they have a regular spatial pattern.

where $|\boldsymbol{k}|$ is the *wavenumber*. Evidently, these waves have their angular frequency independent of the wave direction. Examples include acoustic waves (Chapter 49) and surface waves (Chapter 50). Inertial waves from Chapter 51 and internal gravity waves from Chapter 54 are the complement, with their dispersion relation independent of the wavenumber yet dependent on the wave direction,

$$\omega = \varpi(\hat{\boldsymbol{k}}) \quad \text{with} \quad \hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}|. \tag{47.5}$$

Finally, the Rossby waves introduced in Chapters 52 and 53 have a dispersion relation that depends on both the wavenumber and wave direction; i.e., on the wavevector, $\boldsymbol{k}$.

47.2.3 Conventions for space-time description of waves

The suite of dispersion relations encountered in geophysical fluids motivates the following conventions that form the basis for our space-time description of waves. Readers should be aware that certain of these conventions are not universally followed in the literature.

- ANGULAR FREQUENCY: Following *Bretherton* (1971), the angular frequency of a stable linear wave that results from the dispersion relation, $\omega = \varpi(\boldsymbol{k})$, is chosen as a non-negative real number,

  $$\omega \geq 0, \tag{47.6}$$

  so that the wave period, $2\pi/\omega$, is also a non-negative number and the wave advances forward in time with the wave direction determined by the wavevector.

  This convention is not universally followed in the literature. One reason to allow for a negative angular frequency is that dispersion relations typically lead to quadratic equations that have a positive and a negative root. When choosing both roots, one interprets them as representing oppositely moving waves. Even so, we follow a convention that always chooses to the positive root, so that the wave direction is determined by the wavevector (see next point) rather than the sign of the angular frequency. Additionally, we are not generally interested in waves traveling backward in time, which is sometimes used to interpret cases with $\omega < 0$.

  One will encounter a negative angular frequency when conducting time-frequency Fourier analysis in the complex plane, as in Section 4.5. But in that context, the negative frequency is not physical, but instead is a mathematical expedient that allows one to work with a complex Fourier transform. There is nothing physical associated with the negative frequency in

this context, since one could equivalently work with real Fourier sine and cosine transforms where the angular frequency is non-negative. See Section 4.5.1 for more discussion. Furthermore, if using complex Fourier analysis, then switching the sign of the angular frequency and the wavevector merely leads to the complex conjugate wave function. Since the physical wave is real in classical physics, the complex conjugate wave function is the same wave.

- WAVE DIRECTION: The direction of a wave is specified by the wavevector, $\boldsymbol{k}$ (Section 47.5), and its wavelength is $2\pi/|\boldsymbol{k}|$, where $|\boldsymbol{k}| \geq 0$ is the wavenumber.
- PHASE SPEED: The phase speed, C_{p}, is a non-negative number. It is not a vector so that we do not consider components to the phase speed. Rather, we consider components to the phase vector, which is a vector whose direction is given by the wavevector and whose non-negative magnitude, along with the angular frequency, determine the phase speed (Section 47.5.2).

47.3 Two classes of linear waves

We distinguish two types of linear wave phenomena: non-dispersive waves and dispersive waves. In this section we present a mathematical overview of these waves, offering examples of each type of wave along with pointers to the physics and maths to come later.[3]

47.3.1 Non-dispersive waves

The canonical non-dispersive wave phenomena is described by "the" wave equation

$$(\partial_{tt} - c^2\,\nabla^2)\Phi = 0, \tag{47.7}$$

where Φ is a wave function (e.g., velocity potential, streamfunction, surface height), and $c^2 > 0$ is the squared wave speed. As discussed in Section 3.6, this wave equation is hyperbolic and its wave solutions all transmit signals with speed, $c > 0$, without distortion. That is, waves satisfying equation (47.7) of arbitrary wavelengths travel at the same speed so that there is no mixing across the spectrum of wavevectors. We find that for non-dispersive waves the angular frequency divided by the wavenumber equals to a constant phase speed shared by all waves. The acoustic waves of Chapter 49 and the shallow water gravity waves of Chapter 53 are example non-dispersive waves considered in this book.

To expose some of the mathematical details, consider the wave equation (47.7) in one space dimension and written in the factored form

$$(\partial_t - c\,\partial_x)\,(\partial_t + c\,\partial_x)\Phi = 0. \tag{47.8}$$

As discussed in Section 3.6, the solution to this hyperbolic partial differential equation takes the form of two signals moving in opposite directions

$$\Phi(x,t) = F(x - c\,t) + G(x + c\,t), \tag{47.9}$$

where the functions F and G are specified by boundary and initial conditions. Their respectiive functional dependencies, $x \pm c\,t$, determine the propagation direction of the signal, with $F(x - c\,t)$ a signal propagating in the $+\hat{\boldsymbol{x}}$ direction whereas $G(x + c\,t)$ is a signal propagating in the $-\hat{\boldsymbol{x}}$ direction. A key point is that the signals all move with the same speed, with F and G arbitrary

[3] Chapter 1 of *Whitham* (1974) provides a thorough mathematical introduction to the variety of linear and nonlinear waves.

functions that may be built from a single linear wave or any number of waves (including an infinity of waves). Also note that the wave equation (47.8) has been factored into the product of two linear operators, so that a simpler hyperbolic wave equation is either of the two first order equations

$$(\partial_t \pm c\,\partial_x)\Phi = 0. \tag{47.10}$$

In other parts of this book this equation is referred to as the *advection equation* for a one-dimensional signal with constant advection velocity (e.g., see Sections 64.5 and 64.6).

It is common to be introduced to wave physics through solutions to the hyperbolic wave equations (47.7) or (47.10). Correspondingly, much of our experience with waves is based on the non-dispersive nature of these waves. For example, when listening to a symphony, we hear the sounds from various instruments "in concert". That is, the speed that the acoustic waves propagate are independent of the wavelength. Indeed, imagine how difficult it would be for an audience spread throughout a concert hall to equally appreciate a symphonic performance if acoustic waves were dispersive!

47.3.2 Dispersive waves

Upon studying geophysical waves, we soon realize that non-dispersive waves are the exception rather than the norm. That is, most waves in geophysical fluids are dispersive, with their governing wave equations sometimes mathematically classified as hyperbolic though many are not. A dispersive wave is one that admits solutions of the form

$$\Phi(\boldsymbol{x}, t) = A\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \varpi\, t)} = A\,\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x} - \hat{\boldsymbol{k}}\, C_{\mathrm{p}}\, t)} \tag{47.11}$$

where the speed of a surface with constant phase,

$$C_{\mathrm{p}} = \varpi(\boldsymbol{k})/|\boldsymbol{k}|, \tag{47.12}$$

is a function of the wavevector. As such, the movement of the dispersive wave signal (i.e., the *phase velocity*) depends on the wavelength of the wave. For example, if we prepare a packet of dispersive waves with a particular shape in space, the evolution of the packet is characterized by the dispersion of the packet.

Waves visible by eye on the surface of a pond or surface of the ocean offer a canonical example of dispersive waves. As explored in Section 50.5.3, long surface gravity waves (which also have low frequency) travel faster than short and high frequency surface gravity waves. Indeed, it is this dispersion for surface gravity waves that surfers appreciate when assessing the suitability of coastal surf conditions following an offshore storm.[4]

47.3.3 Comments about time derivatives

As noted when discussing the non-dispersive wave equation (47.8), the presence of two time derivatives provides the means for two wave signals to arise from solutions to this equation, where the waves move in opposite directions. This case occurs for acoustic waves, gravity waves, and inertial waves. It manifests as a dispersion relation written for the squared angular frequency. In contrast, when there is only one time derivative in the wave equation, then the dispersion relation is written for the angular frequency rather than its square. Furthermore, the system chooses a preferred direction for the wave signal, with the Rossby wave offering the canonical example of

[4] See *Butt et al.* (2004) for a scientific view on surface ocean waves geared towards surfing.

such anisotropic waves. Rossby waves also offer a clear example of how the non-negative angular frequency convention helps to understand the phase velocity.

47.4 Monochromatic patterns

A *monochromatic pattern* is a feature characterized by having all points maintain the same time periodic motion with single angular frequency, ω. Hence, all points within a *monochromatic wave* have the same angular frequency. The trigonometric functions, $\cos(\omega\, t)$ and $\sin(\omega\, t)$, both exhibit time periodic behavior, which explains the factors of 2π appearing throughout wave physics. As noted in Section 47.2.3, we choose the convention in which the angular frequency is a non-negative number, $\omega \geq 0$, so that the period of the oscillation is $2\pi/\omega$.

It is often convenient to make use of the *Euler identity*

$$\mathrm{e}^{-\mathrm{i}\,\omega\, t} = \cos(\omega\, t) - \mathrm{i}\, \sin(\omega\, t), \tag{47.13}$$

to thus write a time periodic *wave function* as[5]

$$\Phi = \mathrm{Re}[\Phi_0\, \mathrm{e}^{-\mathrm{i}\,\omega\, t}], \tag{47.14}$$

where Φ_0 is a complex function further specified below, and Re[ ] is an operator that returns the real part of its argument (see Section 4.2). For linear calculations we can safely omit the Re operation until the end of the calculations. However, for products of wave fields, such as when performing energetic analyses, more care is needed, with details given in Section 4.2.[6]

47.5 Free plane waves

Plane waves are characterized by a single wavevector and single angular frequency, with the wave exhibiting symmetry in directions perpendicular to the propagation direction (hence the "plane" in its name). Any linear wave, be it acoustic, gravity, Rossby, etc., can be decomposed into a sum or integral of plane waves with a suite of frequencies and wavevectors, and with modulation by an amplitude function.

The general form of a stationary plane wave function is given by

$$\Phi_0 = \mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\, \boldsymbol{k}\cdot\boldsymbol{x}}, \tag{47.15}$$

where $\mathcal{A}(\boldsymbol{k})$ is a complex wave amplitude and $\boldsymbol{k}$ is the *wavevector* or *wavenumber vector*. The wavevector has dimensions of inverse length and it characterizes the wavelength of the wave as well as the spatial direction of the wave propagation (as per travelling plane waves in Section 47.5.1). The magnitude of the wavevector, $|\boldsymbol{k}|$, is referred to as the *wavenumber* as it measures 2π times the number of waves per unit length (we further discuss this notion in Section 47.5.2). We allow the wave amplitude, $\mathcal{A}(\boldsymbol{k})$, to be a function of wavevector so that different plane waves can have distinct amplitudes. We also allow for $\mathcal{A}(\boldsymbol{k})$ to be complex so that different plane waves can have their phases shifted relative to one another (we discuss phases in Section 47.5.1).

[5] The minus sign is motivated by convenience for when we consider a traveling wave and the phase velocity in Section 47.5.2. See in particular Figure 47.1.

[6] As noted when developing the basics of Fourier analysis in Chapter 4, we use complex variables solely for mathematical convenience, with all physical fields producing real numbers in the classical physics studied in this book.

Given that the plane wave possesses symmetry in planes perpendicular to $\boldsymbol{k}$, it is spatially dependent only on the direction parallel to the wavevector,[7]

$$\boldsymbol{k} = |\boldsymbol{k}|\,\hat{\boldsymbol{k}}. \tag{47.16}$$

We say that the plane wave function (47.15) is *free* since it exists throughout all of space and is unaffected by boundaries. Furthermore, we are uninterested in how the plane wave was formed. Indeed, since it is present throughout all of space, we imagine that the plane wave has existed for all time. Clearly these notions are not physically realizable. Even so, the mathematical simplicity of the plane wave, along with the superposition principle, affords it a central role in the study of wave mechanics. Furthermore, through the construct of wave packets studied in Sections 47.6 and 47.7, which are built via the superposition of plane waves, we can build wave forms that are spatially and temporally localized and are thus physically realizable.

47.5.1 Traveling plane wave

Allowing for time to evolve renders the traveling monochromatic plane wave function

$$\Phi = \mathrm{Re}[\Phi_0\,\mathrm{e}^{-\mathrm{i}\,\omega\,t}] = \mathrm{Re}[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t)}] = |\mathcal{A}(\boldsymbol{k})|\,\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\omega\,t+\alpha)}]. \tag{47.17}$$

We here wrote complex wave amplitude according to a real amplitude and a phase shift

$$\mathcal{A}(\boldsymbol{k}) = |\mathcal{A}(\boldsymbol{k})|\,\mathrm{e}^{\mathrm{i}\,\alpha} \quad \text{with} \quad \tan\alpha = \mathrm{Im}[\mathcal{A}(\boldsymbol{k})]/\,\mathrm{Re}[\mathcal{A}(\boldsymbol{k})]. \tag{47.18}$$

The traveling plane wave *phase* function is given by

$$\mathcal{P} = \boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t + \alpha, \tag{47.19}$$

so that

$$\Phi = |\mathcal{A}(\boldsymbol{k})|\,\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,\mathcal{P}}] = |\mathcal{A}(\boldsymbol{k})|\cos\mathcal{P}. \tag{47.20}$$

The traveling plane wave function, Φ, depends on the wavevector as well as the space and time point. It is also a function of the angular frequency, ω. However, recall that for the study of waves realized by a physical system, once the wavevector is known then the angular frequency is specified through the dispersion relation (47.1).

The phase factor on the wave amplitude in equation (47.18) is generally a function of wavevector, $\alpha = \alpha(\boldsymbol{k})$. However, for most applications it is taken as a constant, in which case it is referred to as the *standard phase*.

47.5.2 Characterizing the wave

Wave period

The wave function (47.17) for the traveling plane wave takes on the same value for all space and time points with a phase, $\mathcal{P}$, that is shifted by any integer multiple of 2π. By fixing a point in space, the plane wave is identical for all times, t_n, satisfying

$$\omega\,t_n = \omega\,t + 2\,\pi\,n = \omega\,(t + 2\,\pi\,n/\omega). \tag{47.21}$$

[7]Caution: many authors write $\hat{\boldsymbol{k}}$ for the unit vertical direction, whereas in this book we write $\hat{\boldsymbol{z}}$ for the unit vertical direction whereas $\hat{\boldsymbol{k}}$ is the direction of a wave.

FIGURE 47.1: Top panel: a cosine wave, $\Phi = A\cos(k\,x - \omega\,t)$, along the x-axis at $t = 0$, with wavelength $\Lambda = 2\pi/|k|$, wavevector $\boldsymbol{k} = k\,\hat{\boldsymbol{x}}$, and real amplitude, A. Lower panel: two snapshots of a traveling cosine wave, one shown at $t = 0$ as in the top panel, and another shown a quarter period later, at $\omega\,t = \pi/2$. With $k > 0$ and $\omega\,t > 0$, as shown in this figure, a point with constant phase moves in the $+\hat{\boldsymbol{x}}$ direction, whereas if $k < 0$ then the phase propagates in the $-\hat{\boldsymbol{x}}$ direction. Correspondingly, as the phase becomes more negative (as time increases), the wave form moves to the right, in the direction of the wave propagation.

Hence, the wave period is given by

$$\text{wave period} = 2\,\pi/\omega. \tag{47.22}$$

Wavelength

By fixing time, we see that the plane wave is identical for all space points, $\boldsymbol{x}_n$, satisfying

$$\boldsymbol{k}\cdot\boldsymbol{x}_n = \boldsymbol{k}\cdot\boldsymbol{x} + 2\,\pi\,n = |\boldsymbol{k}|\,(\boldsymbol{x}\cdot\hat{\boldsymbol{k}} + 2\,\pi\,n/|\boldsymbol{k}|), \tag{47.23}$$

which allows us to identify $2\,\pi/|\boldsymbol{k}|$ as the *wavelength*, which we write as[8]

$$\Lambda = 2\,\pi/|\boldsymbol{k}| \Longrightarrow \boldsymbol{k} = 2\,\pi\,\hat{\boldsymbol{k}}/\Lambda. \tag{47.24}$$

Figure 47.1 provides an example cosine wave in one-dimension, illustrating the wavelength and traveling nature of the wave.

Phase velocity and phase speed

When observing a traveling plane wave from a fixed point in space, one wavelength passes by the point within a single wave period. We refer to the *phase velocity*, $\boldsymbol{c}_{\rm p}$, as the velocity of a point

[8] We choose the uppercase, Λ, to denote wavelength rather than the more commonly used λ. We do so in order to distinguish the wavelength, Λ, from the longitude, λ, that commonly appears in this book.

fixed on a phase surface and traveling in the direction of the wavevector. Its magnitude is the *phase speed*, $C_{\rm p}$, which is the speed that the phase moves in the direction of the wavevector,

$$\boldsymbol{c}_{\rm p} = C_{\rm p}\,\hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|)\,\hat{\boldsymbol{k}} \Longrightarrow C_{\rm p} = \boldsymbol{c}_{\rm p}\cdot\hat{\boldsymbol{k}} = (2\pi/|\boldsymbol{k}|)/(2\pi/\omega) = \omega/|\boldsymbol{k}| \geq 0, \tag{47.25}$$

which allows us to write the angular frequency as

$$\omega = \boldsymbol{c}_{\rm p}\cdot\boldsymbol{k} = C_{\rm p}\,|\boldsymbol{k}|. \tag{47.26}$$

Figure 47.2 provides an illustration of the phase velocity and phase speed.

An equivalent means to understand the phase velocity is to consider the time derivative, $\mathrm{D}_{\rm p}/\mathrm{D}t$, defined to measure time changes within the reference frame of a point on a constant phase surface

$$\frac{\mathrm{D}_{\rm p}\mathcal{P}}{\mathrm{D}t} \equiv \partial_t + \boldsymbol{c}_{\rm p}\cdot\nabla, \tag{47.27}$$

in which case

$$\frac{\mathrm{D}_{\rm p}\mathcal{P}}{\mathrm{D}t} = (\partial_t + \boldsymbol{c}_{\rm p}\cdot\nabla)(\boldsymbol{x}\cdot\boldsymbol{k} - \omega\,t) = \boldsymbol{c}_{\rm p}\cdot\boldsymbol{k} - \omega = 0. \tag{47.28}$$

We are thus led to the expression for the phase speed and angular frequency

$$C_{\rm p} = \hat{\boldsymbol{k}}\cdot\frac{\mathrm{D}_{\rm p}\boldsymbol{x}}{\mathrm{D}t} \quad \text{and} \quad \omega = \boldsymbol{c}_{\rm p}\cdot\boldsymbol{k} = \boldsymbol{k}\cdot\frac{\mathrm{D}_{\rm p}\boldsymbol{x}}{\mathrm{D}t}. \tag{47.29}$$

The wave phase time derivative (47.27) is directly analogous to the material time derivative,

$$\frac{\mathrm{D}\mathcal{P}}{\mathrm{D}t} = \partial_t + \boldsymbol{v}\cdot\nabla, \tag{47.30}$$

defined in the reference frame following the velocity of a fluid particle (Section 18.8). Likewise, in Section 48.3.2 we define the time derivative following the group velocity, $\boldsymbol{c}_{\rm g}$, in which case $\boldsymbol{c}_{\rm p}$ in equation (47.27) is replaced by $\boldsymbol{c}_{\rm g}$.

Phase distance

We can define the phase speed in another manner by introducing the projection of the position vector along the direction of the wavevector

$$S_{\hat{\boldsymbol{k}}} \equiv \hat{\boldsymbol{k}}\cdot\boldsymbol{x}, \tag{47.31}$$

which we refer to as the *phase distance*. Note that $S_{\hat{\boldsymbol{k}}}$ can be positive or negative, depending on the direction of the wavevector. The wavelength as defined by equation (47.23) takes on the form

$$\boldsymbol{k}\cdot\boldsymbol{x}_n = \boldsymbol{k}\cdot\boldsymbol{x} + 2\,\pi\,n = |\boldsymbol{k}|\,(S_{\hat{\boldsymbol{k}}} + 2\,\pi\,n/|\boldsymbol{k}|). \tag{47.32}$$

As such, the phase speed is the change in the position of the constant phase lines in the direction of the wavevector, so that

$$C_{\rm p} = \left[\frac{\partial S_{\hat{\boldsymbol{k}}}}{\partial t}\right]_{\mathcal{P}} = -\frac{\partial\mathcal{P}/\partial t}{\partial\mathcal{P}/\partial S_{\hat{\boldsymbol{k}}}} = \omega/|\boldsymbol{k}|. \tag{47.33}$$

For this equation we made use of some basic mathematics of generalized surfaces as detailed in Section 59.12.2. Finally, this notation allows us to write the phase function as

$$\mathcal{P} = \boldsymbol{k} \cdot \boldsymbol{x} - \omega\, t + \alpha = |\boldsymbol{k}|\, (S_{\hat{\boldsymbol{k}}} - C_{\mathrm{p}}\, t) + \alpha. \tag{47.34}$$

FIGURE 47.2: A mesh plot of a plane wave with phase velocity, $\boldsymbol{c}_{\mathrm{p}} = C_{\mathrm{p}}\, \hat{\boldsymbol{k}} = (\omega/|\boldsymbol{k}|)\, \hat{\boldsymbol{k}}$, pointing perpendicular to surfaces of constant phase.

47.5.3 Wavenumber and factors of 2π

The magnitude of the wavevector, $|\boldsymbol{k}|$, appears in many places in wave kinematics, such as in the definition (47.24) of the wavelength. As a shorthand terminology, we refer to $|\boldsymbol{k}|$ as the *wavenumber*, with the wavenumber related to the wavelength via

$$|\boldsymbol{k}| = 2\pi/\Lambda. \tag{47.35}$$

The wavenumber measures 2π times the number of waves per unit length, so that the wavenumber measures the *spatial angular frequency* of a wave. In some contexts it is useful to introduce the *reduced wavelength*

$$\lambda\!\!\!^{-} = \Lambda/2\pi, \tag{47.36}$$

so that the wavenumber is given by the inverse reduced wavelength

$$|\boldsymbol{k}| = \lambda\!\!\!^{-\,-1}. \tag{47.37}$$

Alternatively, it is sometimes convenient to work with the *reduced wavenumber* as introduced in Section 4.4.7 when discussing Fourier transforms

$$\bar{k} = |\boldsymbol{k}|/2\pi. \tag{47.38}$$

Hence, the reduced wavenumber is the inverse wavelength

$$\bar{k} = 1/\Lambda \tag{47.39}$$

so that $\bar{k}$ measures the number of waves per unit length.

In Section 4.4.7 we raised some issues about various conventions for placing 2π factors in Fourier analysis. We further those concerns by noting that the 2π factor associated with wavenumbers can be unclear in the literature. The ambiguity occurs when a particular length scale, L, is considered, yet it is not specified whether the length scale refers to a wavelength, in which case the corresponding wavenumber is $|\boldsymbol{k}| = 2\pi/L$, or to a reduced wavelength, in which case the

corresponding wavenumber is $|\boldsymbol{k}| = 1/L$. The bottomline is that care is necessary to ensure the proper usage.

47.5.4 Superposition of plane waves

Through the principle of superposition respected by linear waves, realistic linear waves can be decomposed into the sum or integral of modulated plane waves. Indeed, this decomposition forms the mathematical basis for *Fourier analysis* detailed in Chapter 4. We here offer an illustration of this decomposition by considering how two plane waves combine, and then how three plane waves combine.

Consider the sum of two plane waves, each with same real amplitude of unity (in arbitrary units), and with distinct (but close) wavevectors and angular frequencies

$$\boldsymbol{k}_\pm = \boldsymbol{k} \pm \Delta\boldsymbol{k} \quad \text{and} \quad \omega_\pm = \omega \pm \Delta\omega \quad \text{with} \quad |\Delta\boldsymbol{k}|/|\boldsymbol{k}| \ll 1 \quad \text{and} \quad |\Delta\omega/\omega| \ll 1. \tag{47.40}$$

The resulting superposition of the two waves is given by

$$\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_+ - t\,\omega_+)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_- - t\,\omega_-)}] = 2\cos(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{47.41}$$

The $\cos(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)$ factor acts as a low wavenumber and low frequency modulation of the second factor, $\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)$, which is much more rapidly varying in space and time. We illustrate this superposition of two plane waves in Figure 47.3 for time $t = 0$. Adding a third wave, also with unit amplitude, $\exp[\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t)]$, renders the superposition

$$\mathrm{Re}[\mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_+ - t\,\omega_+)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k} - t\,\omega)} + \mathrm{e}^{\mathrm{i}\,(\boldsymbol{x}\cdot\boldsymbol{k}_- - t\,\omega_-)}] = 4\cos^2[(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)/2]\cos(\boldsymbol{k}\cdot\boldsymbol{x} - \omega\,t). \tag{47.42}$$

The third wave serves to double the amplitude through constructive interference, while also broadening the width of the low amplitude destructive interference region. Additionally, the modulation function, $\cos^2[(\Delta\boldsymbol{k}\cdot\boldsymbol{x} - \Delta\omega\,t)/2]$, is rendered non-negative when adding the third wave. We also illustrate this superposition in Figure 47.3.

FIGURE 47.3: Superposition of two plane waves (red lines; equation (47.41)) and three plane waves (black lines; equation (47.42)), with all plane waves having equal real amplitudes and here shown for time $t = 0$. Notice how in both cases, a high wavenumber wave (short wave) is modulated by a low wavenumber wave (long wave). The units in this figure are arbitrary.

47.5.5 Wave ansatz

The principle of superposition allows us to study properties of a linear wave equation, in particular the dispersion relation, by inserting a plane wave solution into the wave equation. In this manner we refer to the plane wave as an *ansatz*, which is a German word meaning "educated guess".

47.5.6 Summary of kinematic wave properties

In Table 47.2, we summarize the variety of kinematic properties of waves. In this book we work mostly with the angular frequency, ω, the wavevector, $\boldsymbol{k}$, and the wavenumber, $|\boldsymbol{k}|$. Even so, it is useful to be versed in the alternative choices.

NAME	MATH SYMBOL	DIMENSIONS	MATH RELATION
period	τ_{period}	T	$\tau_{\text{period}} = 2\pi/\omega$
angular frequency	ω	T^{-1}	$\omega = 2\pi/\tau_{\text{period}}$
frequency	f	T^{-1}	$f = \omega/2\pi = 1/\tau_{\text{period}}$
wavenumber	$\lvert\boldsymbol{k}\rvert$	L^{-1}	$\lvert\boldsymbol{k}\rvert = 2\pi/\Lambda$
wavevector	$\boldsymbol{k}$	L^{-1}	$\boldsymbol{k} = \lvert\boldsymbol{k}\rvert\,\hat{\boldsymbol{k}}$
reduced wavevector	$\bar{\boldsymbol{k}}$	L^{-1}	$\bar{\boldsymbol{k}} = \boldsymbol{k}/2\pi$
wavelength	Λ	L	$\Lambda = 2\pi/\lvert\boldsymbol{k}\rvert = 1/\lvert\bar{\boldsymbol{k}}\rvert$
reduced wavelength	$\lambda\!\!\!^{-}$	L	$\lambda\!\!\!^{-} = \Lambda/2\pi = 1/\lvert\boldsymbol{k}\rvert$

TABLE 47.2: Summarizing the variety of terms used to kinematically describe waves. In this book we mostly use the angular frequency, $\omega \geq 0$, the wavevector, $\boldsymbol{k}$, and the wavenumber, $|\boldsymbol{k}|$.

47.6 Free wave packets

The modulation of waves in Figure 47.3 serve to organize waves into $\boldsymbol{x}$-space regions known as *wave trains*. A *wave packet* is a train of free waves that are organized into a localized (and moving) region of $\boldsymbol{x}$-space. Localization is enabled by a *modulation function* and the plane wave modes that are organized within the packet are known as *carrier waves*.[9] Wave trains and wave packets are generated by a *wavemaker*. For example, consider a wavemaker oscillating at a known frequency, ω_0. Ramping up the wavemaker amplitude for a period of time, and then ramping it down towards zero, then produces a group of waves that are localized in time and have angular frequency and wavenumber centered on ω_0 and $\boldsymbol{k}_0$, where $\boldsymbol{k}_0$ is determined by the dispersion relation given ω_0. In the laboratory, the wavemaker might be an oscillating piston placed in a tank of water, such as considered for acoustic waves in Section 49.8. In the natural environment, a wavemaker might be a storm that passes over the ocean and generates surface gravity waves, or an atmospheric convective event that generates atmospheric internal gravity waves.

Mathematically, wave packets are described by complementary wave functions in $\boldsymbol{k}$-space and $\boldsymbol{x}$-space. The $\boldsymbol{k}$-space representation, $\mathscr{A}(\boldsymbol{k}, t)$, is also called the amplitude function for the $\boldsymbol{x}$-space wave function, $\Phi(\boldsymbol{x}, t)$. In the world of mathematical abstraction, we prepare wave packets with a specified $\boldsymbol{k}$-space initial condition, $\mathscr{A}(\boldsymbol{k}, t = 0)$, that has a corresponding $\boldsymbol{x}$-space initial condition, $\Phi(\boldsymbol{x}, t = 0)$, determined by the inverse Fourier transform. Upon initializing the packets we study their evolution. Since the packets are constructed by linear plane waves, their evolution is determined by the superposed and evolving constituent plane waves. What distinguishes a packet of acoustic waves from a packet of gravity waves, for example, is the dispersion relation, which is specific to the physics describing the particular waves.

47.6.1 Phase velocity, group velocity, and the dispersion relation

Examination of Figure 47.3 suggest that the velocity of a wave packet's center is not directly related to the phase velocity of the constituent plane waves. Rather, it is determined by motion

[9] From an engineering perspective, the carrier wave carries the most useful information contained in the wave packet signal, hence the name.

of the modulation function. For the one-dimensional examples of Figure 47.3, the packet motion is determined by $\Delta\omega/\Delta k$. In this section we generalize this result to the *group velocity* determined by[10]

$$\boldsymbol{c}_{\mathrm{g}} = \nabla_{\boldsymbol{k}} \varpi(\boldsymbol{k}). \tag{47.43}$$

In this equation, we introduced the wave dispersion relation (47.1) that specifies how the angular frequency is functionally connected to the wavevector. We see that the group velocity is determined by the gradient of the dispersion relation in wavevector space, which prompted us to expose a wavevector subscript on the gradient operator. As defined, the group velocity points in the $\boldsymbol{k}$-space direction of maximum increase for the angular frequency. Figure 47.4 illustrates two dispersion relations for a one-dimensional wave.

FIGURE 47.4: Example dispersion relations for one-dimensional waves. Left panel: a non-dispersive wave has a phase speed, C_{p}, that is a constant so that all waves, regardless their wavelength or angular frequency, move at the same speed. Right panel: a dispersive wave, here shown for a wave whose phase speed increases as the wave number increases, as does the group velocity.

The dispersion relation for non-dispersive waves results in phase speeds that are independent of the wavenumber so that

$$\varpi = C_{\mathrm{p}}\, |\boldsymbol{k}|, \tag{47.44}$$

where $C_{\mathrm{p}} > 0$ is the constant phase speed. Evidently, the angular frequency is identical for all waves having the same wavenumber. That is, the angular frequency only cares about the wavelength of the non-dispersive wave and not about its direction. Furthermore, we see that the continuum of wavenumbers results in a continuum of angular frequencies, with higher wavenumbers rendering higher angular frequencies. This behavior is familiar for both electromagnetic and acoustic waves, which are both non-dispersive, in which waves of smaller wavelength (higher wavenumber) have higher frequencies. We depict this sort of dispersion relation in the left panel of Figure 47.4.

Dispersive waves are characterized by a dispersion relation with the phase speed a function of the wavevector

$$\varpi = C_{\mathrm{p}}(\boldsymbol{k})\, |\boldsymbol{k}| > 0. \tag{47.45}$$

Again, the phase speed and angular frequency are positive, but now we find the phase speed depends on the wavenumber and possibly the wave direction. We provide an example for this sort of dispersion relation in the right panel of Figure 47.4.

[10] Many dispersion relations are naturally written as ω^2, in which case it is simpler to compute the group velocity according to $\nabla_{\boldsymbol{k}} \omega^2 = 2\,\omega\, \boldsymbol{c}_{\mathrm{g}}$.

47.6.2 A continuum of traveling plane waves

Consider the superposition of a continuum of traveling plane waves given by the integral expression for the wave function

$$\Phi(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k}. \tag{47.46}$$

The wave function, $\Phi(\boldsymbol{x},t)$, is constructed through combining a continuum of traveling plane waves, with the amplitude function, $\mathcal{A}(\boldsymbol{k})$, determining which wavevectors contribute to the packet and by how much they contribute. The integral in equation (47.46) is computed over all the three-dimensional wavevector space ($\boldsymbol{k}$-space). For example, a Cartesian representation of a wavevector volume element is written

$$\mathrm{d}\boldsymbol{k} = \mathrm{d}k_x\,\mathrm{d}k_y\,\mathrm{d}k_z, \tag{47.47}$$

with the integration limits $k_x, k_y, k_z \in (-\infty,\infty)$, corresponding to waves traveling in all directions and spanning all wavenumbers. Furthermore, the angular frequency in equation (47.46) is specified by the dispersion relation,

$$\omega = \varpi(\boldsymbol{k}) \geq 0, \tag{47.48}$$

so that the wave function (47.46) is built from a continuum of wavevectors with corresponding angular frequencies.

47.6.3 The wave function is real

For brevity we often drop the Re operator on the wave function (47.46). Even so, it is critical to note that the wave function is real, which has implications for how we compute the $\boldsymbol{k}$-space amplitude function, $\mathcal{A}(\boldsymbol{k})$. For example, if the amplitude function is real[11]

$$\mathcal{A}(\boldsymbol{k}) = A(\boldsymbol{k}) = A^*(\boldsymbol{k}), \tag{47.49}$$

then the wave function takes the form

$$\Phi(\boldsymbol{x},t) = \frac{1}{(2\pi)^3}\int A(\boldsymbol{k})\cos[\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t]\,\mathrm{d}\boldsymbol{k}. \tag{47.50}$$

However, there are cases where we need the extra phase degree of freedom afforded by a complex amplitude function, in which case the real part of equation (47.46) leads to

$$\Phi(\boldsymbol{x},t) = \mathrm{Re}\left[\frac{1}{(2\pi)^3}\int \mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k}\right] \tag{47.51a}$$

$$= \frac{1}{2\,(2\pi)^3}\int \left[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)} + \mathcal{A}^*(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\right]\mathrm{d}\boldsymbol{k}. \tag{47.51b}$$

Since the integral is over all of $\boldsymbol{k}$-space, we can write

$$\int \mathcal{A}^*(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k} = \int \mathcal{A}^*(-\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,(\boldsymbol{k}\cdot\boldsymbol{x}+\varpi(-\boldsymbol{k})\,t)}\,\mathrm{d}\boldsymbol{k}, \tag{47.52}$$

in which case the wavefunction takes the form

$$\Phi(\boldsymbol{x},t) = \frac{1}{2\,(2\pi)^3}\int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\left[\mathcal{A}(\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \mathcal{A}^*(-\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t}\right]\mathrm{d}\boldsymbol{k}, \tag{47.53}$$

[11] The star is the complex conjugate operator.

and its time tendency is

$$\partial_t \Phi(\boldsymbol{x}, t) = \frac{\mathrm{i}}{2\,(2\pi)^3} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} \left[-\varpi(\boldsymbol{k})\, \mathcal{A}(\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \varpi(-\boldsymbol{k})\, \mathcal{A}^*(-\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t} \right] \mathrm{d}\boldsymbol{k}. \tag{47.54}$$

47.6.4 Initializing the wave packet

We often consider wave packets in the context of initial value problems, whereby the packet is initialized according to some process such as described at the start of this section. We are concerned with freely moving wave packets, so that boundary conditions are not considered here. Thus, we consider three possibilities: initializing the packet's wave function, initializing its time tendency, or initializing both the wave function and its time tendency. To describe these initial conditions requires the use of complex $\boldsymbol{k}$-space amplitudes. Setting $t = 0$ in equation (47.53) for the wave function and equation (47.54) for the time tendency leads to

$$\Phi_0(\boldsymbol{x}) \equiv \Phi(\boldsymbol{x}, 0) = \frac{1}{2\,(2\pi)^3} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} \left[\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k}) \right] \mathrm{d}\boldsymbol{k} \tag{47.55a}$$

$$\dot{\Phi}_0(\boldsymbol{x}) \equiv \partial_t \Phi(\boldsymbol{x}, 0) = \frac{\mathrm{i}}{2\,(2\pi)^3} \int \mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}} \left[-\varpi(\boldsymbol{k})\, \mathcal{A}(\boldsymbol{k}) + \varpi(-\boldsymbol{k})\, \mathcal{A}^*(-\boldsymbol{k}) \right] \mathrm{d}\boldsymbol{k}. \tag{47.55b}$$

Inverting the Fourier transform for the initial condition (47.55a) and the initial tendency (47.55b) renders

$$\mathcal{A}(\boldsymbol{k}) + \mathcal{A}^*(-\boldsymbol{k}) = 2 \int \Phi_0(\boldsymbol{x})\, \mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\, \mathrm{d}\boldsymbol{x} \tag{47.56a}$$

$$-\varpi(\boldsymbol{k})\, \mathcal{A}(\boldsymbol{k}) + \varpi(-\boldsymbol{k})\, \mathcal{A}^*(-\boldsymbol{k}) = -2\,\mathrm{i} \int \dot{\Phi}_0(\boldsymbol{x})\, \mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\, \mathrm{d}\boldsymbol{x}, \tag{47.56b}$$

which then leads to the $\boldsymbol{k}$-space amplitude

$$\mathcal{A}(\boldsymbol{k}) = \frac{2}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})} \int \left[\varpi(-\boldsymbol{k})\, \Phi_0(\boldsymbol{x}) + \mathrm{i}\, \dot{\Phi}_0(\boldsymbol{x}) \right] \mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\, \mathrm{d}\boldsymbol{x} \tag{47.57a}$$

$$\mathcal{A}^*(-\boldsymbol{k}) = \frac{2}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})} \int \left[\varpi(\boldsymbol{k})\, \Phi_0(\boldsymbol{x}) - \mathrm{i}\, \dot{\Phi}_0(\boldsymbol{x}) \right] \mathrm{e}^{-\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\, \mathrm{d}\boldsymbol{x}. \tag{47.57b}$$

Notice that

$$\mathcal{A}(\boldsymbol{k}) = \mathcal{A}^*(-\boldsymbol{k}) \quad \text{if } \dot{\Phi}_0 = 0, \tag{47.58}$$

which is referred to as *conjugate symmetry* when studying Fourier transforms in Section 4.4.2, whereas

$$\mathcal{A}(\boldsymbol{k}) = -\mathcal{A}^*(-\boldsymbol{k}) \quad \text{if } \Phi_0 = 0, \tag{47.59}$$

which we refer to as *conjugate anti-symmetry.*

Now substitute the amplitude functions (47.57a) and (47.57b) into the wave function (47.54), and rearrange to find

$$\begin{aligned} \Phi(\boldsymbol{x}, t) = {} & \frac{1}{(2\pi)^3} \int \left[\int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})} \left[\varpi(-\boldsymbol{k})\, \mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \varpi(\boldsymbol{k})\, \mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t} \right]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \right] \Phi_0(\boldsymbol{\xi})\, \mathrm{d}\boldsymbol{\xi} \\ & + \frac{\mathrm{i}}{(2\pi)^3} \int \left[\int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{\xi})} \left[\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} - \mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t} \right]}{\varpi(\boldsymbol{k}) + \varpi(-\boldsymbol{k})}\, \mathrm{d}\boldsymbol{k} \right] \dot{\Phi}_0(\boldsymbol{\xi})\, \mathrm{d}\boldsymbol{\xi}. \end{aligned} \tag{47.60}$$

This equation can be written as the convolution of the initial conditions with two kernel functions

$$\Phi(\boldsymbol{x},t) = \int [\dot{G}(\boldsymbol{x}-\boldsymbol{\xi},t)\,\Phi_0(\boldsymbol{\xi}) + G(\boldsymbol{x}-\boldsymbol{\xi},t)\,\dot{\Phi}_0(\boldsymbol{\xi})]\,\mathrm{d}\boldsymbol{\xi}, \tag{47.61}$$

where the kernels are

$$G(\boldsymbol{x},t) \equiv \frac{\mathrm{i}}{(2\pi)^3}\int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} - \mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t}]}{\varpi(\boldsymbol{k})+\varpi(-\boldsymbol{k})}\,\mathrm{d}\boldsymbol{k} \tag{47.62a}$$

$$\dot{G}(\boldsymbol{x},t) \equiv \frac{1}{(2\pi)^3}\int \frac{\mathrm{e}^{\mathrm{i}\,\boldsymbol{k}\cdot\boldsymbol{x}}\,[\varpi(-\boldsymbol{k})\,\mathrm{e}^{-\mathrm{i}\,\varpi(\boldsymbol{k})\,t} + \varpi(\boldsymbol{k})\,\mathrm{e}^{\mathrm{i}\,\varpi(-\boldsymbol{k})\,t}]}{\varpi(\boldsymbol{k})+\varpi(-\boldsymbol{k})}\,\mathrm{d}\boldsymbol{k}. \tag{47.62b}$$

In fact, the kernels are related by a time derivative, which can be seen by writing them in the following form

$$G(\boldsymbol{x},t) = -\frac{2}{(2\pi)^3}\int \frac{\sin[\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t]}{\varpi(\boldsymbol{k})+\varpi(-\boldsymbol{k})}\,\mathrm{d}\boldsymbol{k} \tag{47.63a}$$

$$\dot{G}(\boldsymbol{x},t) = \frac{2}{(2\pi)^3}\int \frac{\varpi(\boldsymbol{k})\cos[\boldsymbol{k}\cdot\boldsymbol{x}-\varpi(\boldsymbol{k})\,t)]}{\varpi(\boldsymbol{k})+\varpi(-\boldsymbol{k})}\,\mathrm{d}\boldsymbol{k} = \partial_t G(\boldsymbol{x},t). \tag{47.63b}$$

Evidently, the kernels provide a wave mechanism to propagate information about the initial conditions outward in space as time moves forward. In this manner, these functions are *Green's functions* such as those studied in Chapter 5. Indeed, the solution (47.63b) corresponds to the Green's function (5.233), which was derived for the initial-boundary value problem with non-dispersive waves. Here, we are just concerned with the initial condition problem for free wave packets where the waves are generally dispersive. It is satisfying that even dispersive waves allow us to write the wave packet evolution in terms of Green's functions as in equation (47.61).

47.6.5 The case of non-dispersive waves

To help further understand the nature of the wave packet equation (47.61), and to connect it to the non-dispersive Green's function (5.233), consider a packet of non-dispersive waves for $t \geq 0$ and in one space dimension.[12] For this case the dispersion relation takes the form

$$\varpi(\boldsymbol{k}) = C_{\mathrm{p}}\,|k| \Longrightarrow \boldsymbol{k}\cdot\boldsymbol{x} - \varpi(\boldsymbol{k})\,t = k\,x - C_{\mathrm{p}}\,|k|\,t, \tag{47.64}$$

where $C_{\mathrm{p}} > 0$ is the constant phase speed. In this case we make use of the Dirac delta expression (4.110) in the form

$$\delta(x) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\,k\,x}\,\mathrm{d}k = \frac{2}{2\pi}\int_0^{\infty} \cos(k\,x)\,\mathrm{d}k, \tag{47.65}$$

[12] This case corresponds to the infinite string discussed in Section 7.8 of *Stakgold* (2000b). We also consider packets of non-dispersive waves in Section 47.7.7, with a focus on Gaussian packets.

so that

$$\dot{G}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \cos(k\,x - C_{\rm p}\,|k|\,t)\,{\rm d}k \tag{47.66a}$$
$$= \frac{1}{2\pi}\int_{-\infty}^{0} \cos(k\,x + C_{\rm p}\,k\,t)\,{\rm d}k + \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x - C_{\rm p}\,k\,t)\,{\rm d}k \tag{47.66b}$$
$$= \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x + C_{\rm p}\,k\,t)\,{\rm d}k + \frac{1}{2\pi}\int_{0}^{\infty} \cos(k\,x - C_{\rm p}\,k\,t)\,{\rm d}k \tag{47.66c}$$
$$= [\delta(x + C_{\rm p}\,t) + \delta(x - C_{\rm p}\,t)]/2. \tag{47.66d}$$
$$= \delta(C_{\rm p}\,t - |x|)/2. \tag{47.66e}$$

Hence, $\dot{G}$ is built from two Dirac delta wave fronts that move in opposite directions at speed $C_{\rm p}$. Its time integral leads to the Green's function as a Heaviside step function (see Section 5.3.5)

$$G(x,t) = \mathcal{H}(C_{\rm p}\,t - |x|)/(2\,C_{\rm p}). \tag{47.67}$$

To within a constant factor, the Green's function (47.67) is the causal free space Green's function (5.221a) derived for the one dimensional non-dispersive waves. Making use of these results in the wave packet equation (47.63b) leads to

$$\Phi(x,t) = \frac{1}{2}\int_{-\infty}^{\infty} \delta(C_{\rm p}\,t - |x-\xi|)\,\Phi_0(\xi)\,{\rm d}\xi + \frac{1}{2\,C_{\rm p}}\int_{-\infty}^{\infty} \mathcal{H}(C_{\rm p}\,t - |x-\xi|)\,\dot{\Phi}_0(\xi)\,{\rm d}\xi \tag{47.68a}$$
$$= [\Phi_0(x - C_{\rm p}\,t) + \Phi_0(x + C_{\rm p}\,t)]/2 + \frac{1}{2\,C_{\rm p}}\int_{x-C_{\rm p}\,t}^{x+C_{\rm p}\,t} \dot{\Phi}_0(\xi)\,{\rm d}\xi. \tag{47.68b}$$

For the second equality we used

$$\int_{-\infty}^{\infty} \mathcal{H}(C_{\rm p}\,t - |x-\xi|)\,\dot{\Phi}_0(\xi)\,{\rm d}\xi = \int_{-\infty}^{\infty} \mathcal{H}(C_{\rm p}\,t - |y|)\,\dot{\Phi}_0(x+y)\,{\rm d}y \tag{47.69a}$$
$$= \int_{-C_{\rm p}\,t}^{C_{\rm p}\,t} \dot{\Phi}_0(x+y)\,{\rm d}y \tag{47.69b}$$
$$= \int_{x-C_{\rm p}\,t}^{x+C_{\rm p}\,t} \dot{\Phi}_0(\xi)\,{\rm d}\xi. \tag{47.69c}$$
